"(4) The colon bacillus causes fermentation with production of gas in media containing sugar; the typhoid bacillus does not.

"(5) In nutrient agar or gelatine containing lactose and litmus tincture and of a slightly alkaline reaction, the color of the colonies of colon bacillus is pink and the surrounding medium red; while the colonies of typhoid bacillus are blue and there is little or no reddening of the medium.

"(6) The colon bacillus produces indol in cultures of bouillon or peptone; the typhoid bacillus does not.

"(7) When a twenty-four-hour-old bouillon culture of the colon bacillus is mixed with the blood or serum of a patient suffering from genuine typhoid fever, in a dilution of one to ten or more, after the first week of the disease, the Widal reaction is negative; cultures of the typhoid bacillus treated in the same manner and examined in the hanging drop give the characteristic agglutination and clumping of the bacilli." (*Reference Handbook of the Medical Sciences.*)

4. (*a*) *Four pus-producing bacteria: Staphylococcus pyogenes aureus, Staphylococcus pyogenes citreus, Staphylococcus pyogenes albus,* and *Streptococcus pyogenes.*

(*b*) The Widal phenomenon "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their mobility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. A posi-

tive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

(*c*) To demonstrate *gonococci* in a urethral discharge.—On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly-made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

6. (*a*) The decreased velocity of the blood, in inflammation, is probably due to some change in the vessel walls, which increases the friction.

NEUROLOGY.

1. The ganglia connected with the fifth pair of cranial nerves are: (1) The Gasserian; (2) the ophthalmic; (3) Meckel's; (4) the submaxillary; (5) the otic.

2. The *median nerve arises* by two roots, one from the outer cord, the other from the inner cord of the brachial plexus.

Its *principal branches* are the muscular, anterior interosseus, palmar cutaneous, muscular (to the thumb), and digital branches.

It is distributed to all the superficial muscles on the front of the forearm except the flexor carpi ulnaris; all the deep muscles on the front of the forearm except the inner half of the flexor profundus digitorum; the skin over the palm of the hand; the abductor pollicis, opponens pollicis, and the outer head of the Flexor brevis pollicis; the outer three and a half fingers, and the first and second lumbricales.

3. The trochlear nerve is the motor nerve to the superior oblique muscle of the eye. When this nerve is paralyzed the patient is unable to turn the eye outward and downward.

5. *Cerebral softening* is a degenerative process occurring in the brain as a result of occlusion of an artery and consequent local deprivation of blood-supply. This obliteration of the artery may be due to thrombosis or to embolism. The stages in the process are: Obliteration of the artery, local anemia, degeneration of tissue, necrosis, and softening.

6. In *locomotor ataxia* the posterior columns and posterior nerve roots of the cord are involved.

In *progressive muscular atrophy* the ganglion cells in the anterior horns of the cord are involved.

MEDICAL JURISPRUDENCE.

1. *Abortion is justifiable.*—"(1). In pelvic deformity where there is sufficient space for a seven months' child to be delivered without injury. The object is twofold: (*a*) to save the child's life by obviating the necessity for craniotomy; (*b*) to spare the mother the dangers of craniotomy, cesarean section, symphyseotomy, or other operations that might be required if the pregnancy went to full term. (2) In cases where, in previous labors, the head of the child at full term has been prematurely ossified, or unusually large, so that labor has been difficult and dangerous, even though the pelvis were normal. The period of delivery need only be two or three weeks before 'term' in these cases. (3) In cases where the children of previous pregnancies have died *in utero* during the later weeks of gestation from disease (fatty, calcareous, or amyloid degeneration, etc.) of the placenta. (4) In conditions where the continuance of pregnancy seriously endangers the mother's life, such as: excessive vomiting; albuminuria; uremic convulsions, or paralysis; chorea; mania; organic disease of the heart, lungs, liver, bloodvessels, etc., threatening fatal disturbance of the respiration, circulation, and other vital functions; irreducible displacements of uterus; placenta previa with hemorrhage; and in dangerous pressure upon neighboring organs from over distention of uterus, due to dropsy of ammion, tumors, multiple pregnancy, etc." (King's *Manual of Obstetrics.*)

2. Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

3. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony, the witness testifies only to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

PEDIATRICS.

1. Cases of infantile convulsions are: "Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease."—(From Butler's *Diagnostics of Internal Medicine.*)

3. Spina bifida is a condition in which there is a cleft in part of the posterior wall of the spinal cord; it is due to imperfect development. Through this cleft there may protrude the spinal meninges and cerebrospinal fluid (meningocele); or it may contain in addition some of the cord and nerves (meningomyelocele); or there may be great distention of the central canal, the sac-wall being formed of the thinned cord (syringomyelocele).

MATERIA MEDICA AND THERAPEUTICS.

1. IPECAC. *Source.*—The dried root and part of the stem of the Cephaëlis ipecacuanha or of the Cephaëlis acuminata.

Composition.—Emetine, Cephaëline, another (unnamed) alkaloid, Cephaëlic or Ipecacuanhic acid, Tannic acid, volatile oil, etc.

Preparations.—Fluidextractum Ipecacuanhæ, Syrupus Ipecacuanhæ, Vinum Ipecacuanhæ, Pulvis Ipecacuanhæ et Opii, Tinctura Ipecacuanhæ et Opii.

2. *Agents which affect the organ of vision when locally applied.—Mydriatics* (dilate the pupil): Atropine, Homatropine, Daturine, Hyoscyamine, Coniine, Cocaine; and probably Gelsemine, Muscarine, Hydrocyanic acid, Aconite, and Amyl nitrite.

Myotics (contract the pupil): Pilocarpine, Physostigmine, and probably Nicotine.

Dilators of the pupils, especially atropine and homatropine, are used to dilate the pupil for ophthalmoscopic examination, and to prevent or break down adhesions of the iris. Contractors of the pupil, especially physostigmine, are used to overcome the effects of atropine, to prevent or break down adhesions of the iris, and to prevent too much light entering the eye in painful diseases of it.

Drugs which *impair or paralyze accommodation.*—Atropine, Daturine, Hyoscyamine, Homatropine, Cocaine, Physostigmine, Pilocarpine, Gelsemine, and Coniine.

Intraocular tension is increased by atropine (large doses), hyoscyamine, and daturine. It is decreased by cocaine, hyoscine, and physostigmine.

Gelsemine paralyzes the external ocular muscles, especially the levator palpebræ and the external rectus, by its action on the terminal nerve filaments.

Cocaine, by stimulating the unstriped fibers in the orbital membrane and the eyelids, causes the eye to protrude. Coniine produces ptosis when given in large doses. (From White and Wilcox's *Materia Medica*, etc.)

4. *Escharotics* are agents which, on being applied to a tissue, destroy it, and produce a slough. Examples: Mineral acids, caustic alkalies, zinc chloride, zinc sulphate, silver nitrate, mercuric chloride, mercuric nitrate, bromine, and the cautery.

Astringents are agents which diminish secretion from mucous surfaces and cause tissues to contract. Examples: Acids (especially gallic and tannic), alum, galls, kino, ferric chloride, copper sulphate, bismuth subnitrate, lead acetate, silver nitrate, zinc sulphate.

Styptics are agents which, on being applied locally, arrest hemorrhage. Examples: The cautery, acids, nitrate of silver, alum, collodion, and vegetable astringents.

Emollients are substances which tend to soften, relax, and protect the parts to which they are applied. Examples: Cold cream, cacao butter, olive oil, glycerin, lanolin, paraffin, vaseline, lard.

5. There are only two officinal digestive ferments: (1) *Pepsin*, obtained from the fresh stomach of the hog. In an acid medium it digests the proteid constituents of the food, and converts them into albumoses and peptones. (2) *Pancreatin*, obtained from the fresh pancreas of the hog or other warm-blooded animal. In an alkaline medium it converts the proteid constituents of the food into peptones, converts starches into sugars, and (when recent) emulsifies fats; it may also coagulate milk.

6. In *poisoning by iodine*, large quantities of starch should be given as the antidote; emetics and the stomach tube are also indicated; the body should be kept warm, and hypodermic injections of alcohol, digitalis, and strychnine may be required to maintain the circulation and respiration.

CHEMISTRY, TOXICOLOGY, URANALYSIS.

1. *An alkaloid* is an organic nitrogenized substance of

alkaline reaction and capable of combining with acids to form salts in the same way that ammonia does.

2. *A chemical radical* is a group of atoms capable of passing unaltered from one compound to another, like a single atom.

3. *Acids* are compounds of an electronegative element or radical with hydrogen, part or all of which hydrogen they can part with in exchange for an electropositive element, without formation of a base. *Examples*: Sulphuric acid, H_2SO_4; nitric acid, HNO_3.

Bases are ternary compounds capable of entering into double decomposition with an acid to produce a salt and water. *Examples*: Potassium hydroxide, KOH; Calcium hydroxide, $Ca(OH)_2$.

Salts are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples*: Sodium nitrate, $NaNO_3$; Monopotassic sulphate, $KHSO_4$.

4. *Nitric acid*, HNO_3. It is used externally as a caustic on chancres, chancroids; also on warts, phagedenic ulcers, indolent ulcers, and gangrene. Internally it is used as a tonic, in gastric or intestinal indigestion, and summer diarrhea of children.

Hydrochloric acid, HCl. It is used in indigestion, gastric cancer, and gastric catarrh.

5. *Hypo* prefixed to an acid or a salt denotes less oxygen than the "*ous*" acid or the "*ite*" salt.

Hyper or *Per* prefixed to an acid or a salt denotes more oxygen than the "*ic*" acid or the "*ate*" salt.

Examples:

HClO=*Hypo*chlor*ous* acid: KClO=Potassium *hypo*chlor*ite*.

$HClO_2$=Chlor*ous* acid: $KClO_2$=Potassium chlor*ite*.

$HClO_3$=Chlor*ic* acid: $KClO_3$=Potassium chlor*ate*.

$HClO_4$=*Per*chlor*ic* acid: $KClO_4$=Potassium *per*chlor*ate*.

6. $HgCl_2 + 2KI = HgI_2 + 2KCl$.

7. Sodium: Na.

Sodium hydroxide: NaHO. It is a white solid, hard, brittle, amorphous, soluble in water, and has a strong corrosive action; when exposed to the air it is converted into Sodium carbonate.

Sodium dioxide: Na_2O_2. It is a white solid, amorphous.

Sodium monoxide: Na_2O. It is a grayish-white substance.

8. The *symptoms of poisoning by strychnine* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours.

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

9. The most *common sources of lead poisoning* are the following:

"The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

The *symptoms* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions; and tetanic spasms."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube." (Witthaus' *Essentials of Chemistry.*)

10. The *characteristic symptoms of poisoning by corrosive sublimate* are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; bloody stools, also salivation may occur.

Treatment: The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

12. *Test for albumin*: The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral, or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid; and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for sugar: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Quantitative test for urea: A comparatively easy test is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

PHYSIOLOGY, HYGIENE, AND PHYSICAL DIAGNOSIS.

1. *Functions of the pneumogastric nerve*: "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirke's *Physiology.*)

4. Too little food decreases both the quantity of milk and the percentage of solids. An ample diet increases both the quantity of milk and the percentage of solids. Abundance of proteids in the food increases the fat in the milk; so also does fat in the food, if it is well digested. Watery food increases the amount of milk, but diminishes the percentage of solids.

6. The *functions of the medulla oblongato* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

7. (*a*) The *function of the thyroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion.

(*b*) Removal of the thyroid causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. Complete removal causes death in most animals, and it is not considered justifiable in man.

10. In *hepatic colic* the pain is in the right hypochondriac region; there is no rigidity of the right rectus muscle; there are chills, slight fever, sweats, perhaps syncope, and vomiting; the liver and gall-bladder are tender and swollen, and there may be jaundice.

In *appendicitis* the pain and tenderness are in the right iliac fossa; there is rigidity of the right rectus muscle; there are fever and gastrointestinal disturbances, but no jaundice or tenderness of liver and gall-bladder.

11. In cardiac hypertrophy affecting the *left ventricle*: The apex beat is lower than normal and also further to the left, but not so far to the left as when the right ventricle is hypertrophied; the area of pulsation is increased, and there may be a systolic retraction of the interspaces; the area of cardiac dullness is increased down-

wards and to the left; the first sound is long and low-pitched; the second sound (at the apex) is louder and sharper.

In cardiac hypertrophy affecting the *right ventricle*: The apex beat is lower than normal and much further to the left; percussion shows the transverse diameter of the heart to be very much enlarged; the second pulmonic sound is much accentuated, and at times may be observed by palpation.

12. (*a*) *Cerebral hemorrhage* is generally preceded by vertigo, headache, tinnitus aurium, numbness, loss of memory, dreams, or disturbed sleep. The attack comes on suddenly, with vertigo and unconsciousness; the face is flushed; breathing is stertorous, and later may become of the Cheyne-Stokes type; the temperature is subnormal, but later may rise; there may be incontinence of urine and feces; signs of paralysis are evident; the pupils are unequal. The case is to be diagnosed from acute softening of the brain, from embolus or thrombus, also from the coma of uremia, opium, epilepsy, or alcohol.

(*b*) The most reliable signs of death are: Complete and permanent cessation of circulation and respiration; loss of body heat; rigor mortis; pallor of the body; a bright needle on being plunged into a muscle and left there, on being withdrawn shows no sign of oxidation; on the hand being held before a strong light, with the fingers extended and together, there is no translucence; the eye is not responsive to light or mydriatics, and there is loss of corneal transparency; putrefaction.

PRINCIPLES AND PRACTICE.

2. Spinal sclerosis is a condition of hardening produced by inflammation and accompanied by increase and proliferation of the supporting connective tissue, and atrophy of the nerve elements.

The varieties (as given by Dana) are:

Spinal sclerosis
- Primary and degenerative
  - Posterior spinal sclerosis (locomotor ataxia).
  - Lateral sclerosis.
  - Combined sclerosis.
  - Progressive muscular atrophy; amyotrophic lateral sclerosis.
- Secondary
  - Ascending and descending degenerations.
  - Chronic myelitis and sclerosis following destruction of cord.
  - Multiple sclerosis.

4. The feces may be examined *microscopically* for: The *Ameba coli* in dysentery; the *Spirillum* of cholera; the *Bacillus typhosus* in typhoid fever; the *Tænia solium;* the *Oxyuris vermicularis*, and other parasites and bacteria. *Chemical* examination might show the presence of mucin, blood, albumin, peptones, and bile pigment. *Spectroscopic* examination might possibly show the presence of blood.

5. *Hemiplegia* may be *caused by*: Lesions of the cortex cerebri, corona radiata, internal capsule, corpus striatum, optic thalamus, crura cerebri, pons, or medulla.

6. *Autointoxication* is the condition in which a person is (being) poisoned by the reabsorption of the waste products of his own metabolism, which should have been excreted. The source of the toxins producing this condition is the body of the person so suffering.

8. The *etiology of tuberculosis* is the bacillus tuberculosis of Koch.

Suitable preventive measures would include: Careful disinfection or burning of sputum, etc.; avoidance of spitting in public places; plenty of fresh air and sunlight; an abundance of good and easily digested food; the proper inspection of food supplies; the avoidance of kissing; and reporting of cases to the proper health authorities, and co-operation with them.

"Motor 'Bus Disease."—The *General Practitioner* says that the influence of the motor omnibus on the health of the London police promises to call for serious consideration by the authorities in the near future. Men stationed at such centers as the Bank, Ludgate Circus, Holborn, and the Mansion House Station are suffering very severely from headache and a very peculiar hot and dry feeling at the throat after doing duty. The headache lasts a considerable time, while many men say that the throat trouble is continuous, merely changing in degree. One and all blame the motor omnibus, which is peculiarly offensive in the narrow and crowded streets of the city. A prominent city man who is intimately connected with the police told a representative that if the conditions were not changed for the better, the corporation would no longer be able to consider a constable good for twenty-five years' duty in the streets.

Medical Items.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ended November 1, 1907:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES.			
California, Los Angeles	Oct. 13–19	2	..
San Francisco	Oct. 6–19	3	..
Indiana, Elkhart	Oct. 6–12	1	..
Illinois, Chicago	Oct. 16–22	1	..
Springfield	Oct. 18–24	1	..
Louisiana, Shreveport	Oct. 13–19	2	..
Massachusetts, Somerville	Oct. 20–26	1	..
Missouri, St. Joseph	Oct. 13–19	2	..
New Jersey, Newark	Oct. 13–19	1	..
Utah, Three Counties	Sept. 1–30	11	..
Washington, Spokane	Sept. 1–30	1	..
Wisconsin, Appleton	Oct. 6–12	2	..
Milwaukee	Oct. 15–21	3	..

DISEASES OF THE GASTROINTESTINAL TRACT ON THE BORDERLAND BETWEEN SURGERY AND INTERNAL MEDICINE.*

BY JOHN C. HEMMETER, M.D., Ph.D., LL.D.,

BALTIMORE, MD.

PROFESSOR OF PHYSIOLOGY AND CLINICAL MEDICINE, UNIVERSITY OF MARYLAND.

IT has been a great pleasure to me to have been able to participate, in however trifling a degree, in the proceedings of this Association, which I look upon as a prominent acknowledgment of a principle which is daily forcing its way among us, and which is destined to play an important rôle in the future history and development of American medicine. I mean the interchange of clinicians and surgeons between medical organizations and universities in different States of our Union; and through them the dissemination of the various aspects and view points of medical problems as they present themselves to clinicians and surgeons in the various sections of this great country.

Upon the suggestion of that most brilliant of all monarchs, the German Emperor, an interchange of professors through Germany and this country is at present taking place, and this academic interchange will lead to a better understanding between the two nations than any principles of politics or diplomacy could accomplish. The highest thoughts of a nation are by no means embodied in those affairs that we call political. They are more likely to be represented in the aims of science, and in the principles of that science whose chief object is the preservation of human life.

By the interchange between our States we shall reach a better understanding of the various diseases occurring, as they do, over latitudes that are far greater than the territory of Europe; but one of the greatest prospects to be hoped for is a better understanding between the internist and the surgeon. Of the former we expect the most refined development of the physical methods of examination—percussion, auscultation, palpation, etc.; a more perfect control of the chemical and microscopical methods of diagnosis, and a deeper knowledge of pathophysiological processes; an exhaustive familiarity of the signs and symptoms of disease. All this in the nonoperating clinician on the one hand, and on the other, of the surgeon, the operating clinician, we expect an exhaustive knowledge of regional anatomy; of the many mechanical and physical appliances to aid in the recovery of objective lesions, and a masterly control of technique with all its collateral, chemical, and bacteriological detail.

Between these two domains of internal medicine a cordial understanding is necessary. What we hope for from the internist is not habitual prejudice against operation, not an exclusive and invariable expectant and conservative method of approaching the abnormal phenomena of life; and what we hope for from the surgeon is not invariably to advocate operation; but the attitude in both from which most progress is to be hoped for, is *cooperation.* Operative technique is in a ceaseless state of progress. The surgeons have the advantage that the statistics of operation and the indications and contraindications to operation generally incite extensive discussion. Such elements of surgery are more apt to cause the liveliest interest, not only of the medical profession, but of humanitarians at large. But the internist need not be discouraged at this, for I can say, for the American surgeon at least, that although radical and extreme positions and views have occasionally been announced, they have always been willing to recede from too dogmatic a position, when the untenability of it was demonstrated by a broad experience and conservative critical judgment. Thus the internist has lived to see that diseases which were at one time claimed to be only proper for the surgeon to treat, and that the internist was out of his latitude when attempting to treat them, have been conceded back to him, partially at least. Thus we have it from surgeons of very broad experience that appendicitis need not always be operated upon. They admit the possibility of permanent recovery without removal of the appendix. Such a distinguished surgeon as Treves condemns the operative replacement of the kidney for nephroptosis. Kehr, the greatest gallstone surgeon we know of, concedes that there are forms of cholelithiasis where the operation cannot cure the disease; it may become absolutely necessary to remove the gallstone (or stones), but this does not necessarily cure the abnormal hepatic metabolism which leads to gallstone formation. And in the following I hope to be able to present the evidence that even tuberculous peritonitis may be permanently recovered from under conservative or expectant treatment, although at one time laparotomy was considered the only chance the patient had for recovery.

THE EARLY DIAGNOSIS OF CARCINOMA OF THE INTESTINE.

In early diagnosis of intestinal cancers we must consider theoretically at least two stages: (1) the latent stage, (2) beginning of manifest symptoms. Concerning the first, the latent period, an early diagnosis cannot seriously be considered possible in the present state of our knowledge. Let us assume that a serum reaction for carcinoma had been made feasible as a result of revolutionizing research into the pathology and etiology of cancer. It seems to me that we are not far from a serum diagnosis of carcinoma by means of which we can recognize this disease even before manifest symptoms have occurred. But even if such an early diagnosis could be made on apparently sound individuals for the time being, great difficulties would stand in the way

*Address before the Medical Association of Greater New York, April 11, and before the Academy of Medicine at Cleveland, O., May 12, 1906.

of reaching an early diagnosis, for who cares for his health as long as the admonishing voices of definite disease symptoms do not compel care. Rectal carcinomata lend themselves most readily to an early diagnosis in the second sense—that dating from the first manifest symptoms. My own private cases of rectal cancer during the last fifteen years number sixty-six. Of these forty-eight cases did not consult me nor any other physician until four months had elapsed after the first symptoms appeared. On the average five months had elapsed since the beginning of the first symptoms, before my cases consulted me. There were fifteen cases that came before three months had elapsed, but only ten of these were found proper cases for operation, and of these ten only six lived two years after operation and then a recurrence of cancer took place. Of eighty-four cases of rectal carcinoma (1896-1905) Boas states that sixty-two did not appear before him for relief until at least three months had elapsed since the first symptoms. On the average there was a loss of time of six months. Of only nine cases that came before less than three months had elapsed, four could no longer be radically operated upon, and two had passed the period of a feasible operation.

Carcinoma of the Colon.—In thirty-six cases of carcinoma of the colon the clinical history showed a record of intestinal diseases of two years in fourteen cases; of chronic colitis of four years in two cases. In two cases the symptoms characteristic of obstruction were existing six and seven years respectively, and in three cases the patients asserted they had obstinate constipation and occasional severe colitis for seven, eight, and nine years respectively. In fifteen cases the most searching inquiry failed to reveal any reliable data for the beginning of the intestinal difficulty.

The majority of cases, even of those that come to the clinician early, do not yet come early enough. *The prospects for early diagnosis of intestinal neoplasms are not favorable at present. The time for early diagnosis is beyond the limit of recognition of patient and diagnostician.*

Carcinoma and Sarcoma of the Duodenum, Ileum, and Jejunum.—From records of private practice I am able to report sixty cases of carcinoma and sarcoma of the duodenum, ileum, and jejunum, occurring during the last five years and in the clinical history of which there is a record of the time that elapsed between the appearance of the first noticeable intestinal symptoms and the time at which medical advice was sought.

Average time from appearance of first symptoms to consultation of physician: In twelve cases of carcinoma of the lower ileum, six months approximately (six months ten days to six months and eighteen days).

In twenty cases of carcinoma of the ileocecal valve, cecum, or end of ileum, four months.

In eight cases of carcinoma of the duodenum, extending from the pylorus or gallbladder, two months two weeks.

In eleven cases of carcinoma of the stomach with metastases in jejunum, ileum, and mesentery, average time, three months one week.

In one case of sarcoma of the ileum and splenic flexure of the colon, three months.

In eight cases of carcinoma of the upper ileum with metastases in the jejunum and mesentery, four months and two weeks.

Résumé.—We have before us, therefore, sixty-six cases of rectal cancer, in forty-eight of which the patient did not consult me or any other physician until four months had elapsed since the first noticeable symptoms had become manifest.

Taking them as a whole, five months had elapsed on the average before these patients had consulted me, and even of those who consulted me before three months had elapsed, only ten were operable; and of those ten only six lived two years after the operation.

In thirty-six cases of carcinoma of the colon, twenty-one cases had symptoms of severe intestinal abnormalities existing from two to nine years prior to their consulting me.

Of sixty cases of cancers of the small intestine, the average time from the appearance of the first symptoms to the consultation with the physician varied according to the situation of the cancer. In twelve cases of carcinoma of the lower ileum, this period was six months and fourteen days. The other dates are given above. Here we have a total of 162 cancers of the intestine as they present themselves in private practice, all coming too late for an early diagnosis and arriving at a time when the most enterprising surgeon would decline to do anything more than an exploratory laparotomy.

In the present state of our knowledge, therefore, the time of the early recognition of carcinomas of the digestive tract is so problematical that it will only exceptionally be possible. It is, therefore, of utmost importance that the researches of a biological and pathological nature aiming towards a serum diagnosis of malignant tumors should receive the encouragement of endowed institutions for medical research. I will have to refer the reader to previous publications on this subject for a more complete elucidation of the direction this form of investigation should take.[1]

CURABILITY OF TUBERCULOSIS OF THE PERITONEUM WITHOUT OPERATION.

In 1862 Spencer Wells operated upon a peritoneal tuberculosis owing to a diagnostic error, and for the first time a cure was observed to result from this treatment. Then followed König,[2] whose published observations caused a sustained preference for this method of treatment, and the following three publications, by Lindner[3] in 1892 with 205 cases, by Roersch in 1893 with 358 cases, and by Adossides[4] in 1893 with a report of 405 cases, give account of a total of 968 cases treated in this way. A number of these cases of tuberculosis peritonitis cured by laparotomy were seen at a second operation undertaken for some other cause, on which occasion the peritoneum could be thoroughly inspected and was found free from adhesions and perfectly smooth. The observations had the effect that the majority of surgeons and even of internal clinicians formed the opinion that laparotomy was the only effective treatment for this disease which otherwise would be fatal.

The question for the thinking clinician to decide is whether a tuberculous peritonitis, not treated by laparotomy, is really as malignant, whether its prognosis is actually as bad, as has hitherto been believed. In this connection it would be instructive to learn what the experience of representative clinicians in Europe and this country has been on this subject.

Nothnagel,[5] after emphasizing that the curability of tuberculous peritonitis has been demonstrated by operative observation, does not doubt the possibility of spontaneous cure.

Naunyn, in his lectures, expresses himself as follows: "The prognosis in the majority of cases is bad, but spontaneous cures and improvements are not as seldom as other authors assume." He adds:

"Only a small fraction of our cases have been transferred to surgical treatment."

Strümpell [6] holds that the prognosis of tuberculous peritonitis is absolutely unfavorable; in a few weeks or months a fatal end occurs. In some cases, however, a favorable result occurs in chronic tuberculous peritonitis, or at least a very evident improvement. This cure is only apparent, not an enduring one, for later on the tuberculous process occurs anew in some other organ.

Henoch [7] recommends that the peritoneal tuberculosis of children should be treated by laparotomy, in view of the "hopelessness of any internal therapy." If, in rare cases, a cure results by internal treatment, he considers that they were really not cases of tubercular peritonitis, but some simpler type of chronic peritonitis.

Pribram [8] reports spontaneous improvements which in rare cases have been followed by permanent cure.

Kussmaul [9] describes the case of a young girl with tuberculous peritonitis and incessantly swollen belly, who recovered spontaneously in spite of very impoverished environment.

The surgical and medical treatment of tuberculosis of the peritoneum is very ably compared by E. Graser,[10] but while the results of laparotomy are placed in a brilliant light, the results of conservative treatment are not compiled. The possibility of spontaneous recovery from the disease is, however, mentioned.

H. Braun,[11] in an article on tuberculous peritonitis, says the only successes possible are to be attributed to laparotomy. He does not doubt that spontaneous recoveries may occur, but this fact is not emphasized.

Classification.—The expressions used in classifying the different forms of peritonitis differ according to the view point of the observer making them. Thus we can already see in the literature of this subject three kinds of classifications of peritonitis, according to the standpoint of (1) the internal clinician, (2) the surgeon, and (3) the pathological anatomist. A favorable classification among surgeons is into three forms of peritonitis: (1) the simple exudative form or ascites; (2) the dry or adhesive form, and (3) the ulcerative and purulent form. According to König and Roersch laparotomy is capable of curing all three forms under certain conditions, but other surgical authors do not share this opinion. Pic recommends laparotomy only for the fibrous form with or without ascites, and Frank [12] found a mortality of 100 per cent. in the ulcerative purulent form of tuberculous peritonitis, seventy-four per cent. in the adhesive dry form, and thirty-four per cent. in the exudative form. The anatomical classification is beyond doubt the most exact and had best be considered under two headings, (1) acute and (2) chronic forms of peritonitis; under each of these there are several subdivisions.

Acute Forms of Peritonitis.—(1) Circumscribed, nonpurulent peritonitis. (2) Circumscribed, purulent peritonitis (abscess of the abdominal cavity). (3) Progressive purulent peritonitis: (*a*) Fibrinopurulent, (*b*) purulent, (*c*) gangrenous or ichorous form.

Chronic Forms of Peritonitis.—(1) Serous or serofibrinous peritonitis: (*a*) Purely serous, (*b*) partially adhesive, (*c*) diffusely adhesive form. (2) Purulent peritonitis: (*a*) Encapsulated, (*b*) diffuse chronic, purulent peritonitis. (3) Neoplasms of the peritoneum: (*a*) Tuberculous peritonitis, (*b*) benign neoplasms, (*c*) malignant neoplasms.

Neither the surgical classification above mentioned nor the pathologico anatomical classification can be followed by the clinical internist, for both of these classifications require in most cases that the peritoneal cavity of the living or dead body shall be opened before the diagnosis can be made. *The internist, however, is restricted to methods of physical and chemical diagnosis and the symptomatology of the case.* In a consideration of tuberculosis of the peritoneum, like the present, from the viewpoint of the internist, especially when the object and purpose is to demonstrate the possibility of a cure of this disease by nonsurgical methods, one has to be prepared to meet the objection that any given case of peritonitis which he cures may really not be tuberculous. In the following I will endeavor to give my experience in differentiating the different forms of peritonitis, but I wish to emphasize right here that *it would be very unfortunate for internal medicine if the clinician were allowed to diagnose only those diseases that could be objectively demonstrated to the eye.* The surgeons are given the opportunity for what might be called "an autopsy during life," but in defense of the purely clinical methods of the internist it should be said that the operative era has been of especially great value for the diagnosis of peritoneal tuberculosis, inasmuch as the operators have proven that tuberculous peritonitis is too seldom diagnosed and that it never is absent when the internist suspects it.

Clinical Types of Peritonitis.—In enumerating the various forms of peritonitis that might be confused with tuberculosis of the peritoneum I will, for the sake of brevity, pass over those forms of inflammation that are due to infection (1) through the genital tract in the female perioophoritis, perimetritis, (2) from the digestive tract, perigastritis and perityphilitis, (3) from the biliary apparatus, pericholecystitis, etc. There are forms of peritonitis also which occur secondarily during the course of chronic heart and kidney affections. These will also be passed over.

The more important left then are the following:

1. When peritoneal tuberculosis gradually develops with the clinical picture of simple ascites it is sometimes difficult to distinguish from the ascites due to cirrhosis of the liver. Both diseases may occur together. I have personally observed a case of peritoneal tuberculosis associated with typical hepatic cirrhosis. In those cases the diagnosis is extremely difficult.

2. Infectious diseases like measles, typhoid fever, and dysentery are sometimes found associated with ascites. Cases are on record where an ascites occurring during the course of measles was operated upon and the entire peritoneum was found covered with miliary tubercles.[13]

3. Malignant tumors of the peritoneum, intestine, gallbladder, or pancreas may be very difficult to differentiate from the tumor form of tuberculous peritonitis. For a distinction between such cases reference must be had to special works on the intestine and peritoneum. (Nothnagel, Hemmeter.)

4. There is a type of ascites that occurs in young girls during the period of adolescence called by French authors "ascite des jeunes filles." This is not due to an inflammation but is supposed to be caused by hyperemic and hypersecretory conditions of the peritoneal regions approximate to the inner genitalia. It disappears spontaneously after the first menstruations have occurred.[14]

5. Traumatic peritonitis. Chronic exudative peritonitis that is not tuberculous may occur after injuries to the abdomen. Cases of this type have been described by Henoch.[7]

6. In 1884 Curschmann [15] described a chronic inflammation of the peritoneum of a very peculiar type

and of nontuberculous nature which he entitled "Chronic Fibrous Polyserositis." It is always associated with a perihepatitis of the same peculiar type, giving the peritoneal and abdominal organs the appearance of being enclosed in a cast of opaque sugar "Zuckergussleber," "Zuckerguss der Serosen." The cause of this condition is not known. It has been observed after various infectious diseases and after circumscribed forms of peritonitis (cholelithiasis and perityphilitis). Curschmann states that the disease is characterized by two features, namely, a much reduced small hard liver, cylindrical at its edge, and a very protracted course, lasting from two to sixteen years. A distinction between this disease and tuberculosis of the peritoneum would be very difficult if no other signs of tuberculosis were in evidence, but this so-called Curschmann's disease is so rare that the diagnostician will not often be required to make this distinction.

7. Idiopathic chronic peritonitis. If we deduct from all possible forms of peritonitis those that are due to inflammations starting from the internal abdominal organs, those due to cirrhosis of the liver, to malignant tumors, to traumatic influences, the ascites in young female children and the chronic fibrous polyserositis, very little is left for the so-called idiopathic form. I have never seen a form of this type and doubt its occurrence, and I agree with Nothnagel, who states that the demonstration of a genuine primary idiopathic peritonitis has not yet been given. All of the cases that could possibly be classed as idiopathic would, in my opinion, be found to be tuberculous if some of the exudate were injected into the peritoneum of guinea-pigs or if the tuberculin test were made. Pribram [8] found among 3,500 autopsies by Chiari 165 cases of chronic peritonitis, but not a single one of them could, in his opinion, be designated as chronic idiopathic peritonitis without tuberculosis.

Differential Diagnosis.—In speaking of the diagnosis I shall not attempt to give the objective and subjective signs and symptoms that characterize all the forms of peritonitis which I have mentioned in the preceding, but simply emphasize three methods by the aid of which we are enabled to determine at least what is a tuberculous peritonitis and what is not. They might almost be called specific reactions for tuberculosis. These are:

1. Intraperitoneal injection into guinea-pigs of some of the peritoneal exudate. In three of the cases in my experience this method has helped us materially to make the diagnosis absolutely certain. I would suggest in doubtful cases to have the exudate drawn from the most dependent (lowest) portion of the peritoneal cavity, because the success of the infection in the guinea-pig depends upon the presence of the tubercle bacillus in the exudate; and one is more likely to get the bacilli in the pelvic portions of the peritoneum if the patient has been in the erect position for eight to ten hours.

2. Injections of tuberculin (Koch). With this material I have had a very extensive experience, having used it very often since 1890 for the diagnosis and treatment of pulmonary, gastric, and intestinal tuberculosis. In my work on diseases of the intestines (Chapter of Ulcers), I have described a case of tuberculous ulcer of the rectum which was diagnosed and cured by the injection of tuberculin, it being possible to observe the cure by inspection through the proctoscope.

3. The diazo reaction of Ehrlich. This has, in my experience, been a very valuable aid to secure a diagnosis in doubtful cases. If the diazo reaction is very decided and occurs repeatedly during several weeks, one has a right to suspect that any enlarged gland or abdominal tumor or peritonitis is due to a tuberculous process. A patient in my practice (female), aged thirty-eight, consulted me for severe abdominal pains and symptoms of obstruction. A tumor was palpable in the right iliac fossa that might have been mistaken, and was at first considered an appendical tumor. The diazo reaction was repeatedly found and an operation advised. Prof. L. McLane Tiffany found a tuberculous tumor of the colon involving the iliocecal valve, and at the same time there was a general tubercular peritonitis, but the tumor itself was not due to the tuberculosis of the cecum, but to a large caseous conglomeration of glands in the omentum. It is usually considered that a very evident diazo reaction is indicative of a very bad prognosis in pulmonary tuberculosis, and that such patients should be excluded from treatment in public institutions for tuberculosis. In cases of peritoneal tuberculosis, however, a very strong diazo reaction, lasting for six and even for eight weeks, need not necessarily be a cause of hopelessness, for such cases have been known to become very much improved, and even free from fever. There are cases of peritoneal tuberculosis on record which in spite of the diazo reaction, were cured by the conservative method, and remained cured for two and four years. The reliability of the diazo reaction is doubtless limited; typhoid fever, sepsis, miliary tuberculosis, and other conditions mentioned in most of the works on clinical chemistry, must be excluded; but if the yieldings of the first two methods support the diazo reaction there can be no doubt as to the existence of tuberculosis.

I have compiled eighty cases of tuberculosis of the peritoneum from the statistics and clinical records of the Hospital of the University of Maryland, Bayview Hospital, and from consultation and private practice. Twelve of these cases did not occur in my own private practice, but were seen by permission of other physicians, yet could be studied with sufficient thoroughness to definitely establish a diagnosis of peritoneal tuberculosis, not only from the clinical history, the results of physical examination of the lungs, but also one or more of the objective methods referred to in the preceding.

The question for us to decide was whether any so-called cure was possible by conservative or expectant treatment; and secondly, whether operative treatment could accomplish anything more and give evidence of any better results than the conservative treatment. In the American literature on the subject of prognosis of tuberculosis of the peritoneum, these two points are by no means satisfactorily investigated. There is a compilation of 357 cases collected from literature in the Johns Hopkins Hospital Reports, Vol. II., but there is no effort to ascertain the comparative merits of the operative and the conservative treatment of this disease of the peritoneum; nor could I find this point considered in our standard textbooks on the Practice of Medicine by American authors. Without going into a detailed quotation of American authors on this subject, it can be said that up to the year 1900, at least, the great majority held the view, and still holds the view, that tuberculosis of the peritoneum is almost always fatal unless treated by laparotomy. Even the most conservative internist shared the view of the surgeon that laparotomy gave decidedly better results than conservative treatment. In fact, at one time this operation was almost looked upon as a specific means of cure. It was, therefore, very astonishing to learn of the views of a prominent surgeon, in which he emphasized the possibility of spontaneous cure of tuberculosis of the peritoneum more

emphatically than any internist had ever done before. I consider this contribution so important that I will give a condensed abstract of it in the following:

Borchgrevink[17] found that those cases of tuberculous peritonitis healed most readily in which he found the tubercles already in a process of healing during laparotomy, and vice versa. He describes (p. 430) a primary healing of tubercles during which they disappear entirely, without leaving a trace on the peritoneum. This is the rule in peritoneal tuberculosis, and caseation of the tubercle is the exception. In the tissue of the serosa the growing tubercle produce a histological and physiological reaction that leads to proliferation of connective tissue cells and the appearance of leucocytes in varying numbers. Thus the serosa swells up around the tubercles which apparently sink deeper and deeper into the surface of the peritoneum. Eventually an organization occurs in this proliferation, most pronounced in the most superficial layer, and later a microscopical examination shows no tubercle bacilli nor giant cells. They appear as small fibroid nodules, but sometimes may yet produce tuberculosis when inoculated into guinea-pigs (p. 441). A simple (idiopathic) chronic peritonitis independent of tuberculosis does not exist, according to Borchgrevink. In six of his cases that were formerly sound with no hereditary history of tuberculosis, no tuberculosis of other organs, and that healed readily and definitely, it was proven that they were tuberculous after all, because the infectiousness of their exudate for guinea-pigs was shown by inoculation.

Laparotomy, according to Borchgrevink, exerts no healing influence on tuberculosis of the peritoneum (p. 446). The reported cures attributed to operation were in reality due to the spontaneous healing already described. Borchgrevink, therefore, rejects laparotomy as a curative means for all cases of tuberculosis of the peritoneum (p. 450).

The description of the resolution of the peritoneal tubercles in this article is given with all the evidences that usually reveal a complete mastery of the pathology of this subject. The account of the retrograde metamorphosis of tubercle stamps Prof. Borchgrevink as a very thorough surgical pathologist. He reports a clinical material of forty-four cases, and in addition three cases of perforation peritonitis. Of these, one-half, or twenty-two cases, were operated upon, and one-half were treated by the conservative or expectative method. In the cases that were treated by operation there were sixty-four per cent. of cures, and among the cases that were treated by the conservative method there were eighty-two per cent. of cures. Of those eighty-two per cent. of spontaneous cures there were forty-one per cent. that remained lastingly sound and well; namely, were reported well one to two years after they left his observation. A further twenty-seven per cent. were well two years after; so there are really sixty-eight per cent. of cures which lasted over one year as a result of the conservative treatment.

Borchgrevink is a surgeon, and it is therefore so much the more surprising that he should absolutely deny any curative effect to laparotomy in tuberculous peritonitis. My personal experience and opinion is that this view of Borchgrevink, while perfectly justifiable, if deductions are made only from his own cases, is too sweeping a view, if we should apply it to the results of our American surgical statistics of laparotomy for tuberculosis of the peritoneum. For although there may be a smaller percentage of cures after laparotomy for this disease, one cannot fail to recognize that there are a great many cases in which marked improvement followed, though here again one has to decide how much of the improvement is due to the laparotomy itself and how much is due to the favorable conditions of hospital environment and to the normal processes of repair.

As was said above, of eighty-two per cent. of Borchgrevink's spontaneous cures, forty-one per cent. were reported perfectly sound one to two years; and twenty-seven per cent. two years after they left his hospital; all in all sixty-eight per cent. of cures lasting over one year. This brings me to define what is meant by a permanent cure in operative and nonoperative cases. We should at least require that a case has been *observed by some reliable physician and reported well one year after the laparotomy or after the conservative course of treatment before we should feel justified in classing such a case among the cures.* I have observed in numerous American reports on operative cures of this disease that the writers do not speak of the length of time during which the after history of the operative case was controlled and reported by a physician. In the German reports by surgeons, the same objection can be urged against the great majority.

In an article on "Surgical Tuberculosis of the Abdominal Cavity," with special reference to tuberculous peritonitis, William J. Mayo[18] does not state definitely how long he had observed his cases of tuberculous peritonitis after this operation. In one place he states that since January of this year, meaning January, 1905, he operated on sixteen cases of tuberculous peritonitis; but as the article is published in April, 1905, this does not leave a sufficient time to speak of a cure in the sense of the term as it has been defined above. In another place Mayo asks the question, "Can we prevent a relapse?" and answers, "Certainly we can in many cases," and then continues, "Of twenty-six radical tubercle operations we have made on cases of tuberculous peritonitis, twenty-five recovered, and of these seven had been operated on by simple laparotomy one to four times previously; in not a single patient as yet has another operation become necessary." While this paper of Dr. Mayo is unusually meritorious because it emphasizes the necessity of seeking out the source of infection, either the appendix, the cecum, or the tubes and ovaries in women, and that a cure is more likely to follow if reinfection could be prevented by removal of the original portal of entry, it leaves us in doubt regarding the main condition upon which a claim of a cure can be made; namely, the time during which the patient was authentically observed after the operation. Mayo thinks the failure of simple laparotomy and evacuation of the fluid exudate in tuberculous peritonitis to maintain a high place in surgery is due to reinfection from lesions in the mucous membrane of the Fallopian tube, appendix, or some part of the intestinal tract. He admits, as is undoubtedly true, that the original infecting lesion can many times not be discovered, and that not all cases of reinfection can be explained by overlooking of the original source of infection. Mayo also admits that expectant or conservative treatment may many times cure the primary lesions by aiding a natural process of cure which I have described in the preceding.

We have here a fair-minded surgical presentation of the subject, which endeavors to do justice to the possibilities of cure that may come from a purely conservative treatment. We shall not reach the real truth as to which is the most expedient and correct course to pursue in the treatment of tuberculous peritonitis by asking whether we are to treat them all surgically or all by the expectant or conservative method. Put in this manner, the proposition with which we have to deal could not be settled

except in an unsatisfactory and dogmatic manner. The surgeons should, personally and individually, convince themselves of the spontaneous natural cure of tuberculosis of the peritoneum, to be impressed with capabilities of the normal forces of the body tending towards recovery (phagocytosis, opsonins, etc.), and in any given case be guided by accompanying conditions. For instance, I have known a number of cases operated upon that terminated fatally because the vital resources of the patient were too exhausted to overcome the effect of the narcosis and laparotomy. From the condition of the peritoneum I formed the idea that if the laparotomy had been postponed and executed, say a month later, the patient might have recovered.

The internist, on the other hand, should not gain the impression from Borchgrevink's work, nor from my experiences, as stated herein, that conservative medical treatment will always and under all conditions give better results and a larger number of cures than surgical treatment. There are cases of tuberculosis of the peritoneum which should always be operated; that is, as soon as certain accompanying constitutional signs and symptoms are evident, a laparotomy should be done. The rules that should serve as guiding lines to determine which cases should be operated and which should not, can only be determined by very large and objective experience and mature critical judgment.

I am not dealing in this report with acute peritonitis, nor with perforative peritonitis, nor with traumatic nor postoperative peritonitis; but with that form of peritonitis caused by the tubercle bacillus, and I desire that my remarks should be strictly interpreted as confined to this condition. The fact which William J. Mayo points out that removal of the Fallopian tubes effects a more permanent cure of the peritoneal tuberculosis if they constitute the source of infection, is shown in the following results of Adolf Frank,[12] published in 1900.

The conclusions of Adolf Frank are:

1. The best prognosis is met with in operative treatment of the exudative form of peritoneal tuberculosis, with forty to fifty per cent. definite cures.

2. In the adhesive form there is a grave prognosis; only twenty-five per cent. of operative cases are cured.

3. The ulcerative suppurative form has a very grave prognosis.

4. In the exudative as well as adhesive form the best prognosis is found in those cases of peritonitis that emanate from the female genitalia, and which are treated by removal of the adnexæ. In this manner seventy-five per cent. of the exudative, and fifty per cent. of the adhesive form are cured.

5. The attempt to relieve peritoneal stenotic phenomena by laparotomy and enteroanastomosis, appears justifiable, although the results leave much to be desired.

6. Tuberculous fecal fistulæ yield an exceedingly grave prognosis.

7. In ovarian cystomas associated with peritoneal tuberculosis, a definite prognosis cannot be established on account of the deficiency of material.

8. A compilation of nonoperative cases with a view to learning the permanent cures, and also those treated by abdominal puncture or aspiration, is exceedingly desirable.

The greater frequency of peritoneal tuberculosis in the female is undoubtedly due to the greater liability of infection by way of the adnexæ (Murphy, "Tuberculosis of the Female Generative Organs"). That a conservative treatment in such cases is liable to be followed by reinfection is a point in which I must agree with J. B. Murphy, Ochsner, and the Mayos, and it simply shows that this question cannot be decided by castiron rules one way or the other. It is still a subject that is on the borderland between surgery and medicine; yet I should like to formulate three conditions under which a tuberculous peritonitis should not be operated upon.

1. A diffuse tuberculous peritonitis, with high fever, is not a proper condition for operation. Such patients should be given a chance for improvement under conservative treatment.

2. Diffuse or localized forms of tuberculous peritonitis, with the objective signs of extensive irritation of the peritoneum (irritation meaning sensitiveness, not necessarily inflammation), and with symptoms of intoxication of the entire body. In these the operation should be postponed.

3. A general systemic infection and pronounced weakness should contraindicate the operation.

4. Extensive tuberculosis of other organs (lungs, larynx, liver, pleuræ) is a contraindication for operation.

Personal Observations.—Of the eighty cases of tuberculosis of the peritoneum which I could study personally, eleven could not be traced for sufficient length of time to render them available for this report. Of the sixty-nine cases that could be reached by correspondence with their physicians or because they belonged to my own private practice in Baltimore and its environs, twenty were operative. Of these twenty that were operated upon, the following gives the result one year after the date of operation:

John M. C. Diffuse peritoneal tuberculosis; source of infection unknown; laparotomy; living and well fourteen months after date of operation.

Henry H. O. Acute tuberculosis of the peritoneum and pleura; laparotomy; tuberculous appendix removed; well and sound two years after laparotomy.

Miss Elizabeth J. A. Tuberculosis of the peritoneum; no ascites; permanently cured, four years after operation.

Frank D. P. Tuberculous peritonitis; laparotomy; cured and well fourteen months after operation.

Anna W. J. Ascites, tuberculosis of the pleura; apparently cured three months after operation; relapse; pulmonary hemorrhages, fever; second ascites five months after original laparotomy; second laparotomy in Philadelphia; death.

Annie R. Ascites, tuberculosis of the lungs; laparotomy; improvement of six weeks, then double-sided exudative pleurisy and death. Ascites returned two weeks before death.

Miss R. T. Tuberculosis of the lungs, circumscribed fluctuating mass in the abdomen; laparotomy; no improvement; death four weeks after laparotomy.

Mrs. Julian B. F. Tuberculous ascites; laparotomy; improvement for three months, return of ascites at the end of third month, palpable tumor in right iliac fossa; reported second laparotomy in Washington and death.

Mrs. A. C. H. Tuberculosis of the peritoneum, otitis media, tuberculosis of the skin below the right ear; laparotomy; improvement for six weeks; return of ascites, high fever, pleurisy; death.

Dr. A. S. R. Tuberculous ascites; tuberculous swollen knee joint; laparotomy; writes that he is well six months after laparotomy; eight months after laparotomy report of his death from his physician.

Mrs. E. de V. Tuberculous ascites, tuberculosis of tubes and ovaries, fever of 103.5°, pleurisy; laparotomy; improvement for three months, then

gradual aggravation, pleuritic effusion, which is withdrawn by aspiration; as the pleurisy is recovered from the ascites returns; second laparotomy, removal of tubes and ovaries, which were found tuberculous; death two weeks after second operation.

Mrs. J. H. S. Tuberculous ascites; reports that fluid has already been withdrawn twice by tapping; supposed cirrhosis of the liver, but positive reaction to tuberculin tests; guinea-pigs become infected with tuberculosis by ascitic fluid, withdrawn; laparotomy; high fever continued; no improvement; death one month after laparotomy.

From the service of Prof. Randolph Winslow, University of Maryland, I am enabled to report the following cases of tuberculous peritonitis that were treated by operation:

E. C. E. Attorney, aged fifty-five; great emaciation, ascites; differential diagnosis between tuberculous peritonitis and cirrhosis of the liver could not be definitely established; laparotomy revealed tuberculous peritonitis; greater omentum retracted and rolled up into a strip; first seen November, 1905; improved after the operation, but lived only two months thereafter.

Miss P. T. Aged fifteen; admitted November 2, 1903; discharged December 1, 1903, very much improved; entered with fever, rapid pulse, distended abdomen and ascites; laparotomy revealed peritoneum studded with tubercles; drainage with gauze for forty-eight hours; there is no record of the length of time this case was observed and known to be well after the laparotomy; she is therefore not counted among the cures. (A recent report gives her present condition as favorable. September, 1907.)

W. M. White, male, aged sixteen years; seen by Dr. Winslow at House of Refuge, Baltimore, August 5, 1900; sent to the hospital of this institution with very high fever, pain in the abdomen; was supposed to be suffering from typhoid fever, and then sent to the University of Maryland; admitted August 11; emaciation, diarrhea, abdominal tenderness, irregular temperature, 99° to 103° F.; still supposed to be typhoid fever; a Widal reaction was reported positive; a sudden fall of temperature from 103° to 97° caused the suspicion of a perforation; laparotomy revealed tuberculosis of the peritoneum; complete recovery; reported sound and well six years after the operation.

W. R. B. White, female; probably from service of Prof. Frank Martin; tuberculous pleurisy, which was aspirated a year before admission to the hospital; admitted for supposed intestinal obstruction; ascites; laparotomy; tuberculosis of the peritoneum; recovery from operation, but symptoms of intestinal obstruction continued; death six weeks after the operation; intestinal obstruction due to peritoneal adhesions and large tuberculous mesenteric glands.

From the service of Prof. L. McLane Tiffany, of the University of Maryland:

C. J. Colored, female, aged sixty; tuberculosis of lungs, ascites; laparotomy; death within a week thereafter.

M. S. Colored, female; tuberculosis of the lungs, ascites; tuberculosis of Fallopian tubes and peritoneum; laparotomy; improvement; seen four months after operation; death reported six months after operation.

Mrs. J. White, aged thirty-six; ascites; peritoneum studded with tubercles; laparotomy; reported well two years after operation; may still be living.

J. C. McG. Male, white; ascites; tuberculosis of the peritoneum and of the lungs; laparotomy; death four weeks after operation.

From these twenty cases, then, I conclude that seven have been cured by operation, which makes a recovery of a little over one-third of the cases. Seven of the twenty were males and thirteen were females. It is interesting to note that of the seven cures five were in men. These cures did not occur in my own practice, but in the practice of colleagues, and some of them came from a great distance and lived where surgical help was not near, and I had to depend upon the reports of the physicians in the country for a knowledge of the progress of the case.

Forty-nine cases were treated medically; I include in this medical treatment the aspiration of extreme ascitic effusion by means of the same apparatus which is used for the aspiration of large pleuritic effusion. Thirty-two of the forty-nine cases treated by the conservative method were reported dead within eight months to one year after they were first seen. Seventeen were reported still living one year after they were first examined for treatment. Five were living three years after the first conservative treatment, two four years after the treatment, six two years after the treatment, and four one year and three months to one year and five months after the first conservative treatment. All in all, this makes seventeen lasting cures out of forty-nine cases treated by the conservative method. This is about one-third of the cases treated medically. While the results are about the same as for surgical treatment, it is necessary to point out that *the duration of the cure after the time of the first medical treatment was much longer in those cases that were treated conservatively than in those cases that were treated by operation.*

Koenig[19] claimed that one-fourth of all his operative cases of tuberculous peritonitis were cured. Czerny claimed thirty-eight per cent. of recoveries. Mikulicz and Rotter give forty-three and fifty-six per cent. of recoveries respectively.

A number of the statistics that have been reported, for instance, those of Frank, who give fifty per cent. of spontaneous cure, and those of Pic, who give twenty to thirty per cent. (quoted from A. Rose[20]), are not based upon a sufficiently large number of statistics. While I cannot confirm the results of the Surgeon Borchgrevink that more cases are cured under a purely conservative medical treatment than under operation, nevertheless my experience proves that at least as many cases of tuberculous peritonitis recover under the expectant or conservative treatment as will recover after an operation.

PEPTIC ULCER OF THE DUODENUM AND JEJUNUM FOLLOWING GASTROENTEROSTOMY FOR BENIGN STOMACH DISEASES (STENOSES).

The digestive act in the human being is so arranged that it occurs in media of varying chemical reactions. It begins in an alkaline, or at any rate, a neutral medium in the mouth. This is the beginning of amylopsis by ptyalin. Next follows a proteolytic action in the acid medium of the stomach. The pepsin of the gastric juice is not active in any but an acid medium, in fact, it forms an unstable compound with the hydrochloric acid. The next portion of the digestive tract is not adapted to the same degree of acidity of contents as the stomach, therefore, we find in the duodenum secretions which contain a great deal of alkali, whose immediate effect is the neutralization of the acid gastric chyme. The bile and the pancreatic juice as well as the intestinal juice of the upper part of the bowel, contain enzymes which are active only in an alkaline medium. If the HCl as it passes through the pylorus is not neutral-

ized the pepsin is still active. The columnar epithelium of the stomach has become resistant to pepsin HCl by a process of adaptation, but this is not the case with the epithelium of the duodenum. If there is free HCl in the duodenum the pepsin will attack the epithelium. This together with an altered state of the mucosa of the duodenum constitute the fundamental causes of duodenal ulcer. There are other causes, such as toxins circulating in the blood ("sepsin" of Edwin S. Faust, Pharmaceutical Laboratory, University of Strassburg) and also the toxins which result from extensive skin burns, but for our present purpose the above process of pathogenesis is of more direct bearing. We see, therefrom, that nature's purpose is to compel the acid chyme of the stomach to pass the orifices of the bile and pancreatic duct, and above all things that degree of acidity in the stomach should not, for any length of time, exceed two parts per 1,000. If, therefore, in gastroenterostomies for benign obstructions of the pylorus where the gastric juice is active (indeed very frequently it is hyperactive) it becomes necessary to establish an artificial communication between the stomach and the bowel, care must be taken to insure such a course for the food as nature intended it should take, for if the hyperacid gastric contents containing considerable active pepsin, continually pass over a duodenal mucosa, which is already chronically diseased, it is evident that conditions must become aggravated, and eventually duodenal or jejunal ulcer may develop.

My personal experience with such grave consequences of operation has all been in private practice. I have been consulted in the same case many different times, by surgeons who had operated for obstruction of the pylorus several months before, and who were obliged to operate a second time because of the return of intense pains and blood in the stools. I regret that it is impossible for me to publish my personal experience on such cases in full, the reason for this inability being that the particular patients were not seen often enough and the surgeon in charge preferred to publish the cases at some future period, but my experience does not differ much from that of Tiegel, which I quote in full in the following.

As a representative of that class of clinicians, who are endeavoring judiciously to cooperate with the surgeon, I desire to express the hope that as a result of this symposium there may be an effort on the part of the surgeons to convince themselves by personal investigation of the power for effecting a cure contained in the nonsurgical methods of treatment. This effectiveness of purely medical treatment holds good both before and after operation, even when such operations have become absolutely necessary, for it is possible to reduce the hyperacidity of the gastric juice and to heal a duodenitis and jejunitis.

Max Tiegel[21] reports twenty-two cases. The diagnosis is difficult in chronic cases; a sure diagnosis is impossible. The symptoms are the same as those of penetrating ulcer of the stomach. Medical treatment, because diagnosis cannot be made with certainty, is beset with difficulties. Surgical treatment is even more unfavorable. Of thirteen cases Tiegel states three died immediately after the operation. In eight cases there was a return of jejunal peptic ulcer. Only in two cases was the operation followed by radical cure, and in these two cases a long postoperative observation of the cases is not reported, and as recurrence of jejunal peptic ulcer in some reports is stated as coming on very long after the operation it is necessary to insist on a long observation of postoperative cases. Heidenhain reports a case that was operated upon a second time for recurring jejunal peptic ulcer and studied for four years, during which time he remained free from further intestinal ulcer. Of the recurring jejunal ulcers Tiegel reports two cases operated upon after the gastroenterostomy. In both a jejunostomy was undertaken. The first showed fresh ulcers at the pylorus, the second showed an ulcer at the place of the gastroenterostomy, which ulcer was excised; a jejunal fistula of jejunum was made (*i. e.* a third operation) and the patient was fed for three months through a tube inserted into the fistula. During this time, as well as three and a half months after removal of the tube, the patient was free from complaints. Then followed new symptoms which were found to be due to a new ulcer at the place of enteroanastomosis. The improvement due to jejunostomy was only transient in this case, and Tiegel now advises to discard a subsequent jejunostomy in such types of cases and substitute the digestive process in the stomach by rectal nutrition. Although rectal alimentation has a much inferior value for nutrition it should be preferred, as a transient measure, to a severe operation, very doubtful in its results, especially when one considers that these means and conditions of alimentation during jejunostomy are by no means ideal.

In view of these discouraging results of secondary operations in cases of jejunal peptic ulcers, a longer concession should be made to purely internal treatment. At least a very extensive attempt with the internal treatment should be made before proceeding to another operation. (Bed rest, liquid diet, rectal alimentation, hot external cataplasms, belladonna, alkalies, bismuth subnitrate, nitrate of silver, etc.) The etiology of jejunal ulcer is not uniform. There are three main causes: (1) Effect of gastric secretion retained by contraction of intestine below the point of gastroenteroanastomosis. (2) Circulatory disturbances. (3) Neurotrophic influences.

Dr. Stephen Watts[22] has reported two cases of peptic ulcers of the jejunum occurring in a dog after gastroenterostomy (published also by Mikulicz[23]). This paper contains an excellent illustration of the condition and and analysis of all cases reported in man to that date.

Of peptic ulcers of jejunum observed only after gastroenterostomy for benign disease of stomach, chiefly in males, there are two tpyes: (1) Those that are at first completely without symptoms, then a sudden perforation takes place into the peritoneal cavity. (2) Chronic cases, with severe pains and adhesions to other abdominal organs. These cannot be distinguished from penetrating gastric ulcer and are characterized by great tendency to recurrences.

In the second class the operative results are unfavorable. Treatment by internal therapeutics, rest, and diet is more favorable. Therefore, a purely medical and dietetic treatment, as in gastric ulcer, should be tried for a long time. Acute perforation compels immediate operation.

Posterior gastroenterostomy is less likely to be followed by jejunal ulcers than the anterior type of this operation.

Gastroenterostomy in benign affections (stenoses) of the stomach should be employed less and gastroduodenostomy more, and medical treatment should be more favored after any operation is recovered from, because of accumulating reports of duodenal and jejunal ulcer after these operations. Where an operation is necessary, pyloroplasty (Finney's operation) gastroduodenostomy is to be preferred. After every operation for benign affections of the stomach where a hyperpeptic gastric juice continues to be

secreted, strict diet, olive oil, and alkalies should be recommended for a long time. In short, such operated cases should be turned over once more to the internist for treatment by diet, rest, mineral waters, and such chemical agents as experience and experiments have proven to be of remedial and curative value.

SKIN GRAFTING WITHOUT ANESTHESIA.

BY JULIUS T. ROSE, M.D.,

BROOKLYN, NEW YORK.

SKIN grafting is generally considered to be a difficult surgical operation, requiring a general anesthetic. In reality it is very easy, and it does not require any anesthetic at all, not even local anesthesia, except in rare instances. The preliminary preparations are few, the instruments needed are fewer, and failures to obtain very satisfactory results are practically zero. Instead of being done only in hospitals by eminent surgeons, it can be easily and successfully done by the ordinary physician in his office or in the homes of his patients. It need not bear any resemblance to major surgery. In fact it is minor surgery first, last, and all the time.

But skin grafting without anesthesia is not of minor importance by any means. It is the most useful and practical healing agent we possess in cases where there is loss of skin and subcutaneous tissue, as in burns, ulcers, traumatic amputations, or following excision of tumors, carbuncles, etc. It heals these wounds in a small fraction of the time required by other methods, even if they are successful.

If it is employed early enough, as it can easily be if grafting is done without anesthesia, it prevents the formation of scar tissue with its subsequent contraction. And so, when the denuded area is over a joint, deformity and disability may be easily avoided; when the loss of skin, etc., extends partly or wholly about a limb, as at the ankle, or wrist, later contraction of the scar tissue and constriction of the circulation may be prevented; and, when employed on the face and neck, distortion of the features does not occur, and the skin covering obtained markedly diminishes the usual unsightly scarring.

When traumatic amputations of the extremities occur, with loss of skin extending to a greater or lesser distance beyond the line of amputation, it is not necessary to cut away bone and soft parts back far enough to get a healthy and complete skin flap. Just hasten the separation of the sloughing tissue, and, as the areas clean up, graft them.

Ulcers anywhere, but especially those troublesome ones on the legs, and any granulating wound, may be quickly and easily healed by this simple method of treatment.

No conscientious physician should hesitate, or fail, to use this method of rapid healing whenever and wherever it is needed. The cutting of a very thin graft, composed as it is mostly of the corneal layer of the epidermis, causes very little pain. Patients describe it as a burning feeling, and it causes in nearly all of them only a sharp indrawing of the breath, "ssss," for the few seconds required to remove the grafts; then the pain ceases. The opening of a boil or of an infected finger, the removing of a sliver from beneath a finger nail, the dressing of a sensitive wound or sinus, and many other common things done daily by the physician, without anesthesia, are much more painful while they last, and they last much longer. There is no pain connected with spreading the grafts on the wound or in applying the dressings, so the pain caused by skin grafting without anesthesia is quite insignificant. Yet for hysterical adults, or for very nervous children, it may be best to take the grafts from a friend, or to use local anesthesia, as ethyl chloride spray, ether, or ice, or to infiltrate the skin with a weak solution of cocaine, before attempting to remove the grafts. Covering the eyes of these patients with a bandage is often of use, so they cannot "see the pain."

If the various benefits that the patients will receive from this simple little proceeding, such as quick healing, avoidance of scarring, deformity, and disability, diminution in the number and frequency of painful dressings, each one of which may be as painful as skin grafting without anesthesia—if these and many others be brought to the attention of the patients, they will nearly all, nervous or otherwise, entirely disregard the trifling pain that they will expect to suffer, and choose to be treated by this most interesting and wonderful means of healing.

The following directions, if carefully followed, will give uniformly good results: Clean the skin which is to furnish the grafts with soap and hot water, and thoroughly flush off with physiological salt solution (boiling water 1 pint, common salt 1 teaspoonful). It may be necessary to shave off the hairs, if they are numerous, but hair does not grow on these grafts. Alcohol alone is a perfectly satisfactory cleansing agent. Grafts should be taken preferably from the arm or leg on the same side as the wound.

If the wound is a fresh one, irrigate it with hot salt solution; see to it that all bleeding is stopped, and

lay on the grafts at once. Grafts take readily on fat, muscle, connective tissue, periosteum, etc. If the wound contains tissue that must slough out, then hasten this process as much as possible. When it is desirable to avoid the formation of scar tissue, the grafting must be done as soon as the slough has separated. Do not wait till the whole area is clear, or for hollows to fill up, but cover the little areas of the wound as fast as they clear up every day, or every two or three days, as opportunity offers, until the whole wound has been completely covered. If the wound is already covered with healthy granulations, flush off with salt solution, and apply the grafts immediately. Do not cut down or curette the granulations. Do not rub them, or scrub them, or level them. Leave them alone.

If the granulations are unhealthy, treat them assiduously till they are healthy. It is surprising on what exuberant granulations these skin grafts will take, and how they seem to cut these granulations down, sometimes as much as a quarter-inch, or even half an inch. But it is not advisable to experiment with poor granulations; so, obtain healthy granulations before grafting. Every physician has his own special methods for bringing about this result. The following suggestions are offered as worthy of trial in these cases: (1) Where there is inflammation about the wound apply wet dressings of red wash, which consists of zinc sulphate, one dram, compound tincture of lavender, two ounces, and water, one quart; or use a 5 per cent. aqueous solution of ichthyol. (2) Where the circulation is poor and there is edema, elevate the part, strap the limb with zinc oxide adhesive strips, confine to chair or bed, give strychnine, etc. (3) Where a very rapid growth of healthy granulations is needed to fill in a deep wound, or to cover in exposed tendons, nothing equals diachylon ointment. Naphthalin crystals sprinkled thickly over the wound under the ointment helps to keep the granulations healthy and to separate the sloughing tissues when present. (4) Boric acid ointment is the best preliminary dressing to skin grafting on granulations, and is especially good where wounds are being grafted in sections, as it does not harm the grafts.

The instruments needed are (1) a very sharp, ordinary razor to cut the grafts with, (2) a flat-ended probe or small curette to spread them with, (3) a rectangular block of wood 3x2x1 inches, or a good sized glass syringe, to level and stretch the skin with. Soak them in 5 per cent. carbolic for 10 to 20 minutes, then rinse them off in alcohol, and put them into a dish of salt solution with some cotton wipes.

The skin having been cleaned, wet it with the salt solution, and press an edge of the block down onto the skin and toward yourself, thus securing a flat, tense strip of skin of the desired width for the graft. If an assistant presses the skin sideways around the limb it will help to put the skin on the stretch, and so diminish its sensitiveness. The razor should be held as for shaving, with the blade at a slight angle to the strip of skin, and crossing it at right angles, and with its edge resting gently against it. Do not make any pressure, but engage the edge of the wet blade in the corneal layer of the skin by drawing the edge lightly across it, and then, with a quick sawing to-and-fro motion, let the blade glide under the very thin, bluish graft which heaps itself up on the blade as it advances. Keep the graft thin by holding the blade almost flat on the skin, varying the angle as necessary just to keep it engaged, and no more. Remember, the razor must be *very sharp*, there must be *no pressure* with the edge, the graft must be *very thin*—and just *keep on sawing*. A graft can easily be cut 1 inch to 2 inches wide, and as long as desired, by moving the block along from time to time, as necessary. Of course, the size of the graft, as well as its shape, should depend upon the space to be covered.

Spread the graft at once directly from the blade. Drop some salt solution squeezed from the cotton wipes over the surface of the wound, then lay the edge of the blade against it, fix the end of the graft with the probe, or curette, against the wound or skin edge, and then withdraw the blade from under the graft in the direction desired. This spreads the graft almost perfectly. Any fold or air bubble may be easily worked out by pressure with the probe over it. The edges of the grafts should be made to overlap one another, if possible, and also the edges of the wound. This can readily be done by sliding the grafts by means of the probe to the desired position. Spaces left between grafts, while they heal fairly well in ordinary cases, are peculiarly liable to blister and break down, often involving a much greater area in the ulceration, and proving very troublesome to heal over without grafting again. Then, too, they cause the wound to have a checkered appearance which is far from pleasing.

Apply the dressing as follows: (1) One sheet of silver leaf laid carefully over the grafts. (This material may be obtained where painters' supplies are sold.) (2) A lattice work of strips of silk protective tissue about half an inch in width, and long enough to extend an inch or two beyond the margins of the wound. They should be wet in the salt solution and applied gently. When dry they adhere to the skin, and so fix the grafts firmly from all directions. Do not imbricate them. (3) Two or three thicknesses of gauze, either dry or wrung out of salt solution, and laid smooth. (4) A moist gauze bandage should then be laid very evenly and quite firmly over the grafted area, extending some distance above and below. This completes the inner dressing. (5) Then an abundance of dry, fluffy gauze or absorbent cotton. (6) A splint of wood, or plaster-of-Paris, if necessary to prevent movement of the parts. (7) An outside bandage applied loosely over all. This completes the outer dressing.

This combination of two separate and distinct dressings both fixes and protects the grafts. Any movement of the dressing caused by a bump, or knock, or friction of the clothing, takes place between the two bandages, not extending to the grafts. *This is very important, for if the grafts move they die.* It may be necessary to carry the arm in a sling, or to elevate the hand or the foot when the wound is on these parts, or even to confine the patient to chair or bed to aid the circulation. Strychnine in tonic doses is always indicated.

Dress the area from which the grafts were taken with (1) one sheet of silver leaf, (2) two or three thicknesses of dry gauze, (3) one thickness of dry gauze, larger than the others, stuck down all around with collodion, or adhesive plaster, to hold the dressing on. This is the only dressing required, and it may be removed in a week or ten days, when complete healing will be found to have taken place.

The grafts may be inspected with care in from 2 to 5 days. If there is only a slight discharge, it is better to leave them alone for from 7 to 10 days, but when there is considerable discharge, or the wound is being grafted in sections, the wound may be dressed every one, two or three days, as seems best. Great caution should always be observed in removing the dressing, as well as in applying it, so as not to move the grafts. (1) Cut the outside bandage and remove the dressing down to the inner

bandage. (2) Cut the inner bandage with sharp scissors along a line not over the grafts. Then remove the bandage and the gauze gently and gradually, after thoroughly moistening both with salt solution, especially over the lattice work of protective tissue strips, so as to leave this undisturbed. (3) Free the ends of the protective tissue strips all around; then, keeping the salt solution dropping all the time, turn down the lattice work and separate it very gently from the grafts. If this is done carefully, no grafts will be pulled off, or flushed off, or moved. Never rub, scrub, or sponge the grafts. If any secretion, or bit of silver leaf, adheres after salt solution has been gently dropped over it to flush it away, it is best to leave it alone, as it will do no harm and will come away of itself in due time. Beware of meddlesome cleanliness. Cultivate a certain amount of neglect.

(4) Repeat the dressing, as at first, with the same care and attention to detail. In ordinary cases after the tenth day a simple boric-acid ointment dressing may be applied. If the grafts are on an extremity, and there is any interference with the circulation, with edema, it is best to strap the part with zinc oxide adhesive strips, beginning well below the grafted area, and extending quite a distance above it. Each strip should pass clear around the limb and cross in front at a higher level, like a figure of eight. Each succeeding strip should overlap the preceding one about one-third. A little boric-acid ointment should be smeared over the grafts under the strips. This will protect the grafts from breaking down and keep them in place.

These directions have been given in considerable detail for the purpose of being complete enough to guide a beginner to a successful result. There are many other ways of preparing the wound to be grafted and of applying the dressings, and there are many other kinds of dressings, all of which may be successful in certain cases. But it is better to have one method that will surely give results you desire, and to have it thoroughly understood and carefully carried out, than to have a "grab-bag" full of possible methods from which to draw, so no others will be considered here.

Do not be misled into thinking that skin grafting without anesthesia is difficult, or impracticable, or beyond your skill. Know *what* to do and *how* to do it, then with a steady hand and a cheerful countenance go ahead and do it. Let the patient reflect your confidence and cheerfulness. The pain will be slight, and only for a moment, quite different from the long period of suffering and distress which accompanies a general anesthetic, and then it is so very important in its results. To repeat briefly: (1) Wash the skin with soap and hot water and flush it off with salt solution; (2) cut the graft with a sharp razor and spread it at once with a probe over the wound; (3) apply the dressing of silver leaf, silk protective tissue, gauze, and bandages; (4) redress in 5 days; (5) well in 10 days to 2 weeks.

The following may be noted as possible causes of failure: (1) Grafts were moved in some way; (2) circulation was poor, edema of the part; (3) fever, indigestion, menstruation, etc.; (4) unhealthy granulations to begin with; (5) pressure on the grafts; (6) hemorrhage under the grafts; (7) antiseptics, either on the grafts or the granulations, or both; (8) grafts not applied early enough to avoid the growth of scar tissue, hence subsequent contraction, disfigurement, disability, etc.

The remedies for these troubles have been discussed in the previous pages, and many others will suggest themselves when needed. They are nearly all prophylactic.

The following reports of cases treated by the above methods are offered as illustrations of the practicability and wide range of usefulness in everyday practice of skin grafting without anesthesia:

Case I.—H. H., eight years old. July 26, 1905, while riding on the rear fender of a trolley car, he sustained a compound fracture of the left leg at the junction of the middle and lower thirds. Both bones were fractured, and the opening through the skin was on the outer side over the fibula. The leg was put up in a fracture box with wet dressings of a weak antiseptic solution applied every four hours. July 29, blebs of various sizes had formed over the lower half of the leg, and the skin was very dark about the ankle. The blebs were opened and the leg thoroughly powdered with compound stearate of zinc. Then posterior and lateral plaster-of-Paris splints were applied. July 31, a collar of skin 3 to 5 inches in height, extending entirely around the ankle, was seen to be necrotic. Wet dressings again applied under the splints, and the foot was elevated. August 2, the dead skin and subcutaneous tissue beginning to slough; line of demarcation well defined; naphthalin crystals, and over it a thick dressing of diachylon ointment were applied. August 5, dead tissue being cut away and removed as rapidly as possible, but no areas clear as yet. August 7, same as above. August 9, a considerable area beginning to clear up. Boric-acid ointment applied to this area preparatory to skin grafting next time. The rest of the wound dressed with naphthalin crystals and diachylon ointment. August 11, about one-third of the whole area grafted from his thigh above, using ethyl chloride spray for local anesthesia; the remainder of the wound dressed with naphthalin crystals and boric ointment. August 14, all of the grafts took; a little over half of the remaining area was grafted as before. August 17, redressed; grafts all present and healthy; the remaining area, caused by a very deep slough, not yet clear, so naphthalin crystals and diachylon ointment applied. August 19, remainder grafted; this time the grafts were removed from the thigh of an adult, who was paralyzed and had no sensation of pain. August 23, all grafts healthy. August 28, entirely healed over; he was allowed up in a chair, but directed to keep his leg elevated on account of tendency to edema of the foot; directions not followed. At the next dressing a small area had broken down over a space between grafts. This later was covered by a small graft. Had he been kept in bed a little longer, or had his foot and leg been strapped, the healing would probably have been perfect. After two years this leg is just as healthy and strong and useful as the other. The new skin is movable on the deeper parts, and the tissues have filled out the ankle to normal size. There is no tenderness, and it does not break down under the friction and pressure of the shoe top. There is *no contraction* of scar tissue, because there is practically no scar tissue to contract. The circulation is perfect with no constriction, or obstruction, or edema.

Case II.—Mrs. C., sixty-eight years old. In December, 1905, she was scalded by the spilling of a cup of hot tea over her left shoulder and back. The skin sloughed off completely over an area about 6 by 8 inches. The whole area was grafted, on the removal of the slough, with thin grafts from her left thigh, taken without any anesthesia. She made very little complaint. Nine grafts were applied, but they were not overlapped. They all grew, and healing was complete in seventeen days, except-

ing one place about the size of a twenty-five cent piece. This took longer to heal, without grafting, than for the rest of that large area to be covered with skin. The dressing applied to keep the grafts from moving consisted of silver leaf, protective tissue, gauze, and the wet gauze bandage about the chest. Then fluffy gauze and a modified Velpeau. The dressing was kept wet for forty-eight hours with salt solution.

Case III.—R. D., fifty-seven years old. A carbuncle on the back of his neck was excised, its base cauterized with the Pacquelin cautery, and then packed with iodoform gauze. The wound was encouraged to fill up with granulation tissue. When nearly level with the skin over part of its surface, it was dressed with boric acid ointment for twenty-four hours, and the next day this half was grafted with skin from his thigh without anesthesia. He made no complaint of pain. The grafted area was dressed in the usual way and the remainder was covered with boric ointment. Five days later the dressings were changed and the remaining area grafted as before. On the tenth day the entire area was covered with skin, and a boric ointment dressing was applied. This was a very difficult place on which to fix the grafts, yet none moved or was lost, and the result was very satisfactory.

Case IV.—J. R., thirteen years old. A very nervous, hysterical Italian boy. While pushing material into a cement grinder he slipped and the machinery caught his right foot, crushing the four smaller toes, and tearing away the skin from the dorsum of the foot back to the instep. The toes were removed back to the metatarsal bones.

September 6, 1905. Weak bichloride solution applied as a wet dressing and renewed, as necessary, for forty-eight hours. Then diachylon ointment and naphthalin crystals, were used to stimulate a rapid growth of healthy granulations to cover the denuded area.

September 27. Whole area covered, and boric ointment applied to prepare granulations for the grafts the next day.

September 28. Grafts were removed from the right leg, without anesthesia. He did not make an audible sound while the grafts were being cut. The grafts were carefully overlapped, and the usual dressing applied.

October 3. The grafts were all healthy, and only a few drops of discharge could be found on the dressing, although the area grafted was at least five square inches.

Several months later, after steady use of the foot, there was no tenderness to pressure, and no tendency to break down or blister, and the foot was as useful as the other.

Case V.—J. B., seven years old. The thumb and its metacarpal bone on the right hand were blown off by the explosion of a cannon firecracker, July 3, 1905. The hand was dressed with wet dressings, then later, diachylon ointment and naphthalin crystals until July 20, when argyrol five per cent. solution was applied on gauze for twenty-four hours.

July 21. Boric acid ointment.

July 26. Granulations just right for skin grafting. They were red, they bled easily, and were on a level with the skin, all around the margin of which could be seen the thin bluish layer of advancing epithelium. Grafts were taken from his thigh without anesthesia. He made quite a fuss, but then, he always did whenever the wound was dressed.

August 6. All healed over, area one and one-half inches by two inches. He wore a boric ointment dressing for a few days longer.

During the two years that have elapsed there has been no trouble with the skin covering, and he has a useful hand.

Case VI.—F. S., Italian, twenty-four years old. Trolley accident. First seen July 1, 1905. Three tendons exposed on the dorsum of the foot over the metatarsal bones. Second toe gone. Wet dressings applied for forty-eight hours, then diachylon ointment and naphthalin crystals, and just before skin grafting, boric acid ointment. The granulating wound was from one to one and one-half inches wide and four inches long.

July 29. The grafts were cut from the leg above, without anesthesia. The sharp indrawing of the breath was the only manifestation of pain. The grafts all took nicely. There was considerable edema of the foot, as he was walking about somewhat, and, on the eleventh day, the grafts appeared to have sloughed off. But after elevation of the foot for twenty-four hours it was seen that only the outer layers had been lost, and that the wound was all covered with the thin bluish film, which later thickened and apparently served as well as the whole graft would have done, as there has been no cause for complaint during the last two years, or more.

Case VII.—P. B., nineteen years old.

June 25, 1907. He bumped his leg, and as the circulation was poor in that leg following a chronic osteomyelitis, the skin broke down, and an ulcer formed. The base was raw, and bluish in color and there seemed to be no attempt to form granulations. The base was cleaned, and stimulated, but progress was very slow.

July 6. The leg was strapped with zinc oxide adhesive strips, figure of eight, extending from the ankle to a good distance above the ulcer which was located anteriorly, about the middle of the leg. Granulations formed very slowly.

July 13. The granulating wound was covered with a single graft about the size of a half dollar, which was taken from the leg a short distance above. The skin was sponged off with a little alcohol, only, the graft quickly removed, placed, and its dressing applied, taking very little longer than the regular dressing.

July 18. Graft healthy and entirely covering the wound.

July 23. Same as above. Boric ointment dressing applied with a tight bandage. The gauze was pressed against the graft so as to leave the impressions of the threads. This caused the graft to break down in one place. The bandage was applied looser the next time, but the broken down area seemed to be extending.

July 25. Boric ointment smeared over the graft and the leg strapped from the ankle to above the calf with the zinc oxide adhesive strips.

August 1. Almost completely healed, very satisfactory improvement. Same dressing reapplied.

August 6. All healed. Restrapped.

The patient kept at his work, which required him to be on his feet all day, throughout the treatment. If the adhesive strapping had been used on the tenth day the graft would never have broken down. This is always indicated where there is interference with the return circulation as in forearm, leg, etc.

145 Halsey Street

The Game of Bowls.—In speaking of the revival of the ancient game of bowls, which is again growing very popular in England, the *Medical Press* says that from the medical point of view it has nothing but praise for this most excellent of recreations. It provides open-air exercise and amusement for old and young, it is admirably fitted for many invalids, and, above all, it is one of the best of what may be called natural opiates.

THE RELATIONSHIP OF TRAUMA TO INSANITY.*

By ARTHUR CONKLIN BRUSH, M.D.,

BROOKLYN, NEW YORK CITY.

PROFESSOR OF MENTAL AND NERVOUS DISEASE IN THE BROOKLYN POST-GRADUATE MEDICAL SCHOOL; NEUROLOGIST TO THE KINGS COUNTY, BROOKLYN EYE AND EAR, AND WILLIAMSBURG HOSPITALS.

The study of this subject reveals the fact that there has been in the past a wide difference of opinion among medical writers both as to the frequency and forms of insanity which are caused by physical injury. Some writers have included under the title of traumatic insanity any form of insanity or other abnormal mental state which occurs after an operation or injury to any part of the body, at any period afterwards, no matter how remote, and without even being connected with the injury by any clinical or pathological chain of events.

From this illogical situation there has been evolved, for a medical question, a marked unanimity of medical opinion concerning the questions at issue.

It now appears to be established as a fact that, for a trauma to be the producing cause of an insanity, it must be of a character to cause marked injury to the brain; the insanity must be continuous with the symptoms of such injury or occur within a certain period; and when an interval of time is interposed the two conditions must be connected by a definite chain of symptoms.

That insanity is not a common consequence of brain injury is established by the evidence collected by Meyer, who shows that in the Franco-German war only 13 cases occurred in 8,985 head injuries; that Stalper found only 12 cases in 931 cases of head injury; that Meyer found only 1 per cent. in 3,000 cases, Frost 1.87 per cent., Kiernan 2 per cent., and Edel 2.5 per cent. These figures are supported by the experience of the writer, who found only 1.3 per cent. in 2,100 cases of head injury seen by him.

The character of the producing cause is stated by Kraepelin, Kellogg, and Peterson as that of a severe head injury. This contention is supported by the histories of 27 cases seen by Meyer and of 28 collected by myself. In all of these cases the immediate symptoms of the brain injury were severe. In Meyer's cases it was accompanied by cerebral hemorrhage in six, and fracture of the skull in eight. In my cases the same complications occurred in six cases each.

As already stated, insanity is a rare result of head injury, due to the fact that when it occurs there is an additional factor necessary besides the head injury, which is furnished by the evidence of the previous existence of a neuropathic heredity, alcoholism, or syphilis. This contention is supported by the evidence found in Meyer's cases and those of the writer. In Meyer's cases five had an insane family history, two had suffered from previous attacks of insanity, and four from chronic alcoholism. In my cases there was an insane family history in five, previous attacks of insanity in four, alcoholism in six, and syphilis in eight. This evidence, taken in consideration with the well-known fact that the patient and friends as a rule try to conceal these facts, makes it reasonably certain that they are even of more importance than these figures indicate.

It appears also to be well established that there is but one form of insanity for which trauma can be recognized as the producing cause, and that is acute primary traumatic insanity or the acute encephalitis of the surgical writers. This psychosis is one of the few forms of insanity for which the surgeon and pathologist have been able to show us a definite lesion, which is that of cerebral contusion or bruising of the brain tissues. The associated lesions found in the bones of the skull in some cases are now regarded as of no importance, except when the brain is compressed or penetrated by the bone.

Such contusions are most common about the fourth ventricle and at the tips of the frontal and temporal lobes. Microscopically they consist of minute lacerations of brain tissue, ecchymoses, minute thrombi, edema, and capillary stasis with infiltration of the vascular walls. Complicating meningeal hemorrhage is also common. It is a well-established fact that in healthy brains all these lesions, with the exceptions of large hemorrhages, may entirely disappear, but in some cases changes in the cerebral circulation and nutrition may result.

The clinical picture and course of a case of traumatic insanity are held by Kraepelin and Meyer to be diagnostic of a severe cerebral contusion, and the histories of the latter's cases, as well as those observed by myself, fully support the contention of well-marked injury to the brain; as there was coma lasting from one hour to three days, muscular relaxation, dilated, sluggish, or unequal pupils, pale cold skin and rapid pulse, followed by headache, vertigo, delirium, and a rise in temperature. One symptom of cerebral contusion is held to be diagnostic of that condition, and that is a loss of memory for the facts concerning the injury and often of events occurring just before.

To establish a causal relationship between a cerebral contusion and this form of insanity it must appear that the insanity immediately followed the symptoms of the cerebral contusion, or, if a period of time intervenes, the two must be connected by a definite chain of cerebral symptoms. It appears that this intervening period is usually short, though in one of Meyer's cases it was as long as twenty-three months. This contention is supported by the statement of Kraepelin, that "the connection is not proven if a long space of time occurs between the injury and the gradual development of the insanity," and by the facts shown by Meyer's and my own cases. In eleven of Meyer's cases and nineteen of my own the symptoms of the insanity were continuous with those of the cerebral contusion. In eight of Meyer's cases a period of cerebrasthenia intervened, varying from three days to twenty-three months; and in five of my own cases a similar period occurred, varying from three days to twelve months. During this period the patients suffer from pain in the head, vertigo, mental fatigue, loss of memory, change and deterioration of character, irritability, and insomnia. All of which are made worse by small doses of alcohol or high temperatures. The invasion of the phychosis itself is rapid but not sudden. The patient becomes excited and sleepless or somnolent, or the two conditions alternate. The mood varies at different times, and the patient is anxious, irritable, depressed, or elated, with no idea of illness. Mental confusion is marked; and also loss of memory, especially relating to the facts of the injury, "whose happening is often denied." There is marked loss of knowledge of time, situation, and the identity of those about him. Answers to questions are rapid but rambling and often fictitious, resembling the condition known as Korsakoff's psychosis. There are periods of intense irritability at times, often with violent outbreaks from slight or no appreciable cause. Hallucinations and delusions, brief in duration and changing in character, are common. There is a tremor of the face and hands increased by movement, and often

*Read before the Brooklyn Society for Neurology.

causing indistinctness of speech. Paralytic conditions, localized muscular twitching, or seizures of the Jacksonian or grand-mal type may occur either as permanent or temporary conditions. The deep reflexes are increased and ataxia may be present. The pupils vary at different times, being dilated, contracted, or unequal. After a period varying from a few weeks to several months, gradual improvement occurs, which may end in complete recovery, or partial improvement, or the psychosis may pass into some other form of insanity.

The duration of the psychosis in eleven of Meyer's cases, in which recovery occurred, was from two months to two years; and in eighteen similar cases of the writer's from six weeks to two years. Death occurred in four of Meyer's cases after a period of two days to one month; and in four of my own in from two days to one month. Of the remaining cases reported by Meyer, three recovered, but relapsed, two partially recovered, one became an epileptic, and in four the psychosis was followed by other forms of insanity. Of the remaining six cases of my own, two became epileptic, two recovered partially, and in two the condition still continues. Dementia, when it follows traumatic insanity, is, according to Meyer and Kraepelin, always the result of in intervening epilepsy, alcoholism, or arteriosclerosis. In infancy faulty brain development is also claimed as a result, terminating in oddity, imbecility, or moral perversion. Death, when it occurs, is due to persistent insomnia or continuous muscular movement.

Besides acute primary traumatic insanity, the relation of one or two other forms of mental disease to trauma requires consideration. Acute primary or curable dementia appears as one often ascribed to trauma. It is a question of grave doubt if this psychosis should be be regarded as a result of trauma, as it appears especially in neuropaths between fifteen and twenty, from fright, mental fatigue, physical exhaustion, sexual excesses, and in many cases without known cause; nor does it appear that a brain injury alone is capable of producing the disease. It cannot be said then that an injury to the head was the producing cause in cases in which it has developed after such an injury.

Cases of this psychosis in which injury is claimed as the producing cause are rare in my experience, but three having thus come under my personal observation. These were all males, varying from sixteen to twenty. In none was a reliable family history obtainable. In all the physical injury to the head was slight; nor were the accidents of such a character as to cause much fright in normal persons. In my cases there was some evidence of slight shock, followed by irritability and mental confusion lasting from one to three days. The patients then passed into the characteristic condition, in which they remained motionless with vacant expression, paying no attention to dress or other physical needs, with complete loss of memory of time and place, and of those about the patient, with loss of general sensation, increased reflexes, feeble pulse, and respiration and subnormal temperature.

The duration of this psychosis, as stated by medical writers, varies from a few months to five years. There seems to be no authority for the duration of those cases alleged to follow trauma. In my cases the duration was three, nine, and thirty-six months. Complete recovery is claimed for the great majority of the cases of this psychosis. The few remaining gradually pass into secondary or organic dementia. There seems to be no medical authority as to the termination of the cases alleged to follow trauma. My three cases all made a complete recovery.

It is a well-established fact that secondary or organic dementia is never directly due to an injury, but is the natural result of other conditions which may be so caused, as cerebral hemorrhage, meningitis, epilepsy, acute primary traumatic insanity, and acute primary dementia. It can be claimed, then, if such a chain of events is established that the organic dementia is a natural result of the injury to the brain.

As a result, the patient slowly develops loss of memory, especially for recent events, mental confusion, and defective reasoning, groundless likes and dislikes, deterioration of character, and occasionally delusions and hallucinations.

Once developed, it is an unquestioned fact that the condition is permanent in character, but not necessarily in degree, as periods of temporary or permanent improvement are frequently seen. It has been the writer's experience that in young and healthy persons some degree of improvement can be noted after several years. This statement is based upon the condition noted in 106 of my cases. Of these forty had improved, twenty-six improved but relapsed, and thirty-nine had progressed.

General paresis or paralytic dementia is a disease which was ascribed to head injury by many medical writers, but at the present time the majority of such writers consider the disease of syphilitic origin and, with Peterson, deny that it can be so caused. As a rule, the recognition of the disease after a head injury is accounted for by the fact that its usual long and gradual development causes it to remain unnoticed until an injury calls attention to the patient's condition. It seems to be admitted by all that the course of the disease can be accelerated by a cerebral concussion. Starr, however, still claims that it may be due to a head injury, which is concurred in by Kirchoff and Berkeley. The latter two qualify their opinion by stating that traumatic cases present special symptoms and run a special course.

Assuming the facts already shown in describing the symptoms of acute primary traumatic insanity, such as imperfect articulation, irregular movements, intention tremors, increased reflexes, and the pupillary symptoms, it is evident that mistakes in diagnosis can easily occur without frequent and careful examinations, made over a considerable period of time.

It can be stated, then, as a fact that this disease is a sequel of syphilis, that it cannot be directly caused by a head injury, and that such head injury can accelerate its progress.

29 South Portland Avenue.

CRYPTORCHISM COMPLICATING IMBECILITY.

By B. S. TALMEY, M.D.,

NEW YORK.

GYNECOLOGIST TO THE YORKVILLE HOSPITAL; FORMERLY PATHOLOGIST TO THE MOTHERS' AND BABIES' HOSPITAL.

It is advisable, says Professor Grashey, that the family physician should keep records of mentally defective children he meets with in his daily practice. These records may be of great use, should the children in later life collide with the penal code. For this reason I think the history of the following case will be of some interest to the general practitioner in calling his attention to a class of cases he may discover in the families among whom he is practising.

Before giving the history of this case, it will be expedient to describe briefly the salient symptoms of

this class of mental defectives according to Grashey's lectures before his students at the university of Munich.

The Emotions.—The high-grade imbeciles are, in contradistinction to the complete idiots, able to master their language. In the very slight degrees of imbecility the disease represents only a deficiency of the emotions in a higher and lesser degree. Hence the anomaly can be discovered only in the emotional life of the patient. The most conspicuous symptom is the predominance of the passions. The imbeciles are easily irritated and very irascible. Their rage may reach the highest degree. They may fall into a great passion over a trifle. Their passionate moods are of long duration; they may cherish their temper for hours. A melancholy mood may last several hours, and even days, and under its influence they may commit suicide. A great number of suicides may thus be accounted for. The imaginative life is frequently well developed. The imbeciles may even acquire a vast store of experience, being often possessed of a splendid memory. Still the memory is in so far defective that the receptive power is extended alike upon the important and unimportant things. The splendid memory is the reason why the imbeciles are not recognized in school as such. On the contrary they are believed by their teachers to be talented. Still this deception is only possible if they happen to be good-natured, and not irascible or stubborn. Then they acquire a great amount of knowledge. But if the same is scrutinized a little more carefully, it is found that the imbeciles have not the right understanding of the things they have learned. They have learned everything by heart in a mechanical way, and they only reproduce like an encyclopedia the judgments of others which they have retained by means of their splendid memory.

Ordinarily the educators are able to recognize the mental deficiency of such individuals. The imbecile children cannot endure very long in school, because they cannot stand punishment. If punished they become entirely obstinate, and in their passions they fall into blind rage and become irresponsible. It is, therefore, dangerous to punish children with mental stigmata of degeneracy, especially to lock them up in confinement, for they may jump through the window.

The Ethical Life.—If the faculty of pure reason is closely scrutinized, it is found that imbecile children grasp with great difficulty ethical and moral conceptions. Although they have heard of parental piety, patriotism, truth, honesty, perseverance, gratitude, and know the meaning of the words, the deeper understanding is lacking. A normal person acquires with the ethical conceptions certain indefinable feelings—"Gefühlsbetonungen." At the mentioning of any ethical conception the normal person invariably feels something indefinable; he has a corresponding "Gefühlsbetonung." These accompanying feelings are of extreme importance to the character of the individual. They govern his actions and stimulate him in case of necessity to make the greatest sacrifices. The imbecile, on the other hand, lacks these ethical emotions; he does not possess the "Gefühlsbetonungen"; he is, therefore, not guided by them, they do not govern his actions. Even if he has learned a good deal and has found a good position, he is unable to remain there long. He has to have a change. This vacillation of the will and inconstancy of aspiration is often a very early symptom. Imbecile children are prone to run away. They leave their schools and do not return to their parents. When, as adults, they obtain a position, they remain there a certain length of time. Suddenly they disappear without any reasonable cause. When they have a public office the least disagreeable happenings will cause them to surrender their position and to desert without knowing what to begin afterwards. When the defect is of a very slight degree the patient may remain in his position a little longer, a year or so, but he will finally quit. If the imbecile has been a mechanic for some time, and something does not go according to his wishes, he will suddenly turn to painting or some other vocation to which he does not stick longer than to the first one. This restlessness, this lack of perseverance, indicates the pathological state even in cases where the imbecility is of a very slight degree.

If the mental defectives live in reduced circumstances and are not subject to the scrutinizing eyes of instructors and governesses, their disease remains hidden until they come in collision with the penal code. For the imbecile knows the ethical conceptions only by name and, therefore, comes in conflict with the district attorney's office through actions done in a temper, immoral crimes, or arson committed out of revenge. It is then often very hard for the expert to convince a jury that the criminal act is due to imbecility.

Exaltation.—The mental defectives have an exalted opinion of themselves. They believe that they possess great learning, and are well satisfied with their knowledge, while the normal man, even if he is very learned, knows that there remains enough for him to learn yet.

Physical Constitution.—In regard to the physical constitution of the mentally defective individual there is often nothing abnormal to be discovered, but sometimes there is to be found microcephalia or an excessive development of the thyroid gland, which may be degenerated by cysts, or otherwise enlarged. The physiognomy shows then certain peculiarities which tend to indicate the mental deficiency of the individual. At the autopsy it is at times found that the weight of the brain is diminished, or that the frontal gyrus is split and thus four frontal gyri are found. Sometimes there are imperfections in the corpus callosum.

This is a brief outline of the symptoms of the high-grade imbecile. Now we will study the history of my case.

P. P. is 22 years of age, stout, healthy looking, and about 5 feet 6 inches tall. The father is of an excitable disposition and the mother is very nervous. The grandmother is his father's half-sister; his father is thus his mother's uncle. His father was 31 years and his mother 19 years of age when they married. A year and ten months later the patient was born at full term in a small town abroad without artificial help. He began to walk and speak when ten months old. As a child the patient was always well, good-natured, and obedient.

Imaginative Life.—His parents came to live in this country when he was five years old, and he attended school in this city. He was very industrious and loved to read a good deal. He devoured especially books of history and biography and he had a splendid memory for dates. He graduated from public school with honor and attended high school for two years.

Emotions.—From the time of puberty he became irascible and easily excited. He began to practise masturbation when 14 years of age. At 17 years of age he began to have regular intercourse with venal women, but not oftener than once or twice a week. He reached his mental limit in his seventeenth year and began to deteriorate. His splendid memory be-

gan to diminish. He became careless in his personal appearance. His habits became unclean. He can now lie in dirt and filth without noticing it, and once his father found that he did not change his clothes at night or fix his bed for several weeks. The least little thing throws him into a rage. Thus he used to become very violent while in the hospital and repeatedly insulted the head nurse in the nastiest way. When reprimanded by his favored nurse he confessed that he knew it to be wrong to use such bad language, but something seemed to drive him to do so.

Ethical Life.—After he left high school he found employment in a jewelry business, but left the same after three weeks. He stayed then several weeks at home, helping his mother in the housework until he found a position in a library, where he remained six months. Suddenly he left this place and began to work in his father's store. Three months later he left the same to study dentistry with a dentist. Suddenly, after seven months' stay, he left the dentist and boarded in the lodging houses of the Bowery. There he led the life of a tramp in company with the scum of the big city for several weeks and returned home in the most shocking condition. He was literally covered with dirt and filth. His father took him again in his store, where he remained eight months. Suddenly, without any reason, he left it again to associate with the women of the Bowery. From this time on his life was divided between working in drug stores in Brooklyn, Yonkers, and Paterson, and the Bowery lodging houses. The characteristic part of his departures from the places of employment is the suddenness and unreasonableness. Without any justifiable reason and without giving notice he suddenly leaves the places, often even taking along the keys of the store, to stay several weeks with tramps, thieves, and venal women in the Bowery. After four to six weeks' tramping it looks as if the attack was over and he returns to his forgiving mother to begin to look again for work.

During his migratory life he came twice in conflict with the district attorney's office. The first time he was released from a magistrate's court, the second time the supreme court justice suspended sentence and put him under the supervision of the board of correction. He has absolutely no affection for his parents. Although he was always pampered by his mother and he knew that she spent sleepless nights worrying over him, yet he never wrote or let her know where he was while the "Wanderlust" took possession of him. Once he left his father to work alone in the store although the latter had just returned from the hospital after having undergone a dangerous operation and could not as yet walk properly. The sense of gratitude is entirely lacking in him. He did not think it worth while to greet on the street the teacher who gratuitously gave him private lessons in Latin.

Exaltation.—The exaltation of his ego was best shown while he was in the hospital. He boasted before the nurses about his great knowledge, claiming that he knew more than anybody else and that he could dispute with everybody on every topic.

Physical Constitution.—When nine years old, the patient's mother discovered one day that the boy had only one testicle, but the father laughed at her discovery and no further attention was paid to this anomaly. Five years ago the patient noticed a swelling in the right inguinal region which increased in size by degrees, but caused him no particular discomfort until a year ago when, jumping from a train, he was suddenly seized with acute pains which compelled him to stay in bed for thirty-six hours and to apply strong tobacco-poultices on the swelling. Since that time he frequently felt pains and was often doubled up on the street. When I first saw him he was also in bed suffering with pain.

Status Presens.—There is a swelling of the size of a hen's egg in the right inguinal region at the internal ring. There is no spermatic cord leading to the scrotum on the right side, nor can the right testicle be felt within the scrotum. The diagnosis was made "cryptorchismus and inguinal hernia," and an operation was recommended.

On March 1, 1907, the patient was operated upon. In severing the superficial fascia the peritoneal sac was opened inadvertently, it being adherent to the fascia. Through this opening we made a thorough examination of the peritoneal cavity and no trace of a testicle nor of a cord could be discovered. The opening was then closed with a tobacco-bag suture, the terminal sac removed and, the construction of a new canal not being necessary in this case, the externus muscle was sutured over the opening and the wound closed.

At the end of a week a stitch abscess developed and compelled the patient to remain five weeks in the hospital. He then went home and was directed to return every other day for a dressing. But he came only once, leaving his home to return to his former haunts on the Bowery.

Epicrisis.—If we analyze the emotional life, the imaginative life, the ethical and moral standard, and the exaltation of our patient, we find that his symptoms are almost identical with those of the high-grade imbecile. Probably the consanguinity of the parents may have something to do with the mental defect of our patient. The lack of the testicle may or may not be a contributing cause, but the entire absence of physical stigmata is not so infrequent in the high-grade imbecile.

There is, therefore, no doubt in my mind that we are dealing here with a mental defective. The prognosis in this case is very bad. If the patient is left to himself he will surely land in jail some day. The only safety I can see for him is in a congenial occupation in sequestration under constant unremitting supervision.

62 West One Hundred and Twenty-sixth Street.

Deviations of the Spine in Young Girls.—Ester gives the predisposing causes of scoliosis as feebleness of the muscular system and heredity. Myopia and bad position maintained at school are also causes. Young girls should be encouraged in all sorts of proper exercises so as to develop good muscular conditions, instead of being shut up in the house over sewing and books. The disease is very apt to develop in girls whose parents have had the same trouble, and some families are particularly liable to its development. Bad attitudes assumed in school at the desk in reading and writing are causes of its occurrence. When a girl is predisposed to it we should adopt a preventive treatment, consisting of placing the girl under the best possible hygienic conditions, allowing her extra amounts of sleep and rest in the horizontal position, and encouraging sea bathing and mountain air. She should never be allowed a corset that will at all compress her thorax, and should be supplied with a chair that will support the back and an inclined desk. Scoliosis is curable only in its earliest or formative stage. When the deformity cannot be removed voluntarily, but can be by suspension, it has reached the second degree. To these hygienic measures must now be added orthopedic gymnastics and an orthopedic corset made over a plaster cast of the body in suspension. In the third degree not even suspension will straighten out the spine, and forced movements under ether are necessary. But in this stage a true cure cannot be obtained.—*Annales de Médecine et Chirurgie Infantiles.*

RADIOGRAPH OF MUMMIFIED FOOT.

By EUGENE H. EISING, M.D.,

NEW YORK.

ADJUNCT SURGEON, LEBANON HOSPITAL; ASST. ADJUNCT SURGEON, MOUNT SINAI HOSPITAL.

THE mummified foot pictured below came into my possession through the family of an army officer

FIG. 1.—Mummified foot of an ancient Peruvian.

who was sent to Peru to gather specimens for the Centennial Exhibition of 1876.

Curiosity prompted me to make a fluoroscopic examination of the foot. The bony structures of the

FIG. 2.—Radiograph of the mummified foot shown in Fig. 1.

foot were found in so excellent a state of preservation that this remarkable finding was considered of sufficient interest to justify its publication in these pages.

Mummification was practised by the ancient Peruvians 3,000 years ago, and was still in vogue at the time of their conquest early in the sixteenth century. The purpose of embalming was to preserve inviolate the body for the corporeal resurrection of the dead. The soul after death was supposed to perform a painful probationary pilgrimage through the mysterious underworld, which journey consumed a period of time varying from 3,000 to 10,000 years. The wicked were condemned to permanent habitation in the subterranean regions, there to expiate their crimes in ages of wearisome toil, while the good were rewarded with a life of luxury and ease.

Compared to the Egyptians, the Peruvians were amateurs in the art of embalming. The Peruvians used, as did the Egyptians, balsams, oils, resins, and spices in that art, but the process they employed was relatively simple and rendered so by the peculiar atmospheric conditions under which they lived.

Vast mounds were erected for the reception of the dead. These mounds were penetrated by passages, the walls of which were arranged in galleries. In these galleries were placed the embalmed bodies, usually in the sitting posture.

With the deceased noble was buried some of his apparel, his utensils and treasures, and, to complete the gloomy ceremony, his wives and favorite domestics were sacrificed to bear him company and do him service in the happy regions beyond the clouds.

On certain festivals the royal mummies would be brought from their eternal resting place into the public square, where reverential entertainment would be provided to emulate the memory of the deceased hero.

I am indebted for the excellent radiograph and photograph to Mr. J. Harney of the Radiographic Department of the Mount Sinai Hospital.

18 EAST SIXTIETH STREET.

Acetonuria.—A discussion on this subject was recently held at a meeting of the Hunterian Society in the course of which Dr. W. L. Brown said that the presence of diacetic acid in the urine was more important than that of acetone, but diacetic acid was unstable and broke down into acetone if not excreted very rapidly. It was found not only in diabetes, but in recurrent vomiting in children, pernicious vomiting of pregnancy, mountain sickness, delayed chloroform poisoning, and starvation. Acetonuria was a symptom of tissue degradation, of acidosis with insufficiency of oxygen. It was possible that biliousness and migraine were both due to acetonuria. The most successful treatment consisted in the administration of large doses of sodium bicarbonate. Dr. L. A. Smith insisted on the importance of acetonuria in the differential diagnosis between diabetes and alimentary glycosuria. He demonstrated the fact that the urine of a patient who was taking salicylates gave a reaction with a solution of perchloride of iron similar to that given by urine containing diacetic acid. He spoke of the marked changes seen in the epithelium of the renal tubules in some fatal cases of diabetes. Dr. H. R. Andrews remarked on the fact that acetone was found sometimes in the urine after labor, particularly in cases where the labor had been difficult and prolonged, and asked whether it was possible that prolonged administration of chloroform was responsible. The theory that acetonuria could be looked on as a sign of intrauterine death of the fetus had been disproved. In some cases of necrobiosis of uterine fibroids acetone was found in the urine.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 16, 1907.

TUBERCULIN TREATMENT IN THE TUBERCULOSIS OF CHILDREN.

IN considering this topic in a recent issue of the *British Medical Journal* (October 26), Clive Riviere groups his cases under the two headings of strictly localized disease and not strictly localized, that is, accompanied by symptoms of general disturbance, such as fever. It is in the former group that the most notable successes have been achieved. The author says that success resolves itself into a question of dosage, and believes that this has often been too large. He names as average doses 1-12,000 to 1-8,000 mg. for one year of age, 1-4,000 mg. for five years, and 1-3,000 mg. for from ten to twelve years. During administration the opsonic index should be watched. If this cannot be secured, we must rely on the patient's weight and general progress. In the strictly local cases, tuberculin leads to increase in appetite, gain in weight, color, and general vitality; there is a marked change toward cheerfulness and renewed interest in life, and there is a distinct tendency toward local healing. In the category of cases thus treated have been instances of superficial abscess, dactylitis, gland disease, and joint disease, all tuberculous. The gland cases generally require prolonged treatment. In the second class of cases, such as phthisis and peritonitis, good results have also been obtained. In such cases the general poisoning shows itself, says the author, by a fluctuating and often high opsonic index, and it would seem probable on theoretical grounds that the introduction of fresh tuberculous elements, as in a tuberculin injection, would only add to the patient's disability. In practice this is not so; under tuberculin the opsonic power is steadied, though it rises no higher, and striking improvement in the general and local symptoms often takes place. This contradictory result impresses him with a conviction that there is much underlying the action of tuberculin which we do not yet understand, and that the changes in opsonic power present to us but a partial view of the effects of its injection.

Quite noteworthy results follow the injections as regards the effect on secondary lesions, open tuberculous processes frequently become the habitat of other germs, especially staphylococci and streptococci, and it has been shown that the dissemination of tubercle is favored by the existence of such a mixed infection. In wide lesions a condition of sapremic poisoning is kept up, which largely contributes to a downward course of the case. The author refers to the experiments of C. J. Shaw, who, by examination of the opsonic index of asylum patients to tubercle and other organisms (staphylococcus, *Bacillus coli*, and *Micrococcus rheumaticus*), discovered that a lowered index to tubercle among them was accompanied by a lowered index to these other organisms also. This seems to indicate a proneness on the part of the tuberculous or pretuberculous to infections by other organisms, and he also found that a large dose of tuberculin depressed the opsonic power, not only to tubercle (its specific effect), but also to the other organisms above mentioned. The converse to this, in absence yet of proof, may be taken as probable—namely, that the opsonic power to other organisms rises *pari passu* with its rise to tubercle under suitable doses of tuberculin. If this is so, it will explain the remarkable manner in which the secondary infections clear up under skilled tuberculin treatment.

In conclusion, Riviere urges that tuberculin given according to modern methods be more generally employed in pediatric practice. Failure in the past has been due more to faulty administration than to the uselessness of the remedy itself.

A NEW OPERATION FOR THE PERMANENT ENLARGEMENT OF A CONTRACTED PELVIS.

PREMATURE delivery, cesarean section, symphyseotomy, and pubiotomy are considered competitive procedures by some, while others claim that each has its own special indications and contraindications. No matter which view is held, when any of these operations is performed for a contracted pelvis, none of them cures the condition, and at subsequent pregnancies the same obstruction is encountered. In order to overcome this objection, Léon Maire (*La Presse Médicale*, August 28, 1907) devised the following operation, which permanently enlarges the pelvis, and thus permits subsequent labors to take a normal course.

The patient is placed on her back with the buttocks brought down to the edge of the table, the thighs being hyperextended and abducted. A horseshoe-shaped incision is then made through the skin and subcutaneous tissue, beginning at a point four-fingers' breadth below the right pubic spine, running upward toward it, then transversely across to the left pubic spine, describing a slight curve with its convexity upward, and then descending from the latter spine downward to a point four-fingers' breadth below it. The cutaneous flap thus mapped out is thrown downward by cutting close to the fibrous structures covering the pubes. This flap carries away with it the suspensory ligament of the clitoris, which is detached from above downwards, with the vein which traverses it. The nearer one reaches the ligamentum arcuatum while bringing down the flap, the more closely one must hug the pubes in order to avoid the deep dorsal vein of the clitoris and the plexus of Santorini. The adductor tendons are now severed perpendicularly to the adductor fibers, and to expose the superior border of the pubes the two recti and pyramidal muscles are cut from spine to spine, and the transversalis fascia is pushed back in order to expose the prevesicular space. To protect the vessels and soft parts behind the pubes, a flat metal retractor is inserted behind the symphysis from below, thus holding them back.

A Gigli saw is now passed behind the right pubes opposite the spine, and the bone is sawed from behind forward, as during a pubiotomy, but instead of bringing it through the whole thickness of the bone, the saw is carried only through one-half its thickness when its direction is changed, it being carried transversely across both pubic bones through their middle until a point opposite the left pubic spine is reached; the direction of the saw is now again changed, and it is brought directly forward through one-half the thickness of the left pubic bone. The bones then separate spontaneously from three to four centimeters, and if necessary they can be brought further apart. This separation is made permanent by placing a metallic plate between the two fragments of the right pubic bone behind, or, still better, by sutures which unite the superior and inferior borders of the separated fragments. The severed adductor tendons are then sutured together, and the recti are sewed to the fibrous tissue in front of the pubes; the suspensory ligament is repaired, and the skin flap is brought up and sutured into place.

Maire has performed this operation successfully several times, permanently enlarging the pelvis so that future deliveries took place without any operative interference.

PREVENTIVE MEDICINE.

It would be indeed a trite remark to make at this date that preventive medicine is the medicine of the future. This fact has been dinned into the ears of medical men and others in all parts of the civilized world more or less constantly during the past few years. Undoubtedly, then, it may be taken for granted that future efforts will tend perhaps more in the direction of preserving health than in the attempt to cure disease. Up to the present the commercial spirit had taken so strong a hold of the inhabitants of the foremost nations that public health had been neglected. The truth has now, however, become evident to the lowest intellect that without health a nation cannot prosper materially or in any other way, and consequently all the prominent countries are proceeding to place their houses in order from a sanitary standpoint.

Many addresses dealing with this phase of the matter have been delivered from time to time, one of the latest being the introductory address delivered at the opening of the winter session of the Middlesex Hospital, London, by Mr. A. G. R. Foulerton. The speaker pointed out that England had experienced a long period of indifference to all that concerned the public health, which had grown upon her with a prolonged period of commercial prosperity, but that she was now awakening to the extent of her folly. Mr. Foulerton drew attention to the fact that the people of the United States, the people of Germany, and the Japanese are profiting to-day by the work which has been rejected or ignored by the British party politicians. The British Government has turned always a deaf ear to the cries for sanitary reforms, and it has not been until the authorities have been compelled by public clamor to listen that any heed has been paid to such plaints. All this was in contradiction to Osler, who, when last in this country, took occasion to berate America for her neglect, and to laud Great Britain for her assiduous cultivation of the science of public health and sanitation. But Foulerton is to the manner born, and probably knows the existing conditions sufficiently to talk of them authoritatively. The latter part of this address was the more interesting, in that the remarks will apply to some extent to all civilized nations, especially to those of Europe, and in a lesser degree to this country. In referring to the unemployed, members of which army abound in all countries, the speaker said that for years the unemployed had been looked upon as representing the countryman who had come up to the towns to find work and could not get it; when the matter came to be investigated the healthy countryman out of work was searched for in vain. Instead the town-bred degenerate was found, the physically useless waste product which had been accumulating during long years of commercial prosperity during which the health of the worker had been neglected. The birth rates were then investigated, in order to observe if the town wastage was being made good in the country, and the serious discovery was made that the decline of the birth rate had been greatest in the rural and smaller urban districts, that there had been comparatively little decline in the factory towns and large cities, and that the most prolific of the population were the undesirable foreigners who were populating whole quarters of London, and who were adding to the population children who would be no more desirable citizens than their parents.

Although the evils of a falling birth-rate, and the deterioration of physique and mental degeneration consequent upon urban and factory life, are not confined to Great Britain alone, it is in that country that such conditions are most accentuated. Great Britain in some respects may be regarded as an object lesson to other countries, showing that too close attention to business and to heaping up riches is attended with so great drawbacks that on the whole the game may not be worth the candle. However, it all goes to confirm the truth of the text of this article, that preventive medicine will be the medicine of the future, not only for Great Britain and the crowded European countries, but even for America. The birth-rate among native-born Americans is very low; the quality of the immigrants who are now pouring into the country, despite restrictions and rigid inspection, cannot be described as, on the whole, very desirable; some of the large cities, notably New York, have become overcrowded, and, lastly, the tendency of the present-day immigrants is to herd together in towns. Thus, America has her problem of race degeneration, due to the same causes as produce it in Europe, which must be met by preventive medicine. The potentialities which lie in preventive medicine, properly applied, are described in a recent issue of the London *Times* in the following words: "No physician entertains the slightest doubt that the ordinary current disease of this country could be diminished by a single year of effective sanitary legislation and administration, say, to one-half of its present amount, and that it is becoming a matter of vital necessity that a correct understanding of this aspect of medical questions should be forcibly presented to the public." This is an unexaggerated statement, and may be recommended to the community at large for grave consideration.

A CASE OF MISSED LABOR.

A WELL-AUTHENTICATED case of "missed labor," that is, of ineffectual pains ending with the retention of the fetus for months, or even years, has been but rarely reported. Indeed, since E. Müller[1] in 1878 demonstrated that many alleged cases were those of ectopic gestation or of pregnancy in one horn of a bicornuate uterus, many obstetricians have been inclined to doubt that the product of gestation could be retained *in utero* for any considerable period of time after the physiological process of labor, however ineffectual at the time, had taken place.

A case reported by Balashov in No. 37, Vol. VI, of *Russkii Vratch* is therefore of considerable interest, being well authenticated by the objective findings and throwing light upon the etiology of this unusual phenomenon. A peasant woman who has had eight previous pregnancies was affected during her ninth pregnancy by some acute infectious disease, that may well have been typhoid fever according to the patient's description. During the disease the fetal movements, distinct up to that time, ceased altogether, and a short time after her sickness the woman went into labor. The amniotic fluid escaped in due time, and was followed by an abundant hemorrhage, but no fetus; soon after the pains of labor ceased, and there remained only the sensation of weight and of a "foreign body" in the pelvis. During the three succeeding years the patient suffered very much from leucorrhea, and once or twice passed some small bones per vaginam. She came to the hospital complaining of the offensive, purulent discharge, and general ill-health. An examination showed a small, flat bone in the cervical canal, and this was removed, together with many other small bones and a quantity of other matter. The bones were firmly attached to the internal wall of the uterus, and either during their withdrawal, or as a result of the curettage and bichloride douche that followed, the uterine wall was perforated and symptoms of shock appeared. An immediate abdominal section, performed for the repair of the perforation, now disclosed the probable cause of the "missed labor." The uterus proved to be thinned out and degenerated in many places, and, together with the adnexa, was firmly bound to the neighboring structures by many old adhesions. The perforation was repaired, the pelvic cavity sponged to remove the purulent material and the bichloride solution that entered it, and the woman made an uneventful, though a slow recovery.

It appeared probable that the infection which led to the death of the fetus was complicated by a mild peritonitis, and the weakened and adherent uterus could not expel its contents at the time of labor. An atonic uterus, firmly bound down by adhesions, may therefore be looked upon as one cause of "missed labor." The case reported is interesting because of the full and objective data given, and also because of the recovery of the patient after such a grave accident as the introduction of septic material and of bichloride solution into the peritoneal cavity. The fact that only half an hour was allowed to elapse between the discovery of the perforation and the abdominal section, which led to the complete recovery of the patient, points the moral of quick and decisive action as offering the best chance of safety in such accidents.

[1] E. Müller, De la grossesse utérine prolongée indéfinitement, etc., Paris.

THE ESTIMATION OF THE PEPSIN CONTENT OF THE GASTRIC JUICE.

WHILE for practical purposes the determination of the peptic power of the gastric juice may be roughly tested by observing its effect on discs of egg albumen coagulated by heat, accurate measurements of this function are far from simple. Of the two methods most often used, Hammerschlag's, in which the amount of undigested albumen left in a solution of known strength, to which the gastric juice has been added, is determined by means of Esbach's albuminometer, is not very accurate, while Mett's method, in which the amount of digestion taking place in capillary tubes filled with albumen and immersed in the juice to be tested, is troublesome, and requires extreme attention to detail if the results are to be worth the effort. A method that promises well is one that has been devised by Jakoby (*Zeitschrift für klinische Medizin*, Vol. 64, Nos. 1 and 2), and depends on Solms' observation that the cloudiness of acid solutions of ricin is cleared by the addition of pepsin. The steps of the method are as follows: A 1 one per cent. solution of ricin is made in 5 per cent. salt solution. Of this opalescent fluid 2 c.c. is placed in each of a series of test tubes, together with 0.5 c.c. of decinormal hydrochloric acid solution, which increases the cloudiness. To these tubes 1 c.c. each of different dilutions (ordinarily 1:10 to 1:1,000 of filtered stomach contents obtained after an Ewald test breakfast) is added, and the whole series, together with a blank control tube, is placed in the incubator for three hours. At the end of this time one observes which dilution in the series is the first to give a clear solution. The result is expressed in "pepsin units," one hundred of which represent the amount of pepsin in 1 c.c. of gastric contents of such strength that a 1 per cent. dilution under the above conditions causes the ricin solution to become clear. The method has been tested by Witte (*Berliner klinische Wochenschrift*, October 21, 1907), who finds it both convenient and reliable. In order to increase its theoretical accuracy, he recommends neutralizing the gastric juice with decinormal sodium hydrate solution before making the dilutions, but this would hardly be necessary in routine work. A disturbing factor of rather greater importance would be the difficulty that is sometimes experienced in obtaining filtrates of the stomach contents that are themselves quite free from cloudiness.

A NEW CLINICAL ENTITY—INTESTINAL LIPODYSTROPHY.

THAT the history, physical examination, and clinical course of a case often lead to one diagnosis while the autopsy reveals other conditions, is an established fact, and is well illustrated by the history of a case reported by Whipple in the September number of the *Johns Hopkins Hospital Bulletin*. The remarkable observations at autopsy led him to conclude that he was dealing with a definite and hitherto unrecognized picture which he called intestinal lipodystrophy. The patient complained of a long-standing cough, fever, progressive emaciation, abdominal swelling, and tenderness, and had stools containing many fat crystals indicative of defective fat absorption, all decidedly suggestive of a pul-

monary and mesenteric tuberculosis. The physical signs, however, did not justify a diagnosis of pulmonary tuberculosis and examination of the sputa was negative; the absence of a reaction to tuberculin was also strong evidence against the presence of an active tuberculous process. These observations, together with the finding of hard, enlarged mesenteric glands at an exploratory laparotomy led to a final clinical diagnosis of sarcoma or of Hodgkins' disease of the mesenteric glands. The lesions of interest at autopsy were found in the intestines and the lymphatic tissue draining this region. The intestinal mucosa showed enlarged villi due to deposits of large masses of neutral fats and fatty acids in the lymph spaces, and an infiltration of the interglandular tissue by large uninuclear and multinuclear cells. The mesenteric glands showed the same deposits in even greater amounts. The lymphatic tissue of the bronchial glands, bone-marrow, and lungs showed no abnormalities of importance. The other organs presented no changes relating to the intestinal lesions. Whipple advances several possible causes for the large amount of unsplit fats in the stools, and believes that some of the facts indicate that the deposits of fat in the tissues are in themselves in some way abnormal, or that they hold in suspension some abnormal or toxic substance. Since the pathological changes are limited to the apparatus which has to do with the absorption of fats, he believes the condition to be some obscure disturbance of fat metabolism.

The Infection of Scarlet Fever.

The general belief to-day is that scarlet fever is caused by a microorganism, though the specific germ is still unknown. This belief is justified, inasmuch as the erythematous angina, which can hardly be ranked as a complication since it is nearly as constant as the scarlatinal rash and is at its height with the maximum temperature, is always accompanied by some coccus. In view of this fact we have as much right to consider the secretions from the throat carriers of the contagion as the desquamated skin. In fact some believe, says G. H. Lemoine in the *Bulletin médical,* No. 48, 1907, that the throat is the original source of the contagion and that the desquamated particles of skin are not necessarily infectious, but may be the carriers of the contagion just as bedding and clothing, and that when they are, it is usually the particles from the face and hands which are the carriers, since they can easily become infected by the secretions from throat and mouth. Lemoine discharged fifty-one scarlet fever patients during the stage of desquamation, and in none of their families did any scarlet fever develop. In most of them the remaining desquamating area was confined to the lower extremities, and all the patients had their throats and mouths sprayed with antiseptic solutions throughout the disease, irrespective of the presence or absence of subjective symptoms. Another argument against the contagiousness of the scales was that none of many sufferers from measles and mumps who were placed in a ward which had been previously occupied by scarlet fever patients developed scarlet fever, though some scales of epidermis must have remained in the ward. He believes the mucous membrane of the mouth and pharynx to be the source of the contagion, and therefore holds that the chief prophylactic treatment consists in the disinfection of this part, carried out even during convalescence. To-day the prophylactic treatment of most practitioners still consists in isolating their patients until desquamation has stopped, while they pay but little attention to the throat unless subjective symptoms require it. Until we are certain as to the contagion and its location, it is certainly unwise to discharge desquamating patients, but it might be well to give more attention to the throat, as Lemoine suggests, throughout convalescence, whether symptoms referable to it are present or not.

The Treatment of Inoperable Tumors.

Malignant tumors that have become inoperable present so hopeless a prognosis that it is not astonishing to find many suggestions of the most varied nature made, if not for their cure, at least in the hope of prolonging life. Unfortunately, for the most part, but little success has attended these efforts except in alleviating to some extent the patient's suffering, and therefore interest attaches to any new measure proposed until its uselessness has been clearly demonstrated. Bier, for example, has attempted to influence such growths by the injection of foreign blood, apparently with some success, though in other cases the application of artificial hyperemia by the congestion bandage gave such unfavorable results as to make it seem that it was the character of the injected material, and not the hyperemia that was effective. Ritter, about a year ago, reported ten cases in which hyperemia was induced by the use of suction cups, and, while his results were not discouraging, the patients were all in so wretched a condition that not much could fairly be expected from any therapeutic measure. Recently (*Münchener medizinische Wochenschrift,* October 22, 1907) he has reported another case, that of a young and vigorous man, in which the effect was certainly very striking. On coming under observation, this patient was found suffering from an extensive new growth of the shoulder, which was so far advanced as to be wholly inoperable. A small section of the tumor for microscopic examination could be removed only with considerable difficulty, owing to the profuse hemorrhage, and was shown to be a small, round-celled sarcoma. As a last resort, daily applications of the suction cups were made with the astonishing result that the growth promptly began to diminish in size, and in a month had completely disappeared, so that the patient could be discharged freed from all disability, and to all intents cured. Of course, a single instance of this sort proves nothing, and what is perhaps the most important feature of the case, the patient's future history, is still unknown, but the fact that an individual suffering from such a condition was even for a time restored to health is both suggestive and encouraging.

News of the Week.

Dr. Finlay Honored.—On November 4, Dr. Carlos Finlay, chief of the Department of Health and Sanitation of Havana, was presented by Gov. Magoon with the Mary Kingsley medal in recognition of his work in connection with the transmission of yellow fever by mosquitos. The medal is awarded by the Liverpool School for the Study of Tropical Diseases to commemorate Miss Mary Kingsley, the African traveler.

A Local Treatment for Diphtheria.—Professor Rudolf Emmerich of the University of Munich has made public the results of his investigations on the bactericidal properties of substances formed in cultures of *Bacillus pyocyaneus,* particularly as applied to the treatment of diphtheria. By insufflation of

this material, which he calls pyocyanase, into the throat of a diphtheria patient, the bacilli of that disease are said to be destroyed in a short time.

Cancer Increasing in this State.—According to the monthly bulletin of the State Board of Health, deaths from cancer show no signs of decreasing. In September, 1907, 572 deaths from this cause were reported, as against 526 for the same month last year, and an average of 456 for the past five years. The tuberculosis mortality is said to be practically stationary.

Smallpox in Persia.—At a session of the Central Health Bureau in Teheran, it was stated that the mortality from smallpox in Persia is in the neighborhood of 75,000 annually. In spite of this fact the institute for the preparation of vaccine material, which was authorized in 1905, has not yet been started, although the necessary funds have been provided.

Losses Due to Cattle Ticks.—A report issued by the Department of Agriculture states that the annual loss occasioned through the cattle ticks is in the neighborhood of $100,000,000, which is equal to about 10 per cent. of the value of the cattle. The quality of the animals is the lowest and the loss is greatest in the regions where the natural conditions without the tick should produce the finest cattle with the least loss.

Doctor's Office Robbed.—A man, said to be about thirty-six years of age and 5 feet 10 inches in height, with dark complexion and hair, is being sought by the police for having last week robbed the office of a Brooklyn physician. The thief called during the doctor's absence, and at the servant's suggestion sat down to wait his return. He promptly disappeared after having entered several rooms in the house and abstracted jewelry, etc., to the value of $1,000.

Vaccination in St. Louis.—Since September 1, 6,500 children of the public schools of St. Louis have been vaccinated.

Free Vaccine is to be supplied from now on to the physicians and health officers of the State of Minnesota for use among the poor

State Control of Medical Colleges.—A bill, which gives the Illinois State Board of Health power to regulate and control medical colleges, and to determine the educational qualifications of applicants for admission to medical colleges, was recently passed by the Senate by a vote of 36 to 1.

Bequest to Philadelphia Hospitals.—By the will of the late Eliza R. Weeks of Philadelphia, the sum of $5,000 is bequeathed to the Episcopal Hospital for the endowment of a free bed in memory of her husband, the late Dr. Alfred Weeks. By the will of the late Miss Anna T. Jeanes, the interest and dividends on 148 shares of the capital stock of the Pennsylvania Company for Insurances on Lives and Granting Annuities is bequeathed to the Woman's Hospital, as long as the hospital will take care of women and children only to the exclusion of men; the sum of $10,000 is bequeathed to the West Philadelphia Hospital for Women, to Hahnemann Hospital, and to the Cancer Ward of the Philadelphia Home for Incurables, as an endowment in perpetuity, and the sum of $10,000 to the Women's Homeopathic Hospital and the Pennsylvania Hospital absolutely; the sum of $5,000 is bequeathed to the Red Bank Sanitarium Association of Philadelphia. The sum of $200,000 is to be set aside for the establishment of a new general hospital or infirmary for cancerous, nervous, and disabling ailments. By the will of the late Charles Hewett of Cheltenham Township, Montgomery County, Pa., the sum of $5,000 is bequeathed to the Episcopal Hospital of Philadelphia for a bed in memory of his two deceased wives, Anna Cordelia Hewett and Mary Ann Hewett.

Dr. Robley D. Owen has been appointed by Mayor Reyburn, surgeon to the police and fire departments of the city of Philadelphia in succession to Dr. Francis D. Patterson, resigned.

Medical Mayors.—At the recent election in New Jersey seven medical men were elected mayors in as many towns, and one undertaker, who was a candidate for mayor, was defeated.

New York Academy of Medicine.—The anniversary meeting and reception of the Academy of Medicine will be held at 8:30 P.M. on Friday, November 29, 1907. The anniversary discourse will be delivered by Col. W. C. Gorgas, M.D., U. S. A., Chief Sanitary Officer, Isthmian Canal Commission, the title being, "Sanitation of the Canal Zone."

Harvey Society Lectures.—The second lecture in the Harvey Society course will be delivered by Professor James Ewing of the Cornell Medical College, this evening, November 16, at 8:30 o'clock, at the Academy of Medicine. Subject, "The Etiology of Tumors." The lectures of the Society are open to all interested.

Sixteenth International Medical Congress.—The preliminary program of this Congress has been issued, and announces that it will be held in Budapest, August 29 to September 4, 1909, under the patronage of Emperor Francis Joseph I. Twenty-one sections are provided for, as well as two general sessions at the opening and closing of the congress. Several of the sections will also hold sessions in common. The manuscript of papers to be read must be in the hands of the secretary of the congress by January 31, 1909. The membership fee is five dollars; wives and daughters of members pay half the membership fee. Correspondence is to be directed to the office of the Sixteenth International Medical Congress, Budapest, VIII., Esterhazy-Utcza, 7.

International Congress on Tuberculosis.—Committees have been appointed in the following States for the purpose of participating in the congress which is to be held in Washington in September and October of next year: California, Utah, Montana, North Dakota, Minnesota, Wisconsin, Illinois, Iowa, Indiana, Michigan, Ohio, Missouri, Kentucky, Kansas, Tennessee, South Carolina, North Carolina, Maryland, New York, Massachusetts, Vermont, Maine, and West Virginia. A national committee for Holland has also been appointed.

Third District (Ark.) Medical Society.—At the recent meeting of this society at Helena, the following officers were elected: *President,* Dr. E. D. McKnight of Brinkley; *Secretary,* Dr. H. H. Rightor of Helena; *Treasurer,* Dr. R. L. Saxon of Holly Grove. The next meeting of the society will be held at Forrest City in November, 1908.

Eaton County (Mich.) Medical Society.—This organization has elected the following officers for the ensuing year: *President,* Dr. L. H. Quick of Olivet; *Vice-President,* Dr. A. H. Hixson of Grand Ledge; *Secretary,* Dr. A. H. Burleson of Olivet.

Central Illinois Homeopathic Society.—This society held its annual meeting in Bloomington on October 29 and elected officers as follows: *President,* Dr. W. P. Armstrong of Springfield; *Vice-President,* Dr. Charles Bogardus of Clinton; *Secretary,* Dr. Clara Garber of Decatur.

Hillsdale County (Mich.) Medical Society.—At the meeting of this society, held in Hillsdale on October 25, officers for the ensuing year were elected as follows: *President*, Dr. H. C. Miller of Hillsdale; *Vice-President*, Dr. S. B Frankhauser of Hillsdale; *Secretary*, Dr. H. H. Frazier of Allen; *Treasurer*, Dr. I. J. Stoner of Ransom.

Homeopathic Medical Society of St. Louis.—The following officers have been elected by this society: *President*, Dr. S. W. Coffman; *Vice-President*, Dr. H. Beal; *Secretary and Treasurer*, Dr. H. A. Uhlemeyer.

The Chicago Medical Examiners' Association, at a recent meeting, adopted resolutions severing its connection and affiliation with the American Association of Medical Examiners.

Obituary Notes.—Dr. CAMPBELL C. FITE of this city died on November 9, after a prolonged illness. Dr. Fite was born near Shelbyville, Tenn., in 1855. He studied medicine with his stepfather, Dr. R. F. Evans, and was graduated from the Louisville Medical College. He held several positions on the Tennessee Board of Health, and practised for a time in Nashville. In 1885 he was made assistant superintendent of the East Tennessee Hospital for the Insane at Knoxville, Tenn. In 1899 he removed to this city.

Dr. THOMAS P. CORBALLY of Brooklyn died on November 4, at the age of eighty-four years. He was graduated from the New York College of Physicians and Surgeons in 1868, having been a teacher of languages before he entered the medical profession. He had been connected with St. Peter's Hospital, Brooklyn, for a great many years.

Dr. MORRITZ E. RICHTER of Portsmouth, N. H., died on November 3, at an advanced age. He was born in Germany, and received his medical degree from the University of Leipsig. He had practised in Portsmouth for over fifty years, and retired from active work a few years ago.

Dr. JOHN E. GOGGINS of Conconully, Wash., died on October 21, at the age of thirty-three years. He had been a resident of Conconully for five years, and at the time of his death was health officer of Okanogan County.

Dr. JOSEPHINE KINGSLEY of San Antonio, Tex., died on October 14 of heart disease. Dr. Kingsley was born in Ripley, N. Y., and was graduated from the University of Michigan in 1873. She began practice in Detroit, and for five years was connected with the Women's Hospital of that city. She then removed to San Antonio, where she practised until the time of her death.

Dr. ALBERT M. WHEELER of Houghton, Mich., died on November 1, at the age of thirty-nine years. Dr. Wheeler was a native of New York State, but received his education in Ann Arbor, and in 1878 was graduated from the medical department of the University of Michigan. He had practised in Houghton for the last fourteen years, and had served many terms as county physician.

Dr. ARTHUR H. COWDREY of Stoneham, Mass., died on November 4, at the age of seventy-two years. He was born in Acton, Mass., and received his medical degree from Harvard Medical School with the class of 1857. He served through the Civil War as assistant surgeon in the Seventh Massachusetts Infantry and as surgeon of the Thirty-seventh U. S. Infantry. At the close of the war he settled in Stoneham, where he continued in practice until declining health caused his retirement two years ago.

Dr. THOMAS HILAND, U. S. N., retired, of Concord, N. H., died at Bar Harbor, Me., on October 29, after a long illness, due to cardiac disease. Dr. Hiland was born in Langdon in 1839 and was graduated from the medical department of Dartmouth College in 1862. He immediately entered the naval service, and was retired in 1884 with the rank of medical inspector, owing to an accident received in the service. Since that time he had practised in Concord as a specialist in diseases of the eye and the ear.

Dr. HENRY C. BOENNING died at Philadelphia on November 4, at the age of fifty years. He was graduated from Jefferson Medical College in the class of 1879, and became a resident physician in the Philadelphia Hospital. Subsequently he occupied teaching positions in the Medico-Chirurgical College, the Philadelphia School of Anatomy, the Philadelphia Dental College, and Temple College. He was the founder of the Garrettson Hospital, and he served a term as Port Physician, and later as Quarantine Physician at the Port of Philadelphia.

Dr. WILLIAM CHARLES TODD died at Philadelphia on October 3, at the age of eighty-four years. He was born in Ireland, but came to this country at the age of twenty years. He was graduated from Jefferson Medical College in the class of 1855. At the outbreak of the Civil War he was commissioned surgeon of the Sixty-sixth Regiment, Pennsylvania Volunteers, Infantry. He was subsequently transferred to the Fifth Regiment, Pennsylvania Cavalry, serving until August, 1864. He was the first member of the surgical staff of St. Timothy's Hospital.

Dr. MARY H. CHEYNEY died at West Chester, Pa., on November 9. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1885, and was for many years a member of the medical staff of the Chester County Hospital.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HARVEIAN ORATION AT ROYAL COLLEGE OF PHYSICIANS—BALY MEDAL—TROPICAL SCHOOL—LONDON OPEN TO PLAGUE—"OLD BARTS" ENTERTAINMENT—GUILD OF ST. LUKE—COLLEGE CALENDAR—OBITUARY.

LONDON, October 25, 1907.

THE Harveian Oration at the Royal College of Physicians was delivered on Friday by Dr. Frederick Taylor, the President, Sir R. D. Powell occupying the chair. It was at this college, in 1616, when giving the Lumleian lectures, that Harvey announced his great discovery, and though he had to contend with doubts and opposition he eventually established his position. In his will he left an endowment for an annual oration at this college in which the Fellows (there were no members or licentiates in those days) were to be exhorted "to search out and study the secrets of nature by way of experiment, and also, for the honor of the profession, to continue mutual love and affection among themselves." So for 250 years these orations have been given, and, as we may well believe, it can be no easy matter to impart novelty to a discourse under such circumstances or to add much in praise of Harvey himself and his great work. The advances in medical science in recent years form an interesting chapter, and their close connection with the dispute on vivisection cannot be overlooked. Dr. Taylor pointed out that Harvey's discovery was preceded by experiments on living animals and showed the necessity of testing the vital operations during life. Opposed to this necessity was, he said, the humane sentiment which restricted by law the number of persons making these experiments and the number of their operations. That policy adopted in this country was only saved from disastrous results because our doctors were able to use the knowledge obtained by vivisectionists in foreign countries; at the present time there was a movement to abolish these experiments altogether. It was asserted that vivisection was useless, but the example of Harvey sufficed to disprove the assertion. It was alleged that vivisection was immoral and cruel, but did anyone ever suppose that the medical profession approved it except to benefit humanity, and even the lower animals, too? For centuries the animals

had been killed for food, slaughtered to make way for human beings, maimed for sport, and kept in captivity for amusement. Why should vivisectionists be more blamed than people who did those things? As part of their daily life medical men saw acute human suffering, sometimes borne by persons very dear to them. Was it surprising that they should seek for means of relieving that suffering at the cost of slight pain to a few of the lower animals?

Passing to the consideration of the advances made in recent times, the orator observed that those connected with the circulation of the blood held a first place in any address in memory of Harvey. He therefore first spoke of the heart's beat in relation to the rather undesirable term "heart-block," the structure of the blood and the conditions of arterial tension. Here he referred to the work of Professor Starling, to whom the Baly medal was about to be presented. Next he spoke of asepsis in surgery and then of the treatment of diseases by antitoxins and opsonins. Having instanced these, he turned to the other side of the medal. Of the diseases of which the microorganisms have been discovered, few can be prevented or cured. Influenza yielded up the secret of its cause at its first invasion after bacteriology became an established science. But no advance in treatment had followed, and it still pursued its own sweet way, broke out in scattered epidemics from time to time without obvious cause, attacked some individuals over and over again, spared others entirely, invaded different organs in a most erratic way, and defied all efforts to control it. Referring next to plague and sleeping sickness, he added that after all the cure and prevention of infective diseases was only a part of the task of the profession. Pathology was not all inflammation, even if inflammation was mostly microbic. There remained regenerations, new growths, mechanical troubles, congenital deformities, and so on. There was extensive room for research, and though the number of workers on the highest lines might be limited, the body of the profession would always support Harvey's injunction to search out the secrets of nature. The orator concluded with the usual commemoration of benefactors of the college.

The President then presented the Baly medal to Professor Starling for his distinguished services to physiology, and said he did so with the greater pleasure on account of the peculiarly painful accusations to which the professor had been subjected by some who should have known better and others who, through simple-hearted ignorance, had been misled.

The School of Tropical Medicine began a new session on Tuesday under most promising auspices. The chair was taken by the assistant undersecretary for the Colonies (Mr. Antrobus), who remarked that the Colonial Office could not be accused of backwardness in relation to the study of tropical medicine, for it had been concerned in the foundation of the school and had helped to establish the chair of the subject in the University of London with which the school is connected. Moreover, the school possessed a chair of pathological entomology, one of three founded by the Colonial Office and, if that office became convinced that more money was needed for the investigation of tropical diseases, it would no doubt be able to get grants for the purpose. Knowledge of these diseases and their treatment was of the greatest importance to the Colonies and had already begun to bear fruit. In the last few years a marked improvement had shown itself in the health of the British Colonies and Protectorates in West Africa, and he saw no reason why that part of the world should not, with the help of schools such as this, be made one of the healthiest sections of the Empire. Everyone knew the part Sir Patrick Manson had played in the investigation of these diseases, and he noticed with pleasure that he had been chosen as the first President of the International Society on the subject.

Sir Lauder Brunton delivered an address in which after reminding his audience of the progress made in dealing with yellow fever and malaria since the discovery that they were communicated by mosquitos, he referred to sleeping sickness, which had devastated large tracts of Africa and threatened to do worse. The only chance of arresting it lay in destroying the fly which caused it, and as the same was true of other cases he urged that the government should establish an institute of pathological entomology well endowed and having attached to it men who could carry out original research. Malaria and sleeping sickness were of especial importance, although they did not directly affect the health of this country's taxpayers. But there was another of these scourges which might at any time do so—plague, now working havoc in India. This originated among rats, but not directly. Beyond doubt, though infected food might communicate plague, the fleas of rats were the main agents. Cases of plague arrived from time to time at the port of London, precautions were taken to isolate them, but rats might become infected. They crept along the ropes to the shore and by infecting other rats might start an epidemic. It was extraordinary, but true, that such minute and despised creatures as fleas were a national danger. It was folly to allow rat and flea-infected districts to exist in East London, which was in daily danger of being attacked by plague.

On Wednesday night "Old Barts" indulged in a sort of magnified house-warming in the new building. Some 2,000 ladies and gentlemen accepted the invitation of the medical staff and lecturers to come to see for themselves the last step in the progress of the great hospital. The colleges, universities, societies, naval and army services, and citizens of all degrees were represented among the guests who were received by the senior physician and surgeon, and in every part something had been prepared for their entertainment. The waiting hall was decorated with flowers and the band of the Life Guards. The building contains special departments for ophthalmic, laryngological, aural, dental, dermatological, gynecological, electrical, orthopedic, pharmaceutical, and chemical work. There were demonstrations in all directions, one of *x*-rays. Exhibitions, too, there were of whatever is important in modern hospital methods. One exhibition was devoted to showing the importance of pathology, and that illustrated the need of the new block now in course of erection for that department and stimulated the appeal for funds for that purpose. As one of the teachers remarked rather sadly, the public give freely to the immediate relief of suffering, but do not understand that the object of pathology is to prevent disease.

The annual service organized by the Guild of St. Luke was held at St. Paul's Cathedral on Tuesday evening There was a large congregation, and many of the doctors paraded in their academical robes. The collection was for the College of St. Luke, a residential institution for students training to be qualified medical missionaries.

The calendar of the Royal College of Surgeons gives 1,387 Fellows on the roll (an increase of 24 over last year). There are 17,544 members and 308 licentiates in midwifery, the discontinued diploma, now remain. The income amounted to £24,326, 17s. 8d., the chief item being fees for the membership, £15,219. But the members have no voice in the government, not even a vote for the council.

An "Olde Englyshe Faire" is being held in aid of the Bolingbroke Hospital, in Battersea Town Hall, which is built on a site which at a similar entertainment in 1881 was occupied by a family who took a leading part in getting it up. The site on which that hospital fair was itself held has long been built over. The other suburbs are growing as fast.

Dr. T. M. Dolan, J. P. of Halifax, died on the 22d inst. in his sixty-fourth year. He qualified at the two Edinburgh colleges in 1866. Took the Fellowship of the Surgeons in 1879, and M.D., Durham, 1883. He had been Vice-president of the British Gynecological Society and President of the local Medical Society, and held office in other societies. He was Fellow and Prizeman of the Medical Institute of Valencia, was awarded the Fothergill gold medal for his work on whooping-cough 1881, the Royston prize of Harvard University, 1882, for his "Sewer Gas," and obtained the £100 prize essay, 1881, on "Life Assurance." His work on "Rabies" appeared in 1878, and in 1892 on "Pasteur and Rabies." He held various professional offices in Halifax and wrote many other articles, translations, and pamphlets, besides numerous contributions to societies and journals—among them an "Analysis of 3,435 Consecutive Labors."

Dr. Wm. Hy. Day, Consulting Physician to the Samaritan Hospital, died on the 22d, aged seventy-six. He qualified in 1854, took M.D., St. And., 1857, and M.R.C.P., 1867. He wrote a work on "Diseases of Children" which went to a second edition in 1885, and a volume on "Headaches," which reached a fourth edition in 1888. Early in his career he entered the army medical service as assistant surgeon to the Buffs and served in the Crimea and during the siege of Sebastopol. Later he settled in London as a consultant and became attached to the Samaritan Hospital. He was a member of several societies, secretary for a considerable time of the Harveian, and a contributor of papers to both societies and journals.

Lt.-Col. Edmond Hoile, M.D., R.A.M.C., died on the 18th inst. in his seventieth year. He entered the service in 1858 and retired on pension in 1883. He served with distinction in the China war of 1860, and displayed unremitting devotion in the yellow fever epidemic at Barbados in 1881. During his long service he had been in the Engineers, the Devonshire, and the Lancers, in China, India, and the Colonies, and always obtained the confidence and esteem of those under his care. He wrote the report on yellow fever in the Army Medical Blue Book and the report on the Hoile military equipment for the War Office.

Deputy Surgeon-General R. W. Carter, A.M.S., who was in his seventy-seventh year, passed away in his sleep on the night of 20th-21st. He qualified M.R.C.S. and L.S.A. in 1854, and at once entered the army service, serving with the 20th Regiment through the Crimean campaign, including the Alma, Sebastopol, and Kinbourn. He afterwards went to India and served through the mutiny, 1858, and received the thanks of the Viceroy and His Royal Highness, the Commander-in Chief, for his devotion in the cholera epidemic in India, 1859. He took the M.D. of Calcutta 1865. He served in the Afghan War 1878-80, and was awarded the medal. He retired in 1884. Afterwards he became surgeon and consulting surgeon to the Weymouth Royal Eye Hospital. He wrote several papers on anesthesia and was the inventor of an ether inhaler.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

APPROPRIATIONS FOR NEW HOSPITALS—PHILIPPINES MEDICAL SCHOOL—CHOLERA—GOVERNMENT DOWRY FOR ORPHAN GIRLS.

MANILA, P. I., October 1, 1907.

THE requirements of the medical and sanitary service of the Philippine Islands have received further substantial recognition by the recent appropriation acts of the Philippine Commission. The sum of 780,000 pesos ($390,000 U. S. currency) was appropriated for the construction of a general hospital for the city of Manila. This sum, in addition to the amount previously appropriated for the site, makes about half a million dollars available for hospital purposes. It is proposed to merge with the new institution the present Civil Hospital, and to take care of the indigent and of such pay patients as may apply for treatment. The building will be of reinforced concrete and will be located upon the exposition grounds next to the buildings of the Bureau of Science, so that the best of laboratory facilities will be readily accessible. The buildings will consist essentially of an administration building, five two-story separate pavilions, which will have a capacity of thirty patients upon each floor, or six patients per pavilion. The present plans provide for 300 beds, and the construction is so arranged that new pavilions may be added as soon as additional appropriations become available. In view of the excellent facilities which this hospital will offer for the study of tropical diseases, and the large staff of the Bureau of Science being available for conducting laboratory work, the hospital will not only be a great benefit to the people of Manila and the Philippine Islands generally, but to the remainder of the world, which will no doubt derive considerable benefit from the study of tropical diseases which will be made there.

The Commission also appropriated the sum of 250,000 pesos ($125,000) for the construction of a new building for the Philippines Medical School, which was started during the past year. In view of the fact that many of the teaching staff have an international reputation, and with the excellent facilities for teaching tropical medicine which will be afforded, Manila bids fair to become the medical center of the Orient, and no doubt students will come from the different nearby countries to participate in the advantages which will be afforded.

The cholera, of which mention has been made from time to time, has shown a tendency to increase in the city of Manila during the past few weeks, although, to date, it has not taken on any of the characteristics of an epidemic, most of the cases being sporadic in character. The disease has been confined, practically, to the city of Manila. During the week ended September 28 there were twenty-eight cases and twenty-seven deaths reported. The disease is, however, virulent in type, the victims succumbing usually in a few hours after the first symptoms appear. To date only a few patients have reached the hospital alive. The presence of the disease has been attributed to the filthy practice in vogue with Chinese market gardeners, of fertilizing vegetables with liquid excrement. It is believed that a stool containing cholera organisms has fallen into the hands of one of these Chinese vegetable gardeners, and persons eating raw vegetables from that garden are being infected. Much evidence has been collected which tends to prove this theory. There is an act of the Commission which prohibits this practice, and appropriate penalties are prescribed, and, during the past week, several Chinese market gardeners were detected infringing the law and were convicted by the courts. The outbreak of the disease in the province of Leyte has apparently been checked; no cases of the disease having been reported for over two weeks.

In a recent appropriation act the Philippine Commission has included a provision which is rather novel in the annals of American legislation. At the Hospicio de San José, where indigent and homeless orphans are maintained by the government, it has developed that a large number of young females have become charges of the government. With a view to conforming to the customs of the country, the Commission has provided that in the event of the marriage of a female inmate of a charitable institution which is maintained at government expense, such inmate shall receive a dowry equal to the expense of maintenance for two years, such payment to be made in the discretion of the Secretary of the Interior.

CONTRADICTORY ADVICE TO CONSUMPTIVES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Referring to your editorial in the issue of November 2, entitled "Contradictory Advice to Consumptives," I beg to say that your reference to the subject is both timely and just. It is passing strange that it should be supposed that rules can be formulated which will enable the lay reader to know what course to pursue. Even the physician is sorely puzzled in trying to separate the "chaff from the wheat." The disease in question is confessedly one of the most difficult to overcome, and no method of treatment yet discovered is of universal application. We need to learn to treat the patient, and not the disease. The patient himself must become the chief weapon of victory in the hands of the skilful physician. Account must be taken of the personal equation and the campaign planned with special reference to the forces at our command.

When we stop theorizing and adopt this common-sense view, it will be found that every plan which has been suggested has something to recommend it and that certain classes of patients will benefit thereby. No further demonstration is needed to prove the absurdity of further effort to instruct the lay reader or to show the importance of leaving the matter in the hands of the medical profession —where it rightfully belongs.

JOSHUA L. BARTON, M.D.

NEW YORK.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 31, 1907.

The Origin of Right-Handedness.—An interesting article on this subject is contributed by George M. Gould, who traces the development of the child in its mentality and physical growth. Physiologically the only reason why an infant puts forth the right hand to grasp objects is because the right eye is the one which is nearest perfect visually, anatomically, or optically. The law derived from the phylum of the entire past is that the right eye and right fore-foot, or right hand, must work together. In all animals the right eye governs the placing and action of the right front foot of the right side of the body, the guarding against dangers on the right side, etc. The left eye has the same office for the left side. Heredity has place in the creation of the more nearly perfect right eye. If the left eye of the infant is the better seeing eye it will grasp at objects with the left hand, and become left-handed. Handedness, if one may devise the word, becomes either right-handedness or left-handedness, according to the dictating condition of the better eyedness, right or left. The writer goes back to the beginning of human records and says that right-handedness and general right-sidedness date back to primitive war, barter, and the tally-stick. The left hand and arm were used to hold the shield and thus protect the heart, while the right hand held the spear. After summarizing the peculiarities of the left cerebral hemisphere as contrasted with the right, in the adult, he states that the child is born with no discoverable differences of cerebral structure or substance of the two cerebral hemispheres, and none ever appears thereafter. But about the sixth month of life the babe, which will naturally become a right-handed one, begins to put forth the right hand instead of the left to grasp an object, and the cerebral matter about the left third frontal convolution, however unchanged or like that on the right side, is thenceforth increasingly and exclusively used to control the organs of speech, of writing, and of memory. The differentiation and complication of the cerebral mechanism whence spring all the acts begins in infancy with simple homogeneity, and grows in complexity with every year of added life. With each added year of differentiation the expertness grows, and it grows because the single cerebral mechanism has become more and more complex. There-

fore with each added year the impossibility of educating the corresponding centers on the right-brain becomes greater. The writer condemns unsparingly and with customary vigor the attempt to convert the occasionally left-handed child into a right-handed one and he also has no sympathy with the "ambidexterity mongers," whose aims he declares are futile. The trend in all human beings is, he says, for them to become more and more exclusively and despotically either right-handed or left-handed. So that with each added generation the impossibility of ambidexterity will increase.

New York Medical Journal, November 2, 1907.

Hyoscine Hypodermic Anesthesia.—F. B. Kirby follows the plan herewith given. The patient is given a hypodermic injection of hyoscine hydrobromide 1/100 gr., morphine hydrochloride 1/4 gr., and cactin 1/67 gr. The room is darkened and the patient encouraged to sleep. One hour later a second dose is given and in half an hour the operation may be begun. If the patient is not completely "under," a little chloroform will suffice. The writer's experience has been mainly in obstetrics and he notes that the patient usually sleeps between the pains which always awaken her to active help in aiding expulsion. In some few cases the child has been cyanotic for a while, but always revived in a short time. This effect on the child is avoided by omitting morphine from the second dose. In no case have any untoward results been observed. It is doubtful whether labor is prolonged, but rather to the contrary, as the mother's strength is conserved to be used *with* the pains and not lost *between* them. The anesthetic is too profound for minor surgery and should be used with care at the extremes of life. The patient is in a state of slumber and will readily respond to a sharp command. The writer declares that in railroad and other accidents the new method is of great value. Here twenty-five or fifty people could receive preliminary pain-relieving treatment while one was being cared for with ether anesthesia and in the hour and a half necessary could be transported to a suitable place for care.

Treatment of Anemia.—After enumerating the causes and classical symptoms of this condition and describing the blood state, C. Pope takes up the question of treatment. He has had the usual disappointing experiences with drugs and makes a strong plea for the more general employment of hydrotherapy and phototherapy. He considers two classes of cases, bed ridden and ambulatory. The details of his plan are as follows: Commence in the first class with the daily use of a dry blanket pack, enveloping the patient tightly in the same for twenty to forty minutes in order to collect heat upon the surface, this to be followed by the cold sponge or ablution at 70° to 50° F., followed by good reaction and general body friction. When the patient's reactive power has been well developed by this method we may substitute for the pack and sponge the following: While the patient stands in a very hot foot bath, the "dripping or sheet bath" is given with vigorous friction, duration three minutes, commencing with a temperature of 70° F., reducing 2° daily to 60°. It should be given in the early morning as an opening procedure for the day. As soon as the patient is ambulatory we may commence with the administration of the incandescent electric light bath until commencing perspiration, or dry hot air to the same point, although the electric light bath is by far the best. As soon as the patient warms up thoroughly give the circular, needle, or rain bath at 102° F. for one to one and a half minutes, reduced to 60° F. for a quarter of a minute, pressure 20 to 30 pounds. Good reaction must be obtained. In women this will be as strong a treatment as they can usually stand with comfort. With men, however, we may use the electric light bath to point of perspiration, followed by a circular, needle, or rain bath at 102° to 104° F. for one minute, this in its turn to be followed by the jet douche to the spine at 60° F. for one quarter of a minute, followed in its turn by the fan douche to the entire body, especially the abdomen, for a quarter of a minute, 20 to 30 pounds pressure. It is sometimes an excellent rule to play the jet douche up and down the posterior aspects of the lower limbs and gently over the surface of the tibiæ, for this oftentimes very materially stimulates the marrow of the long bones to the formation of blood cells or drives the cells into the circulation.

Diet in Tuberculosis.—J. V. White says that there is no specific diet in tuberculosis. Faulty digestion and malnutrition form an etiological factor in every case. Consequently to practise forced feeding as a routine measure is in the highest degree illogical. If it is attempted, serious results may follow. The treatment of digestive disorders in phthisical patients does not differ from that in other patients except in the urgency of the case. A restricted diet is often necessary at the outset. This rests the digestive organs and facilitates elimination of toxic material. Fever, muscular exercise, age, and mental condition all determine the proper diet. For example, much physical labor calls for a large proportion of carbohydrates. If the temperature is high, salt should be diminished and water increased. Autointoxication is a most pernicious factor in the disease. Consequently the greatest vigilance should be directed against the ingestion of food which may contain bacilli. The best way to do this is to investigate the source of the food. To this end much is being done in the inspection of cows. Cows, the milk of which shows the slightest suspicion of tuberculosis, should be excluded from the herd. When we consider the number of babies and children fed upon an exclusive milk diet, and when we recall the fact that the bacillus that keeps up the great white plague is most commonly introduced into the system in this way, and when we further recall the fact that these germs may remain in the system for years before they begin their deadly operations, we are compelled to regard the milk of tuberculous cows with the greatest apprehension. On occasion of some trifling ailment these germs break their fetters, and like dogs of war attack the very citadels of life. The pale and vanquished victims ascribe it to some cold or exposure, but the physician knows that the primary cause was introduced in babyhood or later, very probably in the form of tuberculous milk.

Physical Defects of School Children, Causing Subnormal and Mentally Deficient Pupils.—S. A. Newmayer enumerates as the chief factors in producing this class of backward children, fatigue or chronic exhaustion, starvation, toxemia, nervousness, defective vision, defective hearing, and defective speech. He then elaborates these various headings and submits a form of chart which he has found satisfactory in recording the facts brought out in examining defective school children. He notes that the examination should be thorough, as upon these findings are based the methods of treatment. Nutrition, weight, and height should be noted, and any increase during treatment should be observed. Nerve signs and coordination should be recorded, after using the various tests at our command. The eyes, ears, and nasopharynx, including speech, should best be reported upon by a specialist of these branches. Questioning the pupil tells much as to the mental and nerve conditions, as well as speech and hearing. As to abnormality or asymmetry in formation of skull or other members of body, its presence with mental deficiency is significant. But they are sometimes present without an impaired mental state. Treatment is preventative and curative. The former includes proper school sanitation and the latter the removal of any obvious defects of eyes, ears, throat, etc. A valuable modern advance has been the placing of backward children in special small classes by themselves and under the care of a special teacher. This includes manual training, which is of value as leading to concentration.

Journal of the American Medical Association, November 9, 1907.

Deep Alcohol Injections in Neuralgia.—H. T. Patrick reports sixteen cases of trifacial neuralgia treated by deep alcohol injections according to the method of Levy and Baudouin, which he describes. The exact location of the injection by the physician is not without its difficulties, owing to the anatomic variations that are so common, but the injections are apparently often effective even if the exact point aimed at has not been reached. Fortunately, Patrick says, it is not necessary to get the alcohol into the nerve sheath, though, of course, this is desirable. The only difficult part of the operation is the difficulty of accurately striking the nerve. The dangers of the operation are probably not all known. With proper care the risk of infection is minimal, but it would be serious should it occur. The blunt point of the stylet used reduces the danger of serious hemorrhage. The injection of the orbital division is considered hazardous by Patrick on account of the proximity of the ocular motor nerves, and the optic nerve itself might be involved. The possibility of entering the orbit in operating on the middle branch is also mentioned. Patrick is sure this happened in one of his patients. No serious results followed, but the immediate consequences, enormous edema, etc., must have been annoying. In most of his cases the operation was not especially painful or formidable to the patient. Anesthesia was used in only one case. Ordinarily there is only a feeling of rather uncomfortable pressure or tension following the injection, sometimes a diffuse headache, usually transient and not severe, or a little local stiffness or swelling. In orbital injections the symptoms, of course, may be more severe. In several of his cases the injection was done at his of-

fice, the patients going directly about their business afterward. The therapeutic results have been most gratifying; all his patients were relieved and most of them completely up to the time of report. It is not claimed that the injections will accomplish a radical cure—according to Schlösser recurrence is the rule—but then the injections can be repeated. Experience is needed to enable us to say how long the relief will continue, but it has been known to last over two years. Early relapses are attributed by Patrick to imperfect injections.

Treatment of Diabetes Mellitus.—J. Tyson says that the problem in diabetes is either to restore the carbohydrate metabolism or to substitute some other source of energy and heat. The dietetic treatment is of the first importance, and the first step is to ascertain how much carbohydrate is assimilable and to give this much or a little more. Each patient is more or less a law to himself, and the food trials must be checked by frequent quantitative analysis and weighings of the patient. The best method is to place him at first on a purely proteid diet, and if sugar disappears in the urine to add gradually small amounts of starch-containing foods until sugar reappears, such reappearance beyond 2 per cent. being the signal for stopping the addition of carbohydrates. The patient should be put again on a purely proteid diet for about five days once a month to see how far the sugar output is controllable. Dietetic treatment is rendered more efficient by hygienic and medicinal measures, and of the former he specially mentions keeping up the action of the skin by daily bathing in tepid or hot water, assisted by friction and massage and exercise short of fatigue. Sleeping in a large and well-ventilated room or even out of doors favors the combustion of carbohydrates. Constipation is to be specially avoided. Calomel is a purgative especially indicated, but large doses may be needed. The medicinal treatment, though not very satisfactory, should not be neglected. The only remedies that seem to have a direct influence on diabetes without regard to its cause are opium and arsenic. Tyson prefers codeine, beginning with a quarter of a grain three times daily, and adding a quarter of a grain daily until the desired effect is produced or the daily dose reaches 4 or 5 grains. Arsenic is much less effective than opium, and chiefly in mild cases. Tyson's favorite preparation is Fowler's solution, which he prefers to give in rather small doses extending over long periods without interruption rather than to produce the physiological effect of the drug. There is some prospect of good in organotherapy, more especially in the injection into the blood of the amylolytic secretion of the pancreas. Some claims have been made for "secretin," the active principle of the succus duodenalis. The prophylactic restriction of sugar and starch in the diet of those hereditarily disposed to diabetes and obesity is also mentioned.

Adenoids in Infancy.—Dr. J. L. Morse thinks that the importance of adenoids in early infancy is not sufficiently appreciated by the profession. An idea is extant that their removal is not indicated because of the great likelihood of their recurrence. In a great majority of cases they do not recur and the removal, which is without danger, saves the little patient from a whole series of ills caused by their presence, and even in case they should recur a second operation is easily and safely performed. He goes over the anatomy of the parts in early infancy, showing how greatly the presence of these growths can interfere with the patient's respiration in the undeveloped nasal pharynx and postnasal pharynx. On account of the small size of the superior pharynx and postnasal opening even a very small amount of adenoids may cause very serious obstruction to nasal respiration. This necessitates oral breathing, which is imperfectly performed by the child, especially when asleep. It also interferes with sucking; the child cannot breathe and take its nourishment simultaneously, and it is astonishing how much disturbance of nutrition may be thus caused, as shown by a case he reports. Rickets is also caused by disturbed nutrition from adenoids and chest deformities are common. Adenoids are a very common cause of colds in the head and snuffles in infancy, and also irritating coughs without physical signs, especially troublesome at night, which is only relieved by removal. Attacks of laryngitis and spasmodic croup are also attributed by him to this cause, and sleeplessness at night, even without the marked symptoms, like oral breathing, cough, etc., should lead to a suspicion of their presence. They open the door more frequently to bacterial invasion and the danger of tuberculous infection is a very real one. Morse also says that they are the most frequent cause of otitis media owing to the special anatomy of the parts at this early age, and in his experience repeated attacks of otitis media in infancy are almost invariably due to adenoids.

Contagion as a Factor in the Spread of Typhoid Fever.—C. F. Mason says that the lesson taught by experience in 1898 that personal contact is a most important factor in the spread of typhoid fever has been thoroughly taken to heart by the army medical authorities. He reproduces a circular sent out to all the officers and men in the army, calling particular attention to this point, and giving full directions how to prevent contact infection. Since the issuance of this circular in 1902, further evidence of the spread of typhoid in this way has accumulated from epidemics in various military posts, and further instructions were sent out which are here reproduced. There has been practically a continuous fall in the death rate per thousand from typhoid in the army since 1898, the rate for 1906 being 0.28, a lower rate than that before the Spanish-American war. The admission rate follows the same course up to 1906, when there was a marked increase, notwithstanding the continued fall in death rate. This, however, is believed to be largely due to two factors, one, the increasing recognition of mild cases, which is indicated by the fact that the case mortality fell from 8.5 to 5.2 per cent., and the other to the presence of practically the entire mobile army in the field at maneuvers during the summer; 40 per cent. of the cases occurred while the army was in the summer camps and were believed to have been contracted while on the march through the country districts.

Tardy Malnutrition.—C. G. Kerley discusses a class of cases, familiar to physicians, of children who, without suffering from serious constitutional disease, show marked developmental defects, such as underweight and muscular insufficiency, and also a lack of physical energy and resistance to disease. They almost invariably suffer from secondary anemia, have indifferent appetites, and are often habitually constinated. The chief cause is underfeeding; not necessarily lack of quantity of food, but ill-selected food. The next most important factors are excessive expenditure of energy and lack of adequate rest. These, he states, may be brought about by exacting school requirements or by anything that overtaxes the developing organism. The defects of school management of children are probably overestimated, but still they exist and should be watched for, but not made the scapegoat for home deficiencies. In the management of these cases, each detail of the child's life should be studied and every error corrected so far as possible. Kerley gives his method in detail for cases in which no condition deterrent to growths exist, consisting in a sort of modified rest cure, avoidance of mental and physical stress, a regulated high proteid diet, three meals a day being usually best for children, and agreeable attendance. Malnutrition children who are inmates of a neurasthenic home or one where there are stronger and noisy children do best when changed to quieter surroundings. In a few of his cases the regulated life of a properly conducted boarding school has been found beneficial. Sugar is generally best restricted, as these patients are apt to be overfond of it while bearing it badly. He says: "A common-sense diet, an absence of food and sweets between meals, with one and a half or two hours rest after the noonday meal, has been proved by bi-monthly weighings and blood examinations to be of more therapeutic value than I would have believed possible had I not personally observed it in a great many cases.'

Ocular Symptoms of Nasal Origin.—O. A. Griffin describes and illustrates the anatomic arrangements of the cranial and facial bones as bearing on the production of ocular symptoms from nasal disease, especially when certain irregularities exist. It is not surprising that active inflammatory conditions in the nasal passages are often associated with disturbances in the visual apparatus. Refractive disturbances, muscular imbalance, conjunctivitis, glaucoma, etc., cannot only be simulated, but actual destructive lesions, neuritis, chorioiditis, iritis, and keratitis may result from an infective process in an adjacent ethmoiditis or sinusitis. These conditions have been observed by him so often that he does not consider an ocular examination complete without inspection of the nose and its accessory sinuses. Eight cases of apparent ocular disease relieved by treatment of nasal conditions are reported. In one case a troublesome heterophoria which could be relieved by glasses entirely disappeared after removal of the inferior turbinates for nasal obstruction, to the surprise of both patient and physician. Under the circumstances, the author remarks, the disappearance of a heterophoria is unique.

The Lancet, October 26, 1907.

A Case of Erythromelalgia.—The noteworthy feature of the case reported by R. G. Hann is that it must be considered in the light of the evidence at hand as idio-

pathic, whereas the majority of recorded cases have been intercurrent in the course of central nervous disease. The patient was a married woman of fifty years who had had many illnesses and numerous ailments. She had been living under circumstances producing very great variations of temperature and was also continually on her feet. She showed three distinct stages of the disease: (1) A premonitory one of severe pain, varying in severity without swelling or redness; (2) an acute stage of the most severe pain worse in the dependent position, with a tender, pink, puffy swelling, and (3) a chronic condition with slighter pain, except on using her limb with tenderness only on deep pressure and a brown-red swelling. In the hands the last stage was represented by slight tenderness without swelling or discoloration. The peculiar feature of the case was that pain always preceded the vasomotor signs. The length of the initial attack (two weeks) is unusual. Initial attacks generally last but a few hours. Desquamation is rare, but occurred here. The patient gave various evidences of vasomotor instability.

Acute Spreading Gangrene.—Two cases are reported by R. R. James. Bacteriological results were the same in both, *i.e.* cultures were obtained of a variety of the *Bacillus aerogenes capsulatus* and it was impossible to discover any attempt at spore formation. Case 2 was one of gangrene following compound fracture of the leg, for which amputation was done thirty-one hours after the accident. This patient recovered. Case 1 reported in detail was that of a man of thirty years run over by a 'bus, which caused a compound fracture of both bones in the upper third of the left leg. Posteriorly there was a gaping wound exposing the bellies of the gastrocnemius, one of which was partially ruptured. The wound was very dirty. Pulsation was evident in both tibial arteries at the ankle and an effort was made to save the limb. Twenty-eight hours after admission, a chill came on with fever, and the next morning the wound was definitely gangrenous and the whole limb swollen. The general condition forbade any amputation, so the whole wound was opened up and hot fermentations were applied. On the third day the leg was black and green about the fracture and large black bullæ were noticed. Death came eighty hours after admission. Blood-stained fluid from the bullæ gave the bacteriological results above noted. The author notes that organisms usually anaërobic have been isolated from many cases of spreading gangrene. Though generally identified as *Bacillus aerogenes capsulatus, Bacillus enteritidis sporagenes,* or *Bacillus edematis maligni,* the organisms isolated rarely conform strictly to the classical descriptions of these microbes. In the present instance the bacillus obtained seems to be most nearly related to the *Bacillus aerogenes capsulatus,* though differing in some respects.

Mobility of the Kidneys.—H. Mackenzie gives a general description of this condition, noting its frequency in women, declaring that in the great majority of cases it produces no symptoms and that where local symptoms are absent, it requires no treatment. If symptoms are present, a fair trial should be given to non-operative methods of treatment. If these fail to relieve and if the kidney is diseased, operative intervention is indicated. The author has collected from literature the results in 131 operations. Out of this number nephrorrhaphy or nephropexy was performed 113 times, with a successful issue in 80 cases, but in some of these the time which had elapsed after the operation was too short to enable one to judge of the real result. In 17 cases partial relief only followed, and in 13 the result was failure, and in 5 of these subsequent nephrectomy was performed with a successful issue. In 3 cases there was a fatal result. Nephrectomy was performed as the primary operation in 18 cases; 14 were successful; 1 was a failure; 3 proved fatal. In these cases which were operated on pain was an almost invariable symptom. Dietl's crises were recorded in 2 cases; vomiting was recorded in 11; irregular micturition in 1; the presence of a tumor was noted in 10; and mental distress on account of the tumor in 1. Believing that more recent years would show better results (the foregoing figures were collected eight years ago), the author has consulted the records of St. Thomas' Hospital for the past six years and finds that out of 106 cases admitted during that period 80 were operated on without a single fatality. In 73 nephropexy was done, in 3 nephropexy with nephrotomy, in 1 lumbar incision with gauze packing, in 1 nephropexy followed by subsequent nephrectomy, and in 2 nephrotomy alone. Mackenzie strongly deprecates the teaching that "minor degrees of mobility of the kidneys are the unrecognized cause of much suffering and distress."

British Medical Journal, October 26, 1907.

Removal of Foreign Bodies from the Hand or Foot.—For removal of splinters under the nail, J. B. Nias advises the use of the so-called lens-hook of the ophthalmologist, which is so often found in the boxes of instruments for microscopical dissecting purposes. The hook is passed down the track of the splinter and the point then turned upward so as to press the splinter against the nail. The whole is then withdrawn. In regard to the foot Nias says that the needle of the ordinary hypodermic syringe filled with cocaine solution makes an excellent probe for the location of foreign bodies under the skin. Instead of being withdrawn after injection of the solution, as soon as anesthesia is established the needle should be pushed on and moved about in the soft tissues till its point clicks upon the foreign body. He adds that this is an excellent way of locating needles which have run into the sole of the foot; also thorns which have penetrated under the skin of the forearm or into the orbit and have then broken off.

Anastomosis Between the Common Bile Duct and the Duodenum for Obstructive Jaundice.—In the case of a man of sixty-six years, the following operation was done by G. A. Fullerton; the patient had four doses of calcium chloride, fifteen grains every four hours, the day previous. A vertical incision five inches long was made over the most prominent part of the tumor and the abdominal cavity opened. The gall-bladder was found to be distended so as to be rather larger than a goose's egg. There were no adhesions. The liver was enlarged and was dark purple in color. It was firm in consistence. The peritoneal cavity having been shut off with large gauze pads, the gall-bladder was opened, and a large quantity of clear glairy fluid escaped. Three small black mulberry-shaped calculi were fished out of the gall-bladder, which was now in a collapsed condition. No stones were discoverable by palpation in the cystic duct. On the under surface of the right lobe of the liver was found an irregular whitish scar about the size of a sixpence. On drawing the liver upwards a hugely dilated common bile duct was brought to view, and on tracing this down it was found to lead to a hard mass in the position of the head of the pancreas. Several smaller nodules, thought to be enlarged glands, could be felt extending towards the foramen of Winslow. The dilated duct was almost as large as a piece of small intestine. An attempt was made to empty it by massaging its contents through the cystic duct towards the gall-bladder, but without success, owing to some difficulty at the neck of the gall-bladder, the nature of which could not be determined. Accordingly, it was decided to drain the common duct by anastomosing it with the first part of the duodenum. This was accomplished with some difficulty, on account of its deep position, by means of a small Murphy button, using fine silk for the purse-string sutures and several reinforcing Lembert stitches to prevent possible leakage. Before placing the female portion of the button in the duct an incision was made into the latter and a large quantity of glairy fluid with no trace of bile in it was quickly mopped up. The finger could be introduced into the duct and passed up into cavities in the liver corresponding with the dilated hepatic ducts. To facilitate manipulation of the parts it was found necessary to make a transverse incision at right angles to the upper end of the original wound in an inward direction. The button having been satisfactorily adjusted, the abdominal cavity was mopped dry and a stab puncture was made in the loin to provide drainage. A split rubber tube with a gauze core was passed through the opening so made. The wound in the gall-bladder was sutured to the peritoneum and transversalis fascia and the viscus was drained by a rubber tube which led from its interior to a sterilized bottle. The abdominal wound was closed with through-and-through sutures of silkworm gut, and the patient was returned to bed, having stood the operation well. Five months later the patient was in good condition.

Indications and Contraindications for Cholecystectomy.—Mayo Robson states that out of nearly 1,000 operations on the biliary passages he has done cholecystectomy 64 times. He summarizes his views as to the applicability of the operation as follows: Cholecystectomy is indicated in the following conditions: (1) In cancer or other new growths of the gall-bladder where the disease is local and limited. (2) In contracted and useless gall-bladder the result of repeated attacks of cholecystitis. (3) In dilated or hypertrophied gall bladder resulting from obstruction in the cystic duct. (*a*) Always, if resulting from stricture. (*b*) Usually, if resulting from impacted gallstones which may have induced ulceration that will subsequently lead to stricture. (*c*) Usually, if resulting from kinking of the cystic duct or from adhesions. (4) In phlegmonous or gangrenous cholecystitis. (5) In empyema of the gall-bladder. (6) In calcareous degeneration of the gall-bladder. (7) In mucous fistula of the gall-bladder, the result of stricture or other obstruction

of the cystic duct. (8) In gunshot or other serious injuries of the gall-bladder or cystic duct. It is unnecessary in ordinary cholelithiasis where the gall-bladder is not seriously damaged and where the cystic duct is not ulcerated or narrowed by stricture; and it is contraindicated in all cases where the surgeon cannot be certain that the deeper bile passages are free from obstruction, unless at the same time the cystic or common ducts be short circuited into the intestine.

Berliner klinische Wochenschrift, October 21, 1907.

The Pathological Changes Produced by Alcohol.—Baumgarten describes experiments made by injecting alcohol of various strengths subcutaneously in dogs, rabbits, and guinea pigs with a view to determining particularly the effect of the drug in producing cirrhosis of the liver. These experiments do not afford any confirmation of the clinical view that the chronic administration of alcohol leads to severe degenerative or cirrhotic changes of the parenchymatous organ. The only pathological finding in the experiment animals in the cases of acute fatal intoxication consisted in the presence of numerous hemorrhagic erosions of the gastric mucosa. Other authors have observed these and ascribed them to the use of the stomach tube employed in administering the drug, but Baumgarten used the subcutaneous method of administration. In a large series of autopsies performed during his fifteen years of service in Königsberg he found that only 5 or 6 per cent. of the alcoholics that came to the post-mortem table presented cirrhotic livers, and this fact, together with the negative results of animal experimentation, lead Baumgarten to agree with Hansemann that the abuse of alcohol is only a predisposing and not an etiological factor in the causation of cirrhosis of the liver. He suggests that in such cases the functions of the gastrointestinal wall may be impaired so that the absorption of toxic products that may possibly have the effect of favoring cirrhotic changes is rendered possible. The absence of cirrhosis in animals subjected to chronic intoxication with alcohol might then be explained on the assumption that such toxic bodies are not formed in the gastrointestinal canal of animals.

Münchener medizinische Wochenschrift, October 22, 1907.

The Treatment of Typhoid Bacilli Carriers.—Dehler says that he believes that in cases in which typhoid bacilli are habitually cast off in the feces, but are not present in the blood or urine, operative cleansing of the gall-bladder is indicated. He describes two cases in which the patients, two inmates of an institution for the insane, were apparently freed from the typhoid bacilli by drainage of the gall-bladder. In the first case before the operation 37 out of 39 examinations of the stools were positive for typhoid bacilli, whereas of 176 examinations made after the operation the organisms were found in only 3. In the second patient, who apparently had never suffered from typhoid fever, before the operation 30 out of 55 examinations of the stools were positive; after the operation 28 out of 30 examinations were negative. In both cases the administration of intestinal antiseptics had been ineffectual in removing the organisms from the feces. The occasional discovery of typhoid bacilli in the stools of these patients after the operation is explained by the author through the fact that in the same ward with them there are several other patients who have typhoid bacilli in their stools, and as all of these individuals are insane and dirty in their habits the possibility of infection of the various utensils used cannot be altogether prevented.

The Treatment of Tuberculosis with Marmorek's Serum.—Schenker reports very favorably on the use of Marmorek's serum. A résumé is given of the histories of thirty-nine cases; most of these were of Turban's second and third degrees of severity. The serum was ordinarily given by rectum in doses of 5 to 10 c.c., the average period of treatment being sixty-nine days and the average number of injections thirty-one. The rectal administration is practically more advantageous than the subcutaneous injection owing to the latter's tendency to produce local lesions in the skin. The improvement produced is slow to appear, but is well marked and includes improvement in the general condition and in the appetite, diminution in the fever and night sweats, improvement in the cough, better sleep, increase in weight, and improvement in the local pulmonary signs. The effect of the remedy was also striking in cases of bone tuberculosis, in vesical and renal tuberculosis, and in a case of tuberculosis of the peritoneum. A disadvantage of the serum is its expense.

Deutsche medizinische Wochenschrift, October 24, 1907.

Appendicitis and the Oxyuris.—Hippius and Lewinson quote numerous authors, some of whom attach etiological importance to the oxyuris in appendicitis, whereas others deny or minimize this. They themselves consider that the worm is a not unimportant factor in the production of the disease and describe a case in point. The patient was a child of six years whose appendix was removed in the course of a more or less typical attack of appendicitis. Externally the organ was normal, but on opening it it was found crammed full of parasites, about eighty individuals, mostly mature females, being in its interior. At one point there was a group of worms that had burrowed under the surface of the mucous membrane so that only their caudal extremities projected. Microscopic examination showed extensive destruction of the mucosa and submucosa and also atrophy of the mucous membrane and muscular layers together with the formation of connective tissue. The authors suggest that the lesions induced by the depredations of the parasites may allow bacteria to penetrate into the deeper layers of the organ.

Acute Orchitis Due to Pyocyaneus Infection.—Hirschberg says that while formerly there was some doubt as to the pathogenicity of the *Bacillus pyocyaneus*, of late years numerous cases have been reported in which it seems to have been the sole cause of disease. For the most part the instances described have been cases of generalized sepsis of considerable severity, in which the organism apparently has manifested no mean degree of virulence. Hirschberg now reports a case of localized infection with this germ in which the bacillus did not exhibit very great virulence. The patient was a man who was considered free from gonorrheal, syphilitic, or tuberculous taint, and who suddenly, while in perfect health, without apparent cause, developed an exceedingly painful and tender swelling of one testicle. Examination of the urethra, prostate, and seminal vesicles was entirely negative, as was also that of the urine. On incision a small amount of greenish purulent fluid was obtained and a pure culture of the *Bacillus pyocyaneus* was cultivated from the secretion. A blood culture was negative and the patient's serum at this time did not agglutinate the bacillus, but during the patient's convalescence another trial of the agglutinative power was positive, even at the dilution of 1-1000, although the blood was still sterile. The manner in which the organism gained access to the testicle could not be discovered.

The Intracellular Occurrence of Tubercle Bacilli in the Sputum.—Löwenstein says that among the factors that have to be considered in opsonic work is the individual susceptibility of different strains of bacilli to phagocytosis. For example, all strains of tubercle bacilli do not behave in the same way in regard to the phagocytes, some being readily engulfed by these, while others exhibit great resistance to the process. The conditions in the living body and *in vitro* are also very different, as is shown by a case of tuberculosis of the bladder in which the pus cells never contained tubercle bacilli, although these were present in great numbers between the leucocytes. If some of the patient's own serum and tubercle bacilli were added to the urinary sediment, active phagocytosis took place in a short time. It is therefore possible *in vitro* to secure phagocytosis by the aid of the same factors that in the body itself are ineffectual. The author further discusses the occurrence of phagocytosis in tuberculous sputum. He has found that the leucocytes of the sputum of tuberculous patients contain the bacilli in chronic cases of very long duration and in recent cases in which the prognosis is favorable. The phenomenon is also observed in instances in which specific treatment with tuberculin or bacterial emulsions has been carried out. Until the conditions underlying phagocytosis in the body itself have been more thoroughly investigated, the author believes that the application of the determinations of the opsonic index will not be fruitful in practice.

Stokes-Adams Disease.—Cardarelli considers that Stokes-Adams disease is a condition dependent on a pathological state of the nervous system. The symptoms consist of slow and intermittent pulse not modified by the position of the body or muscular efforts, increased vascular pressure, arteriosclerosis, cardiac arythmia, albuminuria, and epileptiform or apoplectiform attacks. The author's reasons for his belief in the neurotic origin of the condition are based on its infrequency in comparison with that of cardiac myocardial lesion; that the patient does not complain of cardiac symptoms, but of vertigo and epileptic attacks; by compression of the vagus in the neck one can obtain the syndrome of Stokes-Adams, with syncope and epileptic attacks. The author thinks these symptoms cannot be referred to anemia of the bulb. After using atropine the patient does not respond to pressure on the vagus.—*La Riforma Medica.*

Book Reviews.

Atlas and Epitome of Diseases of Children. By Dr. R. Hecker and Dr. J. Trumpp of the University of Munich. Authorized Translation from the German. Edited by Isaac A. Abt, M.D., Assistant Professor of the Diseases of Children in Rush Medical College, in Affiliation with the University of Chicago. With 48 Colored Plates and 147 Black and White Illustrations. Philadelphia and London: W. B. Saunders Company, 1907.

As an atlas this volume is all that can be desired, the plates being of the same high grade as is found in other volumes of Lehmann's Hand Atlases. The text, however, is not so satisfactory—at any rate, for American readers. The book contains much that may be of service to practitioners in Germany, but which is useless here. For instance, the various milk mixtures and artificial foods and some of the medicines mentioned might well have been omitted or replaced by more familiar names. The doses are not indicated uniformly by either the metric or any other system; sometimes one is used, sometimes two are used; the same lack of uniformity obtains in recording the temperatures (both body and room), and the weights and measures in general.

Manual of Diseases of the Ear, Nose, and Throat. By John Johnson Kyle, B.S., M.D., Professor of Clinical Otology, Rhinology, and Laryngology, Medical College of Indiana, etc. Second Edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1907.

The first edition of this manual received favorable comment in these columns, and the appearance of a second edition after the short interval of fifteen months shows that the opinions expressed have coincided with those of the profession at large. Certain sections of the work have been revised, new matter introduced, and a chapter added on diseases of the trachea and bronchia with full descriptions of the technique of modern instruments. Nevertheless the author has considered only those questions which lie within the domain of the laryngologist. He declares that "the invention of the bronchoscope and the perfection of the technique of bronchoscopy by Killian must be acknowledged by all as the greatest of medical triumphs."

Surgical Diagnosis. By Daniel N. Eisendrath, A.B., M.D., Adjunct Professor of Surgery in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Michael Reese and Cook County Hospitals, Chicago. With four hundred and eighty-two original illustrations, fifteen of them in colors. Philadelphia and London: W. B. Saunders Company, 1907.

Diagnosis, whether medical or surgical, is a subject of such vast importance that any book adequately dealing with it and tending to the elucidation of its many difficulties is sure of a welcome. In the present volume the question of surgical diagnosis is handled from the clinical standpoint; the various injuries and diseases being grouped in the manner and order in which they must be considered by the practitioner or surgeon when he examines the patient. The work covers the entire domain of general surgery, but omits the diagnosis of affections of the eye, ear, nose, throat, and skin, as well as gynecology. The book is divided into eight chapters, each with several subdivisions. In the first, the surgical affections of the head are considered; and the various traumatic lesions of the scalp, the skull, and the brain are considered together. The affections of the face, mouth and palate, lips, jaws, tongue, and salivary glands are included in this chapter. Succeeding chapters treat of the surgical affections of the neck, thorax, abdomen, the extremities, and the spine. These are followed by a very valuable chapter on post operative complications. Considerable attention is paid to the description of the various methods of examination, and with the aid of illustrations and tables of differential diagnosis the subject is rendered very clear.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B.A., M.D., LL.D. (Yalen.), Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. Johns, and Christ Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Fifth Edition. New York and Philadelphia: Lea Brothers & Co., 1907.

Nowhere in medicine is the diagnostic use of the .r-ray of greater utility and more certain in the aid it gives than in clearing up the doubtful points in a case of fracture or of dislocation. The shadows are so distinct that the altered contour of the joint or the displacement of the fractured portion of the bone can be seen as clearly as it would be in an artificial dislocation or fracture in a skeleton. Dr. Stimson has made free use of this fact, as the 52 plates, many of them containing two skiagraphs, witness. In addition to these there are 352 illustrations, line drawings and halftones, scattered throughout the text of the work.

The present edition differs but little, in the main, from its predecessor, the changes being chiefly in the way of additions. The section on fractures and dislocations of the bones of the wrist and of the tarsus have been considerably augmented by the incorporation of the addition to our knowledge of these accidents made during recent years. The work is one adapted especially to the needs of the general practitioner, whose special line of work is not surgery, but who may at any time be called upon to manage a case of bone or joint injury and to manage it properly at the risk of a malpractice suit if the result is not satisfactory. The author has laid special stress on the details of diagnosis and treatment. The accidents and complications liable to occur in the course of treatment of these injuries are dwelt upon at length, so that the practitioner is put upon his guard and warned to look for them and to institute measures to forestall them. There is no better monograph on the subject in any language than this classical work—a worthy successor to Hamilton.

Metabolism and Practical Medicine. By Carl von Noorden, Professor of the First University Medical Clinic, Vienna. Anglo-American Issue Under the Editorship of I. Walker Hall, Professor of Pathology, University College, Bristol; Pathologist to the Bristol Royal Infirmary. Vol. I. The Physiology of Metabolism. By Adolf Magnus-Levy, Berlin. Vol. II. The Pathology of Metabolism. By Carl von Noorden, Fr. Kraus, Ad. Schmidt, W. Weintraud, M. Matthes, and H. Strauss. Chicago: W. T. Keener and Company, 1907.

It was no light task to undertake the production of an English version of this monumental German work; but it is evident that the editor and his associates are to acquit themselves well of their laborious project. In the second edition of his treatise on metabolism von Noorden expanded what had been a modest volume into two goodly tomes, which comprise an authoritative exposition of the present status of this intricate and consequently growing subject. The two volumes of the English edition that have appeared are a translation, with some additions, of the first volume of the German original, and as the title indicates it has so happened that the first English volume could be devoted entirely to the subject of metabolism under normal conditions. It is the work of Adolf Magnus-Levy, and is divided into four main sections dealing respectively with the foodstuffs, digestion and absorption, the fate of the foodstuffs in the tissues, and metabolism in man. The subject matter of the second volume includes the following headings: Hunger and chronic starvation, overfeeding, fever and infection, diseases of the stomach and intestines, of the liver, of respiration and circulation, of the blood, and of the kidneys. A comparison with the German original shows that this is followed with adequate fidelity of substance, while the English is untrammeled by any awkwardness of phrase or construction. Indeed, the difficulties of finding suitable equivalents for the tenia-like compounds in which the German nomenclature of particularly this subject is so rich have been met with felicity and ingenuity so that the reader is free from all consciousness of getting the author's meaning at second hand. Noorden himself in an introduction to the present edition pays a high tribute to Professor Hall's qualifications for the task of editing the English version of the work, and those who cannot or do not care to read the German original may rest assured that in this translation they will find an efficient substitute. It is hardly necessary to speak of either the important place the processes of metabolism have assumed in the theory and practice of modern medicine or the authoritativeness that stamps anything on this subject appearing under the sponsorship of von Noorden.

Die chronische progressive Schwerhörigkeit; ihre Erkenntnis und Behandlung, von Dr. August Lucae, Professor an der Koenigl. Friedrich Wilhelms-Universität zu Berlin. Mit 25 Textfiguren und 2 Tafeln. Berlin: Verlag von Julius Springer, 1907.

In this book the well-known Berlin clinician discusses successively the historical aspect of the question, the pathological anatomy of the form of deafness considered, etiology, symptoms, course, methods of examination, diagnosis, prognosis, and therapy. An elaborate bibliography is appended. The volume is the result of a long life's experience in the treatment of aural maladies. The author declares it is wrong to make of otosclerosis a distinct pathological entity and that many cases of chronic deafness which are considered hopeless can in reality be greatly benefited by treatment.

Society Reports.

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

First Annual Meeting, Held October 28, 1907.

THE PRESIDENT, DR. CHARLES E. NAMMACK, IN THE CHAIR.

THE first district branch, comprising the Counties of New York, Westchester, Rockland, Putnam, Orange, and Dutchess, met at the New York Academy of Medicine.

Difficulties of Procuring Pure Milk.—Dr. H. J. SHELLEY of Middletown read this paper. He said that in Middletown the attempt had been to get macroscopical rather than microscopical clean milk, and examinations of the farms and dairies had been made. Much had been accomplished by the various Boards of Health, but the amount of legislation yet to be enacted was appalling. Cleanliness was the great thing aimed at. In the summer of 1906 the conditions were such that the Health Officer made a visit to most of the dairies supplying the city with milk and then existing conditions were brought before the local board. Notices to clean up and keep clean were issued. In the fall of 1906 a milk ordinance was passed which brought about better conditions on the farms and a purer milk for the consumer. The milk producer had to issue a statement to the Board of Health as follows. Where was the dairy located? How many persons were employed? Were they all in good health; if not, what was the nature of the disease or affection? How was the stable lighted, ventilated and drained? Were the walls whitewashed, and how often? How often did they clean the stable? How many cubic feet of air space did the cow stable contain? How often and where did they remove manure? What did they use for bedding? How many cows did they usually keep? Did they know they were all healthy? What did they feed them when not in pasture? Did they keep the cows clean, and how? Did they clean the udder and surrounding parts before milking? Did they use milking garments? Where did they keep the cans during milking? Where was the milk-room located with respect to the stables? How did they clean their cans, pails, and utensils? Did they do anything to sterilize them? If so, what? What was the source of water supply and where was it situated? Did they dispose of their milk; if so, to whom? Did they peddle their own milk from wagons? Rules and regulations were issued by the Board of Health. The room in which the cows were kept should contain at least 500 cubic feet for each cow housed therein, and should be ventilated and lighted, and have a dry, well drained floor, and be cleaned each day, the manure being removed at least twenty feet from the barn at each cleaning. The ceiling and side walls should be whitewashed twice each year and be kept free from dust, cobwebs, and filth at all times. No swine should be kept in the same room with the cows. No musty or dirty litter should be used for bedding. The food and water given the cows should be at all times pure and wholesome and subject to the approval of the Board of Health. All cows should be free from stable filth and loose dirt, and the milkers should have clean hands and clothing at the time of milking. Milk should be removed immediately after being drawn from each cow to a well ventilated milk room separate from the stable room and there aerated and cooled before being placed in cans. Milk should be strained through a cotton flannel or other equally efficient strainer, which should be renewed as often as necessary to be efficient. All strainers should be cleansed and sterilized after each milking. All vessels having contained milk should be washed clean and sterilized after each milking or using. Milk delivered in bottles should be bottled in the milk room, at the dairy or creamery, and bottles should be cleaned and sterilized at the dairy or creamery, even though having been washed by the customers, and no milk should be sold dipped from cans and poured into other vessels. No milk bottles, tickets, or other things should be taken from a house while it was under quarantine for a contagious disease. No milk tickets should be used by customers more than once. All wagons, sleighs or other vehicles from which milk was delivered should be kept cleaned in a manner satisfactory to the Board or its authorized agent. All wagons upon which milk was brought from the dairy or from which it was delivered to customers should be kept covered to protect the milk from the rays of the sun, in a manner satisfactory to the Board or its authorized agent. In closing he quoted Dr. Henry Enos Tully as follows: "What has been said goes to prove that the problems involved in the production of a pure market milk are difficult of solution. Eternal vigilance, elimination of politics, a well-equipped laboratory, with a competent head to that department, veterinary inspection, proper laws and ordinances, education of the public and a public demand for pure milk, milk commissions, and education of dairymen, soliciting their co-operation rather than antagonism, may produce a fairly good supply. However, it cannot be too forcibly impressed that there may be adequate laws governing chemical standards, etc.; no good will be accomplished until inspection can be carried to the dairy, there to include regulation of everything pertaining to the herd, feed, production, and handling of milk and its shipment and handling until it reaches the consumer."

The Problem of Regulation of a Rural Milk Supply.—Dr. S. W. S. TOMS of Nyack read this paper. He said that previous to four years ago the community in which he resided had a most creditable quality of clean milk, the product of a dairy conducted by a public-spirited citizen as a hobby. This enterprise was in no way a profitable one. Strange as it might seem, this philanthropist was driven out of business by the petty annoyances of complaining housewives and servants and soon followed a lower standard of milk. This suggested that the public were lacking in elementary knowledge of what constituted good milk. A propaganda of education was essential to inspire public sentiment in favoring and enforcing sanitation in milk as it had in drinking water sources. For some inexplicable reason the milk supply had not received the watchful care the importance of the condition demanded from the State Board of Health. There should be State and national protection of this supply. He then related the experiences of a medical milk commission organized in Rockland County over two years ago. Three important considerations presented themselves to the commission. First, the improvement of the milk supply; second, the protection of the public against the possibility of spreading infectious and contagious diseases through the milk supply; and, third, to have uniform laws adopted by the various municipal boards of health that would legally enforce rules and regulations whereby these objects might be obtained. These suggestive rules and regulations, which were to become official by-laws after acceptance, were submitted to the State Department of Health at Albany, were duly approved of by said Department, and recommended for presentation to the municipal boards of health for their action. (See *New York State Journal of Medicine*, September, 1905, page 341.) Up to this point few obstacles or objections were encountered. They interviewed some of the members of the Board of Health of Clarkson, from which most of the milk delivered in Nyack came, and one of the members objected on the ground that some of his neighbors had one or two cows and derived an income thereby which was a necessary source of help in supporting his family, and these regulations would be a hardship to them, etc. Dr. Toms had found generally that dairymen were sufficiently appreciative of unsanitary milk as it was not profitable, and would try to get the farmers

to produce a good quality of clean milk. They themselves in most cases were clean in their methods of handling, bottling and caring for it. However, they did not make the necessary endeavor to keep it at or below a safe temperature after it left their milk-houses during the delivery to customers. Some used dirty horse blankets or old filthy bed quilts to cover their cans and bottles. Some had been seen filling bottles in their delivery wagons. Many cans were rusty. Most of the infection was introduced by the milker. He was not clean, his pail was not sterilized and was so open it caught falling hairs and particles of excreta adherent to the animal's flanks which were shaken off during milking and fell into the pail. The hands of the milker or the animal's udder were not washed. The milk was rarely cooled quickly enough after it was produced and the bacterial life multiplied very rapidly, which no straining or after care could purify. Those interested in the Milk Commission in achieving some showing as the result of their labors had encountered much apathy and discouragement from those they expected would take an interest in the movement. Conditions became so bad in Nyack that the citizens appealed to the State Agricultural Department through the State Department of Health. He was satisfied that the solution of the problem for those living in districts similar to that about Nyack, was in the efforts of a Sanitary League, composed of leading citizens, who would take up the matter in a public-spirited way. They must see that the Health Boards enforced their sanitary rules against the abuse of sanitation in all things. The pure milk propaganda must not stop in its education short of all that concerned the customer and user alike, as well as those more concerned in its production and marketing.

Infant Mortality in the Summer Months; the Methods Adopted in Yonkers for Its Reduction; the Results.—Dr. S. F. Getty of Yonkers said that the infant mortality in Yonkers during the early nineties had increased at a greater ratio than the growth of the city. The deaths were at the maximum in July and August and the chief causes were the various forms of digestive disorders. It was decided to take some steps to reduce the mortality. In 1893 the Nathan Straus Milk Laboratory was opened in New York and it was deemed a wise move to establish a similar dispensary in Yonkers, which was done in 1894, and had been in operation during the summer months ever since, with the exception of the summer of 1904. With the establishment of the milk dispensary a vigorous campaign of education was inaugurated through the press, by personal interviews with physicians, and by means of cards of instruction to mothers. The result of the first season did not show a lowering of the death rate, the second season showed a marked decrease, and the third season showed a decrease of 50 per cent. in the number of deaths from digestive diseases. The steps of their advancement in Yonkers might be enumerated as follows: Twelve years ago the appointment by the city of a Milk Inspector, shortly following the adoption of a sanitary code pertaining to production and sale of milk; registration of all producers and dealers in milk; inspection of all local dairies; inspection of stores retailing milk, with the result that the number of places where milk was sold at retail had been cut in half, although the city had doubled in population. Careful observation had failed to show any increased mortality traceable to continued high temperature or humidity. Statistical tables were presented showing the results accomplished in Yonkers; they covered a period of eighteen years, from 1889 to 1906 inclusive, and had been averaged in four periods of five years each, except the last, which three years. The problem of reducing infant mortality from digestive disturbances could be summed up in a few words: Clean milk, properly proportioned for these infants and young children who could not be fed on the breast, and intelligent care and feeding by the physicians and parents. To produce these results he suggested the following means: (1) Rigid State or municipal inspection of all milk from the producer to the consumer. (2) Milk dispensaries, to properly modify clean milk, in feeding bottles ready for infant use. The milk might preferably be Pasteurized, if it was to be used in the tenements. (3) A campaign of instruction education, to instruct both physicians and mothers in the art of infant feeding, and to urge upon the officials the necessity and economic value of clean milk. (4) The employment of trained nurses in the summer months to follow up cases of digestive disturbances in infants and to aid the physicians in this work. (5) The continuous enforcement of improvement of tenement houses, so that the dwellers might have the benefits of proper sanitation and plenty of fresh air and sunlight.

Dr. A. Jacobi of New York said he believed they had with them more bad than good milk, but in New York City a favorable change had taken place. Mr. Nathan Straus had done a great deal in simply giving the clew as to what was required. The Board of Health had done much, and was trying to do more to-day, by asking for more milk inspectors for the purpose of getting clean milk from all over the State. Milk was brought to New York from distances of from 100 to 400 miles, and the Board of Health had a dozen inspectors to-day for a work which could not be done by less than 100 inspectors. All over the State were many difficulties that Yonkers had not experienced. In Yonkers they had gone to work themselves and had told the truth to the public. Dr. Jacobi was delighted with the courage the men had shown in their efforts to get clean milk, and he believed it would be a matter of slow education. Every year each County Society should send out a constituent to post on church doors and elsewhere simple rules, ten or twelve short sentences, for caring for and keeping clean milk, and they should be told that the doctors in the community were of one mind. Educate the public not only as to the necessity of having pure milk, but upon the necessity of doing a great many things not in the interest of the doctors, but in their own interest. He hoped the newspapers would make free abstracts of the papers just read; publishing them would be productive of much good. In some way the public must be reached.

Dr. L. Emmett Holt said the milk question was a difficult problem and was not going to be solved in one year or ten years. The basis of success was education; education so that the public could appreciate the difference between good and bad milk, between clean milk and milk that was contaminated. He said he had secured some figures from a dairy in which the books were carefully kept as to the cost of milk and how the cost had changed in seven years. During the period from 1900 to 1907 the cost of feed had increased 31 per cent. and the cost of labor 45 per cent. The total cost of producing a quart of milk had increased 100 per cent. in seven years. The small dealers should be eliminated, for their greatest difficulties were with the poor producers. They should be absolutely eliminated from the milk trade. This was inevitable. The better class of dairies must receive more money for milk, because now they had to have better ventilation, better light, etc., than they used to, and the cost of labor had gone up so. Educate the public as to what clean milk was. The production of milk was a business; the number of bacteria in the milk depended upon whatever one wanted to pay. Of course, it was the character of the bacteria and not so much the numbers that made milk dangerous. The first thing to consider was dirt, which could be eliminated by cleanliness. As yet there was no conclusive evidence that milk spread tuberculosis, except that the disease was far advanced. The State of Maine had spent $250,000 each year for its Board of Health to investigate and attempt to wipe tuberculosis from the State. They started in on one side of the State and worked

all across and over it, destroying tuberculous cattle wherever found. When reinspected it was found that there was as much tuberculosis as before. He did not believe that they were yet ready to begin the use of tuberculin, as was done in one city in New Jersey.

The Transmission of Typhoid Fever.—Dr. H. D. Pease of Albany said that Mr. George C. Whipple had prepared a paper on typhoid fever in which would appear a chart covering the ground of the transmission of typhoid fever most admirably, and this chart he presented by consent. He considered transmission by water, by contact, by flies, by milk, by shell fish, by raw vegetables, and fruits, and by various means now unknown. In considering transmission *from* the patient, he showed three barriers; inside the first was the medical treatment, urinary disinfection, and instruction as to disinfection of the excreta of the patient, and report to the Board of Health. Within the second barrier was the proper disposal of stools and urine, cleanliness, disinfection of stools and urine, screens to protect from flies. Within the third barrier was sewage disposal, supervision of disinfection and disposal of stools and urine, the Widal examination of the urine, study of the case to ascertain the cause and to protect others, and instruction to members of the household. In considering the transmission *to* the victim he showed three barriers; inside the first was personal cleanliness and the avoidance of certain risks in traveling, and the maintenance of health tone. Within the second barrier was cleanliness in the kitchen, the boiling of water and sterilizing of the milk, care as to the source of milk, of oysters and raw fruits, and the close inspection of shell fish, and supervision of quality of public wells and vendors of special waters. Within the third barrier was the general sanitary inspection and removal of garbage and stable manure, and other things for which the public authorities were responsible. What was contained within the second barrier in both was what the household was responsible for. The matter of education was very important, and the question of price entered into all the digestive diseases which the Health Boards had to contend with. The condition of the water supply in the State of New York was a menace, and the only way to protect the water supply was through the State Health Department. The enforcement of rules must originate from local boards first. Every case of typhoid should be reported. He asked what proportion of cases of typhoid fever was transmitted by water. He showed a chart giving the typhoid deaths per month, taking the average for five years, and this showed as follows for the State (approximately): January, 150; February, 135; March, 130; April, 108; May, 100; June, 80; July, 110; August, 160; September, 200; October, 220; November, 180; December, 175. Deaths in the City of New York averaged as follows (approximately): January, 40; February, 30; March, 40; April, 36; May, 38; June, 35; July, 60; August, 90; September, 88; October, 95; November, 70; December, 60. At Cohoes they had typhoid throughout the year for the inhabitants drank polluted water from year to year; but there was a tremendous rise in the mortality rate during summer which he ascribed to contact with flies. D. D. Jackson, at the meeting of the Public Health Association last month, showed clearly that the prevalence of flies in various sections of New York City was followed by a rise in the number of cases of typhoid fever. He also showed that there were many opportunities for the access of flies to typhoid material. Sixty-eight per cent. (68%) of the cases in Washington could not be traced by a commission which had been appointed for this purpose. He wished, in closing, to emphasize the importance of a tabulation of the facts known regarding typhoid. With proper sewage disposal typhoid fever could be eliminated as caused by shell fish.

The Advantages of a Country Watershed.—Dr. Clark G. Rossman of Hudson read this paper. The three practical sources of a potable water were: 1. From an uninhabited or but thinly populated watershed directly, or, preferably, with the intervention of an impounding reservoir. Such a source might be unobtainable on account of prohibitive distance or geological conditions. It was most available in hilly and poor farming districts. 2. Good ground waters, *i.e.* spring or well water which by its passage through the ground had become thoroughly freed from impurities. It was adapted to small and medium sized towns on account of the usually restricted supply. 3. Filtration of surface waters, which would otherwise be unsuitable for domestic purposes. The advantages of a pure spring or deep ground water were self-evident. The question of potable water became one of purification of sewage, its treatment and disposal. Protective measures were naturally of first importance and were divided into two classes, those which must be enforced during the construction of the works, thereby avoiding epidemics of the type which Ithaca not long ago experienced, and those which must be enforced after the works were placed in operation. The chief aim in managing a rural watershed was to prevent immediate contamination, insufficient natural drainage, or surface washings into the feeders of the supply. The best method of control of privies was the institution of the impervious pail and dry earth system. For the purification of sewage from large institutions or villages the septic tank supplemented by filtration was applicable. Disease germs should not be present in the drinking water. Legal protection of a water supply was a very great safeguard, but it could not guarantee absolute protection. The most important agents of purification were dilution, time, sunlight, aeration, sedimentation, and filtration. In brief, the advantages or disadvantages of a rural watershed as compared to other sources depended upon the ability or inability to prevent contamination and the thoroughness with which water pollution material could be removed. From 1872 to 1905 the city of Hudson drew its water supply from the Hudson river directly in front of the town. The water was purified by slow sand filters, which, however, were not covered and not cared for as they should have been. From 1899 to 1906 there were reported an average of 62 cases of typhoid fever, originating in a city of 10,000. During the same period there was a mortality rate of 8 per 10,000 from diarrheal diseases, including "malaria," principally occurring among adults. By far the larger number of these occurred during the months of January, February, and March, a time which suggested that the diarrheal diseases and malaria should be classed as typhoid. In 1906 a gravity supply was obtained from a thinly populated rural watershed, mostly upland pasture and woodland, which could develop 25,000,000 gallons daily. An integral part of the system was a separate storage reservoir of 90 days' capacity. The bacterial content of the feeders showed a maximum of 1,800 and a minimum of 157 per cubic centimeter. These factors have reduced the number of cases of typhoid fever originating in the city to 4 per 10,000. There had also been a considerable saving in operating expenses of the water supply, due to the fact that water would run down hill more cheaply than it could be pumped up.

The Hudson River as a Source of Water Supply.—Dr. Frederick J. Mann of Poughkeepsie presented this communication. It was claimed that during the next eight years leakage and wastage of water in New York City must be stopped to avoid a water famine. This could best be done by requiring all water to be delivered and sold by the use of meters. The water supply from the Croton and Bronx systems, plus the new Catskill supply, would suffice Manhattan and Bronx, if wastage was not stopped, only till 1922, a period of fifteen years. If complete metering was required and wastage thereby stopped, said sup-

plies would satisfy till 1937, a period of thirty years. After this, or sooner, an additional amount of water would be necessary. This would mean either the use of the Fishkill and Wappingus creeks in Dutchess county and the Jansenkill in Columbia county, or water from the Hudson river above Poughkeepsie, or from still more distant sources. Other possible sources of supply were from the Walkill in Orange county, Lake George, Lake Champlain, the Adirondack waters, or even the Great Lakes. The keynote of the paper was that the Hudson river was the logical source of supply for New York City, and with slow sand filtration would give a safe and abundant water. No matter what the source of supply for New York City, sooner or later it must all be filtered. Filtration was no longer an experiment. The Merchants' Association of New York City, whose report was published in 1900, gave the following reasons why the Hudson river water, taken a little north of Poughkeepsie, was the most advantageous supply: (1) It was the largest possible supply short of the Great Lakes. (2) It was practically as safe as the Croton water and its purity could be controlled by filtration. (3) It was capable of being added to from time to time until a supply of fifteen hundred million gallons a day was reached. This was about five times the total present Croton and Bronx supply. (4) It would help in the creation of a large water power in the upper Hudson valley by the construction of reservoirs in the Adirondacks to control flood waters. New York's typhoid fever rate to-day was much larger than that of many European cities using filtered water, and Dr. Darlington had clearly shown the need of filtration of any water used. Albany had successfully filtered the Hudson river and thereby wonderfully reduced the cases of typhoid. The proposed Catskill supply of two hundred and fifty million gallons per day would not quite equal the present Croton and Bronx supply of three hundred and ten million gallons per day; and these together would only suffice for a few years. To add to them the waters from the Fishkill and Wappingus creeks in Dutchess county and Jansenkill in Columbia county, a total addition of two hundred and fifty million gallons per day, was only postponing the inevitable a little longer. The possible available supply from the Hudson river above Poughkeepsie, which was figured at fifteen hundred million gallons per day, was almost double the total of all the supplies mentioned and would suffice for many years. The best direct proof that the Hudson river could be satisfactorily filtered by a slow sand filter was afforded by the results obtained at Albany. That city took its water from about the worst polluted part of the Hudson. Prior to the installation of slow sand filters in November, 1899, Albany's death rate was excessive, averaging about 100 per 100,000 of population for the five years before that date; since then, with efficient slow sand filtration, it was about 20 per 100,000 per year. During this time the average efficiency of the Albany filters had been about 99.7 per cent. removal of bacterial contamination. In contrast stand Cohoes and Troy, still drinking the Hudson water, with resulting excessive typhoid. Cohoes' rate ran from 50 to 130 per 100,000, and Troy's rate from 30 to 80 per 100,000. In conclusion he said that a logical deduction was that filtration would be easier in proportion to the purity of the raw water and therefore the physicians of this State should help the State Department of Health in every way possible to make and keep free their rivers and streams from pollution.

Pregnancy and Cancer of the Breast.—A warning has been sounded against pregnancy following removal of a carcinomatous breast. The increase in the breast function in all respects because of the occurrence of pregnancy is very likely to cause a redevelopment of the disease, even after all signs of a favorable course to recovery have been noted.—*Clinical Review.*

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-third Annual Meeting, Held at Columbus, O., October 8, 9, and 10, 1907.

THE PRESIDENT, DR. HORACE H. GRANT OF LOUISVILLE, IN THE CHAIR.

(*Concluded from page 791.*)

MEDICAL SECTION.

Address in Medicine.—Dr. GEORGE F. BUTLER of Chicago in this address discussed the medical men and their influence on human progress, and said that if we were to prevent disease as the chief mission, or as the most effective method of warfare upon this chief enemy of human progress, the conditions must be known, not merely the material, mechanical, and social, from which they resulted, but the primary conditions that lay still farther back of the immediate conditions that resulted in diseases. He discussed the relations between physician and the public service, and gave considerable attention to the need for a better understanding of the social question, and deplored the danger to innocents of silence and secrecy. He advocated the abolition of State lines with reference to medical practice regulations. Referring to expert witnesses in legal cases, he condemned "expert liars" in strong language. In the medical profession, as in religion or science, the perils of dominating influence could not be escaped. While the evils flowing from industrial concentration could be met, the evils that followed the syndication of intelligence could not be avoided. The struggle of the ages had been the emancipation of truth from authority.

The Relations Between the Medical Profession and the People.—Dr. H. H. GRANT spoke on this subject. He said that we all realized the world was full of wretchedness, deformity, and disease; that this was due to ignorance and cupidity, distributed well over the whole population, from rich to poor. All realized the measures of relief must be a slow and gradual reform, conducted by a concentration of many influences, yielded by society at large. All realized the obstacles to success, as well as the possibilities of abuse in the methods, and all knew the need of a directing influence which was thoroughly informed and could be confidently entrusted with power. It was his belief that through the trust and the support of the general public, given to a conscientious medical profession, disinterested as a body, with identical concerns with the public, a highly comforting progress would soon be recorded. With a view to the hopeful advance of these noble and world-rewarding benefactions, the profession of medicine, without jealousy or thought of self-interest, should devote its wisest and most faithful workers as chieftains; let the lay and the religious press, every ready upon conviction as earnest and determined associates, with unremitting zeal unphold and champion the cause, and add to this the patient and never-failing confidence of a liberal and trusting general public rallying its invincible support, and there would open up before the coming generation such a prospect of achievement and victory as would be a soul-satisfying record.

Neurasthenia Gastrica.—Dr. CLEMENT R. JONES of Pittsburg reported four cases of this condition, and concluded that neurasthenia gastrica or nervous dyspepsia was frequently due to or complicated by eyestrain. That other gastric disturbances were sometimes aggravated by eyestrain. That along with other points in the examination of gastric cases this should not be neglected. When eyestrain was the cause of gastric symptoms the relief by proper refraction was prompt and satisfactory.

Dr. R. D. CLIPPINGER believed that eyestrain often produced all the symptoms of an old so-called chronic gastritis. The general practitioner was apt to ignore the eyes.

Dr. MARK D. STEVENSON found that very many patients were relieved of nausea and vomiting by the wearing of proper lenses.

Dr. Geo. P. Sprague said that so-called gastric disturbances in neurasthenia were very often roundabout reflex disturbances due to vertigo; in one case a lack of equilibrium due to a visual defect; in some other case not. He found very commonly in sending neurasthenics to oculists for the correction of eyestrain that until the attention of the oculist was called to the possible psychic connection between the patient's condition and the visual defect, he very often failed to give the correction, which he could and did do after that had been called to his attention.

Reinfection with Syphilis.—Dr. A. U. Williams of Hot Springs, Ark., had seen a number of cases in which he had suspected reinfection. In many the history of the first attack was indefinite and unreliable. In but very few cases was the history sufficiently plain to make anything like a positive diagnosis of a second attack. He cited two cases in which the symptoms and history were so plain that he thought he could safely claim both as cases of reinfection.

Toxemia from the Standpoint of Perverted Metabolism.—Dr. Ralph W. Webster of Chicago concluded that toxemia, aside from that following the acute or chronic bacterial processes, was always of metabolic origin. The toxemias under discussion were more the effects of a general metabolic perversion than of a direct organic disorder. A specific toxemia, in the sense that it was due to a specific substance, was unknown in the class of toxemias treated.

Dr. Thomas Hunt Stucky of Louisville, Ky., followed with a paper in which he discussed autointoxications of intestinal origin which resembled typhoid fever.

The Treatment of Scarlet Fever as a Streptococcus Disease.—Dr. J. E. Coleman of Canton, Ill., had treated this disease with carbolic acid internally and externally, together with small doses of aconite, the first few hours until fever was allayed. In all of the cases he had thus treated the disease was materially shortened, the rash rapidly faded, and on the second day the fever disappeared and the throat symptoms were also relieved. When this treatment was used, there was not any desquamation of the skin, nor any after-effects from the disease, such as nephritis, or discharge from the ear. He had successfully treated cases of scarlet fever by the application of the two remedies mentioned since the time of an epidemic of the disease, year after year, admitting, however, that the results obtained might possibly have been due to the fact that the disease ran a benign course.

Relations of the Doctor to the Alcoholic Problem.—Dr. T. D. Crothers of Hartford, Conn., showed the intimate associations of alcohol with a large part of the mortality, disease, and degeneration of the present time, and urged the profession to take up the physical study of the subject. He showed that the mortality from alcohol, both direct and indirect, was from ten to twenty per cent. of all deaths, and at least ten per cent. of all diseases were very largely influenced by or due to this cause; also that from twenty to fifty per cent. of all mental diseases and fifty per cent. of idiocy, pauperism, and other degenerative conditions had an alcoholic causation. Fifty per cent. of all criminals serving sentences for crime in 1906 were due to the influence of alcohol. Nearly half a million persons came under legal recognition for intoxication and petty crimes last year. Reliable authorities showed that fifty per cent. of all railroad and other accidents were due to the mistakes of persons under the influence of spirits. Beyond this the losses, the revolutions, and the injuries noted in every community assumed great proportions. This problem was a physical and medical one. Every advance in science showed that there were physical causes which developed from distinct sources which could be studied and known, and that the whole subject was not a mass of theories, but one of facts the same as that of epidemic and contagious diseases. The evils had reached such a stage that public opinion was making herculean efforts along theoretical lines to overcome and break it up. The author urged that it was a medical subject to be understood by medical men. When the facts were studied and known, the remedies and methods of prevention would be clear and practical. The failure of physicians to know the subject had brought in an army of quacks whose presence was a reflection on the intelligence of the physician who understood and treated these people. The great temperance movement should be directed and managed by physicians along exact lines of scientific study above all prejudice, then they would become practical and reach to the bottom of the great drink problem and point out the methods of cure and prevention. When medical men were taught to recognize the physical side of this problem and study the facts alone, irrespective of all theories, then the mortality and disease would disappear.

The Recognition and Management of Acute Mastoiditis by the General Practitioner.—Dr. Leartus Connor of Detroit, Mich., in a paper on this subject, drew the following conclusions: (1) Patients with acute mastoiditis should be regarded as seriously ill, placed in bed, given a brisk cathartic and a diaphoretic, and the diet limited to at least one-half. (2) If there were present tenderness of the mastoid, redness and bulging of the inner, upper, and posterior external auditory canal and adjacent membrana tympani, Wilde's internal incision should be promptly done. (3) Regular irrigation with water, as hot as could be endured, should precede and follow the incision, and dry heat follow during the interval of irrigation. (4) An aseptic should be applied to the wound after each irrigation. (5) Thus managed, many cases of acute mastoiditis would speedily recover. (6) If they grew worse steadily, the mastoid should be promptly opened, all diseased tissues removed, and the wound dressed aseptically. (7) A painful deaf ear merited quite as careful attention as a red painful eye, or a painful stiff limb. Until this was accorded it, physicians would continue to have cases of extensive destruction of mastoid bones, permanent loss of hearing, infection of lateral sinus, facial paralysis, subdural, cerebral, and cerebellar abscess, and death.

Morphine Addiction.—Dr. George P. Sprague of Lexington, Ky., discussed some of the essential points in the etiology, pathology, and treatment of those addicted to morphine. He divided the cases into three groups: (1) A small one composed of normal individuals, who from unwise treatment for pain in acute illness had contracted the habit; (2) a larger group of moral degenerates who indulged in the vice of morphinism; (3) much the largest group, recruited from among the neuropathic weaklings, from the victims of improper training and lack of early discipline, from the vast army of defectives, who, beginning to lose ground in the race of life, resorted to drugs as a spur, and from the large number who, suffering from sudden shock of disease, loss, etc., resorted to the drug in the hope of obtaining relief. These patients should be under treatment for months; the patient should not be alone a moment when he might procure morphine, day or night; everyone coming in contact with him must be above bribery, and his nurse must be above suspicion, and ever suspicious. The patient's sense of right and power of will should be steadily stimulated, and every physical ill he might have should be found and vigorously combated.

The Nature of Morphine Disease.—Dr. Chas. W. Carter of Richmond, Ind., said that the physician who would understandingly and conscientiously treat the morphine disease must have a generous breadth of view in reading human character, an entire want of prejudice in interpreting symptoms, and a broad and thorough knowledge of remedial agents.

Medical Inspection of Public Schools.—Dr. Frank W. Gavin of Canton, O., said the medical inspector should look after, first, the school building, its condition, ven-

tilation, lighting, heating, seating, etc. Second, the inspection of candidates for teachers' certificates in the principles of preventive medicine and school hygiene. Third, physical and mental condition of the child. He pointed out the advantages of medical inspection and the methods of examination. The salary of a medical inspector should be generous, thus warranting the selection of the best men procurable. He sincerely believed it would be money wisely invested on the part of cities and municipalities.

Urinary Infections in Children.—Dr. I. A. Abt of Chicago pointed out the avenues through which microorganisms gained access to the bladder and to the pelvis of the kidney in these infections. Bacteria might enter the bladder through the urethra and migrate upwards to the bladder and thence to the kidney. The infection might be hematogenous in character, the microorganisms finding access into the bladder through the blood-vessels. The microorganisms might pass in some manner from the bowels through the loose cellular tissue of the pelvis into the bladder. The fact that sometimes a bowel infection, particularly follicular enteritis, preceded an attack of cystopyelitis, had suggested this view. Congenital malformation of the bladder and kidney predisposed to cystitis and pyelitis. Such a case had come under his observation. This was given in great detail. He described the symptoms and course of the disease. With reference to treatment, the ordinary urinary antiseptic in one form or another used internally would usually bring about the desired result. In the severe forms of streptococcus or staphylococcus infection the vesical irrigation might be indicated. In other respects the treatment was purely expectant and symptomatic. The pain and restlessness might require the use of antispasmodics and sedatives.

The following papers were likewise read: "The Profession of Medicine, As It Was, and As It Is," by Dr. Robt. Barclay of Pittsburg, Pa.; "Purulent Conjunctivitis in Infants and Adults," by Dr. Mark D. Stevenson of Akron, O.; "Gelseminine," by Dr. Wm. F. Waugh of Chicago, Ill.; "Colorado and the Eastern Pulmonary Case," by Dr. W. A. Campbell of Colorado Springs, Col.; "Pregnancy When Complicated by Tuberculosis," by Dr. Harold A. Miller of Pittsburg, Pa.; "The General Practitioner's Attitude Toward Eyestrain," by Dr. Richard D. Clippinger of Bellefontaine, O.; "Gallstones as an Etiological Factor in Diabetes," by Dr. J. C. O'Day of Oil City, Pa.; "A Résumé of Gallstone Factors," by Dr. R. Alexander Bate of Louisville, Ky.; "The Psychasthenic States," by Dr. Chas. W. Hitchcock of Detroit, Mich.; "What We Learn from Analysis of the Feces," by Dr. Joseph A. Sweeney of Louisville, Ky.; "A Contribution to the Literature on the Pathology, Etiology, Symptomatology, and Technique of the Operation of Supravaginal Hysterectomy for Fibroid Tumors of the Uterus," by Dr. Frank D. Smyth of Memphis, Tenn.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Arthur R. Elliott of Chicago; *Vice-Presidents*, Dr. F. F. Lawrence of Columbus, O., and Dr. Robert C. McChord of Lebanon, Ky.; *Secretary*, Dr. Henry E. Tuley of Louisville (reelected); *Treasurer*, Dr. Samuel C. Stanton of Chicago (reelected).

Louisville, Ky., was chosen as the place for the next annual meeting in October, 1908.

Revaccination of Soldiers.—According to Bondesen the proportion of successful revaccinations varies among different troops from 30 to 100 per cent., averaging during the past eight years 70 to 78 per cent. In the German Army the percentage of success is about 92 to 95 per cent. The cause of this is undoubtedly due to different views as to the result. Some vaccinators demand a pustule, others scarcely perceptible infiltration at the vaccination point. In France the result in 1902 averaged 42 per cent., varying in the several Army Corps between 19.8 per cent. and 67.7 per cent.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held September 17, 1907.

Dr. Glentworth R. Butler in the Chair.

The Sources of the Contamination of the Air in Greater New York.—Mr. D. D. Jackson, B.S., Director of the Laboratories of Water Supply, Gas, and Electricity, City of New York, read this paper. He said that much interest had been aroused in recent years in the study of city air, and that some progress had been made toward improvement. Relief from existing conditions was gradual, but a continued agitation of the subject tended toward progress and to prevent the establishment of new sources of contamination or the increase in those already existing. The consideration of this subject included, 1. the question of excessive dust, and the bacterial contamination of floating particles; 2, the smoke and cinder nuisance, and offensive trades, and, 3, the transmission of filth and disease-laden material by means of insects. It was a fact that dust which did not contain disease germs was nevertheless capable of producing irritation of the eyes, nose, throat, eustachian tubes, bronchi, and lungs. The soil was made ready for bacterial invasion and propagation. Contaminated dust caused conjunctivitis, nasopharyngitis, middle-ear disease, tonsillitis, quinsy, laryngitis, bronchitis, pneumonia, and influenza. Other diseases, besides, were capable of transmission by floating dust particles. Following gusty winds there were usually epidemics of acute colds and catarrhs, many of the victims of which had been apparently in previous good health. It was only a step to chronic catarrhal and acute inhalation diseases. It was significant that most of the sickness and death due to throat and lung troubles occurred during the months of the year when the most dust was being blown about by the winds. In round numbers the yearly deaths in New York City from the four principal diseases in this list were as follows: Influenza, 500; bronchitis, 2,000; tuberculosis, 8,500; and pneumonia, 10,000. In recent years there had been in this city more deaths from lobar and bronchopneumonia than from any other source, not even excepting the great white plague. Most of the deaths occurred between December and April. A reduction in the quality or in the virulence of the street dust would undoubtedly reduce the enormous death rate from this source. A microscopic examination of the constituents of street dust usually revealed the following substances: Stone dust, plaster, iron rust, and cement from building operations; dirt from excavations or from loosely constructed carts; ashes, house sweepings and dried garbage blown from barrels and cans; chimney soot and cinder from industrial plants, and excrement of horses, dogs, and other animals. It also contained the dried sputum of individuals possibly having tuberculosis, bronchitis, nasopharyngeal catarrh, or the first stages of pneumonia. If this latter material was protected by other accumulations, or did not happen to be exposed to direct sunlight, the germs which it contained were not destroyed, and constituted a direct source of disease by inhalation. The floating dust in the air of our homes had the same composition as that of the streets; it was largely a question of amount. With the wind blowing eighteen miles per hour there were five times as many bacteria in the air as when it was blowing nine miles per hour. On a windy day thousands of bacteria settled on each square foot of sidewalk per minute. They also settled in raw foods exposed for sale. The average New York City dust contained about 500,000 bacteria per gram, but the number varied enormously in different portions of the city. Under average conditions, as computed by Dr. Soper, a single individual inhaled in one day 16.5 mg. of dust, including 8,250 bacteria. If unsanitary conditions prevailed, many of these bacteria were pathogenic. It was incumbent on every one to take a personal interest in the work of the Street Cleaning Department, and to note that

the streets were first sprinkled and then thoroughly swept, that the material was immediately removed, and the streets flushed with water, if necessary, and that proper appropriations were provided to do this work in a thorough manner. From the economic viewpoint the city could not expend money to better advantage. As regards the smoke nuisance, the speaker said that smoke and cinders could not be considered as a menace to health except in an indirect way. Like other forms of dust they served as a mechanical irritant. The sanitary code of the city prohibited the discharge of dense smoke from various sources. The experience in Cleveland, the smokiest city of the Middle West, had been that the mechanical stoker had caused a permanent condition of incandescence and prevented the cooling and clogging of the fires when fresh coal was added, thereby maintaining greater economy and better combustion. Another device used in that city was the down draft furnace having two grates. When the fresh air was fed to the upper grate, the air draft was down through the fire on this grate. All the volatile products mixed with the air were then obliged to pass on their way to the chimney through an intensely hot fire in the lower grate and were therefore completely burned. Firebrick, arches, and checker work maintained at a white heat were also used. When ordinary flat grates were used additional air in the proper amount was supplied by blowers above the grate just after firing. This excess air was afterwards automatically shut off. Other means of smoke prevention had been successfully employed to fit the various cases at hand. A change from improper to proper combustion meant a saving of from ten to twenty five per cent. in fuel. The subject of infection from flies was an important one. Considerable time and money had been spent in a war on mosquitos, yet the cases of malaria reported in New York City in 1905 were but 359 and the deaths only 52. Much more to be feared was the common housefly, which was one of the chief carriers of the infection which in New York City causes annually about 650 deaths from typhoid fever and about 7,000 deaths from diarrhea. The fall rise in typhoid death was considered an established institution. This rise, if set back two months from the report of deaths to the time of the contraction of the disease, probably corresponded to the curve of the prevalence of flies and to the curve of rise in deaths from diarrheal diseases of both children and adults. It also corresponded to the temperature curve. The activity of the house fly was in proportion to the temperature and the times at which it was most active and most numerous corresponded exactly with the time of contraction of diarrhea and of typhoid fever. The immunity from diarrhea of breast-fed babies and its frequency of occurrence among those artificially fed pointed strongly to the food and drink as media of transmission. Much of the actual infection was undoubtedly due to flies. Several epidemics of dysentery of a malignant type had been known to radiate from a single point and to entirely disappear when proper disinfection of closets was enforced. Ordinarily, flies traveled only a few rods from their breeding places, but when the days were warm and sultry the flies were stimulated to extra exertion. They extended their travels in the daytime and flocked indoors at night. They were attracted equally by food and filth, and this commingling of tastes made the ominous buzzing in the pantry more to be dreaded than the high-keyed note of the mosquito in the sleeping room above. The speaker captured, last summer, a fly on South street, and on his legs and in his mouth were found one hundred thousand fecal bacteria. He had been behind the large packing boxes down by the wharf and was on his way to the nearest milk pitcher. There was a crying need for better sanitation on our dairy farms and likewise in our own city. Our entire water front was without decent sanitary toilets, and most of the wharves were without any at

It was not to be expected that the city's air was to be free from dust, but it was to be expected that it should not contain an abnormal amount of dust and that this dust should not be laden with the germs of disease. It was not to be expected that small amounts of smoke and offensive or noxious gases should not enter the atmosphere, but it was to be expected that no industrial institution, factory, or dwelling should be allowed to produce amounts of either of these in quantities sufficient to vitiate the surrounding air or become a nuisance or menace to health. It was also to be expected that a strong movement should be started against the extensive and foul breeding places of that very dangerous insect, the house fly.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 4, 1907.

DR. JOHN F. ERDMANN IN THE CHAIR.

Interscapulo-Thoracic Amputation for Sarcoma of the Shoulders.—Dr. CHARLES GOODMAN presented a Russian boy, aged eighteen years, who was admitted to Beth Isreal Hospital August 6. He had been one year in this country and always enjoyed good health until seven years ago when he had typhoid fever. Both his parents are living and well. Until he was thirteen years old he was of average size; then he began to grow rapidly, now measuring over six feet in height, being several inches taller than either of his parents. He first complained of pain in the region of his shoulder; this was followed by a swelling below the shoulder. Examination revealed a painful mass below the shoulder and restricted movement of the arm. The patient, when admitted, was poorly nourished and overgrown. His physical condition proved negative, except in the region of the left shoulder, where there was a uniform enlargement, tender to the touch. The swelling was aspirated, but nothing obtained. An exploratory incision revealed an extensive, soft, pultaceous mass about the shoulder joint. This was followed by much bleeding. A small section was removed and the pathologist reported it to be sarcoma. Dr. Coley was out of town and his treatment was not given. Resection was out of the question because of the soft, pultaceous character of the growth extending down the shaft of the humerus. Most surgeons agreed that a resection of a joint hardly offered the patient a fair degree of safety as regarded recurrences. Therefore, he decided that a more radical operation was indicated. Operation was performed on August 12. A preliminary ligation of the subclavian vessels and branches of the thyroid axis was done. The incision was along the entire border of the clavicle; the subclavian vessels were ligated in two places and divided. Some difficulty was encountered in this because of the depth of the wound. An interscapulo-thoracic amputation of the extremity was performed. At the close of the operation normal saline infusion was given because of the shock. The pathologist reported the specimen removed to be a large spindle-celled sarcoma. The mortality after such operations, with strict aseptic precautions, was from 8 to 11 per cent. The average duration of life following this operation was three years, although some cases reported lived twenty-six years without recurrences. Dr. Ochsner reported recurrences ten years after operation. Dr. Goodman intended to administer Coley's toxins with the view of preventing recurrence. He also intended to devise some apparatus to obviate the chances of scoliosis, which so often followed amputation of this extremity.

Dr. SAMUEL LLOYD congratulated Dr. Goodman upon the results obtained in this case.

Dr. REGINALD H. SAYRE said the results obtained were excellent.

Acute Perforating Gastric Ulcer.—Dr. C. A. MCWILLIAMS presented a man, twenty-four years old, to illus-

trate an acute perforation at the pylorus. He was admitted to the Presbyterian Hospital at midnight. He had sudden pain in the epigrastrium at four o'clock, eight hours before the patient was seen. He had vomited three times. He could not locate the pain at any particular spot, although at first it was on the right side. His temperature was 100°, pulse 88. The polynuclears were 80 per cent. His history prior to onset of sudden pain was negative. A diagnosis of appendicitis was made. The recti, especially the right, were rigid. Per rectum nothing could be felt except a fullness. There was flatness in the right flank. There was absolute absence of liver dullness. A tentative diagnosis of appendicitis was made, and operation advised. A Kammerer incision was made, the abdomen opened, when a large quantity of turbid fluid, without odor, escaped. It was neutral in reaction, and contained particles of what looked like milk or particles of fibrin. The appendix was found to be normal. The diagnosis of a perforating gastric ulcer was then made. The wound was enlarged and the pylorus exposed. On the anterior surface of the stomach a perforation was found as large as a lead pencil. The edges were indurated. A great quantity of fluid was found under the liver. The pelvis was filled with fluid. A purse-string suture was introduced, with a cigarette drain below the stomach. Convalescence was uninterrupted. The highest temperature was 101.5°. The operation was performed last April, and there has been no stomach trouble since. He was a laborer by occupation, and was accustomed to swing lumber upwards, resting on his abdomen. He was not an alcoholic. For six weeks prior to admission he stated that he had cramp-like pains after eating.

Reduction of Fracture-Dislocation of the Dorso-lumbar Spine by Open Operation.—Dr. C. A. McWILLIAMS presented this patient. This man was admitted to Presbyterian Hospital September 4, 1906. He was thirty-four years old. At one o'clock of the day admitted he was bending over hammering nails when he was struck in the center of his back. He fell to the ground and was unable to walk. He was taken to Portchester Hospital, placed on an air mattress, and later transferred to the Presbyterian Hospital, ten hours after he was hurt. Examination revealed a hematoma in the lower dorsal region, underneath which was an irregularity between the spinous processes of the twelfth dorsal and first lumbar vertebræ. Palpation was painful. There was total loss of motion below the line of fracture. The soles of the feet were absolutely insensitive to stimulus. This extended to the middle of the calves. The popliteal spaces were hyperesthetic. On the back of the toes he could distinguish the prick of a pin, but not on the back of his calves. There were no plantar reflexes. There was retention of urine. It was evident that there was a fracture or possibly a dislocation of the spine, and the question of operation came up. Incision was made over the tenth, eleventh and twelfth dorsal and first lumbar. There was a large amount of subcutaneous bleeding. After exposing the spine, the finger went down between the eleventh and twelfth dorsal vertebræ to the spinal cord. The interspinous ligament had been torn through. The lamina of the eleventh and twelfth dorsal and first lumbar were removed. The bleeding was stopped by pressure and packing. The articular processes on the left side of the twelfth dorsal vertebra seemed to be amputated. There was a dislocation of the left side of the dorsal vertebra anteriorly upon the upper surface of the twelfth dorsal. The right eleventh and twelfth dorsal vertebræ were com-
[illegible] the
German Army[illegible]eral fragments were removed. The dura
per cent. Th[illegible]ed, and was not opened. The dislocation
views as to [illegible] and convalescence was uninterrupted. The
others [illegible]atment was by plaster-of-Paris cast. Catheteriza-
poin[illegible]or about three or four weeks was necessary. The
vary[illegible]ovement was gradual, first shown in the great toe
and 67[illegible]int twitch; then this appeared in the other toes. Finally he got so that he could move both legs. The function returned in the left leg earlier than in the right. The speaker then read the neurological examination as reported by Dr. Ramsey Hunt.

Dr. REGINALD H. SAYRE thought that Dr. McWilliams had had a most beautiful result. He had a case last Saturday, a very extensive fracture, and he was in considerable doubt as to the ultimate outcome. Seeing the case this evening made him feel more hopeful of his own case.

Dr. SAMUEL LLOYD said the case presented was interesting to him because it corresponded so with his original spinal case which he operated on in 1888. He believed he could prognosticate what the outcome would be, that improvement would go on. His patient was an engineer who fell, and was sent to the hospital with complete paraplegia. The only symptom left was a mild drop-foot. Dr. Lloyd referred to the difficulties encountered in reducing fracture dislocations, and said that the lower down the injury the better surgical results.

Dr. REGINALD H. SAYRE said that he was struck years ago, when he read a paper on the subject, in finding so many cases not improved after operation until after some method of immobilization had been applied to the spine. These patients would lie in bed without much relief of the paralysis; but after the jackets had been applied, and the spine so locked up, they were soon able to go about their business.

Empyema (Pyopneumothorax).—Dr. W. S. SCHLEY presented a patient. The boy entered the hospital in May, three years ago. An operation for empyema had been performed by a doctor in the country. One year later, because of a persisting fistula, resection of the ribs was done. When he entered the hospital he was terribly emaciated because of this chronic discharge from the sinus, mostly due to streptococci. The chest was much shrunken. There was a perforation into the bronchus and he coughed up one-half pint of pus every day, mostly streptococcic. The apex beat was displaced. The cavity measured one and a half inches in depth and three or four inches backwards. The walls were dense, hard, and firm, and the discharge was profuse. In five weeks the wound almost closed with the method treated of in his paper. (See below.) He did not believe that the sinus could have been closed by any other method except aspiration drainage.

The Surgical Treatment of Ulcer of the Stomach.—Dr. SAMUEL LLOYD said that acute ulcers of the stomach, or the non-indurated, were in about 74 per cent. curable by medical means. Of the remaining 26 per cent. 21 per cent. were improved, and 2.4 per cent. died, and 2.6 per cent. were unimproved. The usual death rate from gastric ulcer was about 13 per cent., 6 to 7 per cent. from perforation, and 5 to 6 per cent. from hemorrhage. From statistics it was evident that about 13 per cent. of the 26 per cent. not cured by medical means resulted fatally. This would mean a mortality of 50 per cent. If the surgical treatment of these cases showed a mortality of 50 per cent., there would be no object in submitting these cases to operation. All things considered, the operative mortality ranged between 2 and 5 per cent. They could not expect such good results in the hands of the unexperienced, and the statistics given had been compiled only from the reported series of skilful and experienced abdominal surgeons. It was a mistake for the surgeon to undertake this work with the preconceived idea that a gastroenterostomy would answer in every case. That this could not be so was demonstrated when one considered the location and character of the ulcers as they appeared in the statistics of a number of authors. Fenwick, after a study of 1,015 ulcers, found that in nearly 76 per cent. the ulcer was situated in the pyloric region near the lesser curvature and on its posterior surface. Welch's statistics, based upon 793 cases, corresponded very closely with those of Fenwick. These statistics included both the chronic and

the acute types. It was evident, therefore, that in the great majority of the cases the ulceration occupied the pyloric area and the posterior surface. The acute ulcer usually developed at any spot between the cardia and the pylorus, along the upper margin of the stomach, and more frequently on the posterior than the anterior surface. From a consideration of a series of statistics it was evident that it was rarely possible to determine before the examination of the stomach was made by inspection through the wound how extensive the lesion might be, and how much cicatricial change might have gone on in the organ. The general condition of the patient with regard to endurance and the condition of the diseased tissue when exposed should form the basis for the determination of the operative procedure. The Mayos claimed that 85 per cent. of the stomach ulcers coming to operation were indurated, and only 15 per cent. non-indurated. They considered that gastrojejunostomy was the best procedure because it gave rest to the diseased organ by diverting the food and gastric contents. In cases of hemorrhage the best method was to open the stomach, locate the bleeding point, and suture the part firmly with catgut and a curved needle, going well through the coats of the stomach from the mucous side. The outer surface should then be exposed and mattrass sutures of silk or linen should bring together the musculoperitoneal surfaces of the ulcerating area. A hemoglobin percentage below 30 per cent. would not give a very great chance of success. As a general rule a case that had resisted medical treatment for any length of time, or that had persistently recurred, should be operated on. Rodman believed that medical treatment should be carried out for four weeks, and then, if not successful, surgery should be resorted to. Mayo said that "when all the cases are summed up that have been operated upon, it is the non-indurated mucous ulcer that has not been relieved and sometimes not even found. So far as the indurated and callous ulcers were concerned, they were surgical conditions." He facetiously said, when he was asked when he considered a gastric ulcer should be operated upon, "not until it has had nine medical cures."

Aspiration Drainage in Empyema.—Dr. Winfield Scott Schley read this paper. He said the length of time in healing and the persisting sinuses in many empyema cases suggested that the methods of ordinary drainage were inadequate in many cases. As the majority of patients get well through simple drainage, they had regarded the method of thoracotomy, with or without rib resection, and ordinary drainage as sufficiently successful, and had disregarded the smaller number of cases that dragged on for months or years, and perhaps later with shrunken chests and worse complications were obliged to have one of the radical procedures to obliterate the pus-producing cavity or tract. Dr. Schley had tried a number of schemes to facilitate drainage, but without any great success until the present year with aspiration drainage; this year he tried this method in all cases of empyema and of persistent sinuses of the pleura with so much success that he thought the method worthy of further record and more general adoption. He then gave a brief review of the history of surgical drainage in empyema. The healing cavity in the chest in empyema closed much more rapidly from side to side by lung expansion than from above downward, and it was in this factor that the danger of pocketing and retention by unequal expansion laid. In delayed sinus healing unequal lung expansion and the more rapid progress of the skin and fascial planes might so shut off the tract as to interfere with proper drainage. With a lung that had been compressed for a long time by purulent exudate the adhesions were so dense and the exudate so thick that some of them never expanded again under simple drainage. Such a lung needed in addition to pressure from within not only the removal of pressure from without, but the establishment of a decided negative pressure. While he believed the method of aspiration drainage of greater value in the older cases of empyema and in the persisting cavities and sinuses, it had in the simple cases answered so well that he had used it as a routine procedure in all cases. The amount of negative pressure required to overcome the elastic contraction of the lung itself was slight, and had been variously estimated to be from 1/80 to 1/100 part of an atmosphere. It had seemed to him that in addition to the direct effect of expansion upon the lung they had a certain amount of Bier's passive hyperemia. He thought it best to wait several days after operation, allowing the escape of the major part of the purulent material, and then to substitute a single tube of 35 to 40 French caliber, inserting it 2½ to 3 inches within the pleura and packing about it iodoform or absorbent cotton saturated with boric acid ointment. A piece of dentist's rubber dam, four inches square, with a small hole cut in it, was stretched over the tube and run down to the side of the chest. This was overlapped by strips of two-inch adhesive. A circular wad of absorbent cotton was placed about the tube and a chest binder placed on with the tube coming through. A glass connecting piece and smaller tubing connected the Pollitzer bag. The dressing was changed every week and the lung expansion and vertical depth of the cavity or sinus noted. As the cavity was obliterated the tube was gradually removed. Fibrin coagulum seldom occluded the tube; if it did it was easily remedied by probing up the tube. Dr. Schley then reported the histories of eight cases operated on in which this method of aspiration drainage was employed.

Dr. Samuel Lloyd said he did not consider drainage necessary. For a long time he had been interested in this subject and had studied the question of mechanical drainage and expansion of the lung by drainage, and he had had considerable experience with it. He believed the whole question of forced drainage to expand the lung was based on wrong mechanical methods; the idea was to pull the organ down, just as the old method was to allow the chest to fall in. What they wanted to get was a full expansion of the lung, filling the cavity by an expansion of the pulmonary tissues. That was feasible and possible at the time of operation and could be continued afterwards. The idea of pulling down was all right for acute cases, or where the adhesions were not dense or extensive, and where the thickening of the pleura had not advanced too far. What was wanted was a full expansion of the lung and natural adhesions between the parietal and pulmonary pleura for the closure of the cavity. That was better than trying to pull or draw down the lung into place.

Dr. William C. Lusk said that he had seen Dr. Bryant's original case and had followed his work since. He was particularly interested in the report of Dr. Schley's case, the boy with empyema of three years' duration. He called attention to one important point in the technique, as employed by Dr. Bryant; instead of resecting a rib he made a simple incision between the ribs under cocaine, and this did away with the use of an anesthetic and reduced the operation to one of comparatively small magnitude.

Dr. A. V. Moschcowitz said that the general practitioner was not inclined to look upon these cases of empyema, as a rule, as grave or serious. The prognosis was said to be generally good, but he confessed that he always treated a case of empyema with trepidation. It had been his misfortune to lose a case of empyema within one year after operation. He believed it was a mistake to place in a long drainage tube. He made it a rule to introduce a number of drainage tubes, but just within the pleural cavity. He had found cases, comparatively recent, in which the adhesions had not formed to very great depth, which healed promptly, whether one kind of tube or another was used. But those cases which had been neglected, the old cases, they, as a rule, were difficult

to treat. He said he had given up the Estländer and Schede operations except in extreme cases. He endeavored to clean the cavity, and introduced a short drainage tube. He had had excellent results from Bier's cups. He thought good followed drawing down the lungs. A negative pressure was created by this. He applied them twice a day, half an hour at a time. By this method, the insertion of a short drainage tube and application of sterilized Bier's cups, he had been able to cure most of the cases. He asked Dr. Lloyd if he freed the entire lung of adhesions and, if so, was there not danger of infecting the supra-empyemic part of the pleural cavity. He confessed to be afraid of that method.

Dr. Samuel Lloyd replied that he ruthlessly broke down all adhesions. These adhesions walled off certain sections. With the finger, or with scissors, or with a periosteotome, he ripped the adhesions until he had denuded the lung surface; then he allowed the patient to practically come from under the anesthetic and take a forcible inspiration. What he wished to attain was a full expansion of the lung and adhesions between the pulmonary and parietal pleura, in order to close the cavity.

Dr. W. S. Schley, in closing, said that the method was recommended for old chronic cases, with hard and small sinuses or cavities.

Specimen of Gall-Bladder and Concretions.—Dr. A. H. Goelet presented this specimen which was removed June 12. He found everything densely adherent to the gall-bladder, omentum and intestines all being covered by a dense exudate.

Radiograph of Fracture of the Humerus.—Dr. A. H. Goelet presented this radiograph. The patient was an habitual tippler, and was under the influence of liquor all the time. He came in July 21, and said that he had met with an accident on July 4. He was out boating and put out his arm to stop the boat. In doing so something gave way and he was precipitated to the bottom of the boat. The diagnosis was made of a downward dislocation of the shoulder. He tried to reduce the dislocation, but failed. He damaged the shoulder in his efforts at reduction. He made an appointment for the next day, intending to give an anesthetic, but the man got drunk again and was not seen until ten days later. He examined the part again and changed his diagnosis to fracture of the humerus. He made the mistake in his first diagnosis because he found a depression where he expected to find the head of the bone. Seventeen days after the fracture occurred the efforts at reducing a supposed dislocation did not break the bone, because the fragments were firmly united.

Specimen of Sarcoma of Shoulder.—Dr. Charles Goodman presented this specimen. It was a giant-cell sarcoma, and showed the sarcoma starting from the periosteum of the surgical neck, extending down the shaft, and infiltrating the muscles about the shoulder. Nothing short of operation could have offered the patient any hopes of relief. The specimen was removed from the patient presented early in the evening.

Acute Gangrenous Cholecystitis.—Dr John H. Erdmann presented this specimen.

An Ancient Medical Work.—According to the *Tidsschrift for Kemi og Farmaci*, the oldest medical document in the ancient Norse language is the *Icelandic Pharmacopœia*, published in the thirteenth century. It now forms part of a collection of antique manuscripts in the Royal Library of Copenhagen. The work consists of five octavo pages and was intended as a guide to the people in times of sickness and accident. Needless to say the methods of treatment were primitive in the extreme. The remedies were derived mostly from the vegetable kingdom, although a few were taken from the animal and mineral.—*The Physician and Surgeon.*

ON PERIANAL AND PERIRECTAL ABSCESS.

By CHARLES B. KELSEY, A.M., M.D.,

NEW YORK.

Abscesses around the rectum are caused exactly as pathology teaches they are caused elsewhere, by the invasion of the cellular tissue by bacteria causing suppuration. Why this part should be so much more frequently attacked by these pathogenic germs than other parts has always been a matter of interest, and every possible explanation has been given. These may all be generalized under the fact that this part is peculiarly subject to injuries and diseases which create a favorable point of attack for bacteria, by lessening the normal resistance to such invasion upon which health depends.

In this view piles, fissures, erosions, ulcerations, proctitis, blows, foreign bodies, severe constipation with its attendant straining, cold, wet, contusions, anything in fact, which departs from perfect normality is a predisposing cause of abscess.

The exciting cause is the entrance into the tissues through the door thus opened of any pus-producing organism—the *Bacillus coli communis,* the *Streptococcus,* the *Staphylococcus,* or the tubercle bacillus.

It may surprise some to know that of all these the tubercle bacillus is most frequently found, sometimes alone, sometimes associated with others; for in former times the mere mention of a tubercular abscess or resulting tubercular fistula was about synonymous with incurable wasting disease. That this is by no means the case, and in fact that these abscesses and their fistulæ are curable, as are those caused by other germs, we shall hope to show.

It is also known that although this bacillus usually is carried along the bowel in the ingesta until it finds a nest in the rectum, and that this accounts for the frequency of abscess and fistula in tubercular patients; on the other hand, the abscess may be the first and for a time the only deposit of the germ; and that a cure of the local condition may prevent more general and pulmonary deposits.

For the production of an abscess here it is not necessary, as Gosselin taught, that there should be a previous penetration of the anorectal mucosa and extravasation of the contents of the bowel into the cellular tissue such as would follow an injury by a foreign body or a destructive ulceration, for in fact such causation is rare. For the real explanation we must look to the very profuse lymphatic supply around the sphincters and to the fact that even the most trifling abrasion of the skin or mucosa may give an entrance to it. Under this head come the abscesses which follow from fissures, from pruritus, or from simple herpetic vesicles.

One other fact in pathology should always be borne in mind. A lesion of the mucosa of the rectum or anus may be the cause, by lymphatic involvement, of an abscess at a considerable distance, as in the ischiorectal fossa; and conversely, what is of the greatest clinical importance, a lesion of the bones of the pelvis, the prostate, Cowper's glands, or of the broad ligaments and pelvic cellular tissue in women, may show itself as an abscess in the anorectal region by direct extension through the lymphatics.

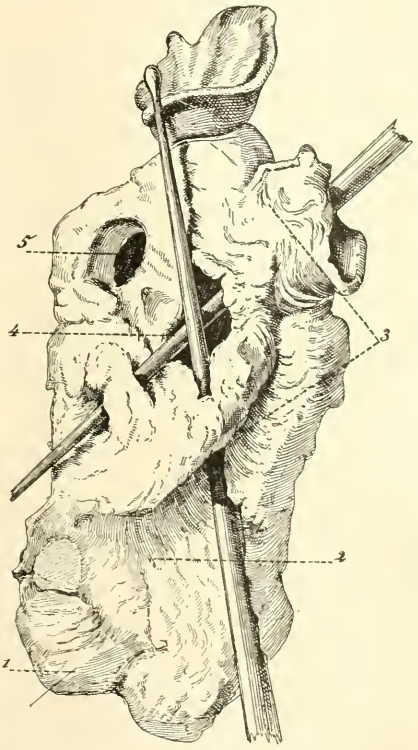

Fig. 1.—Pelvic abscess associated with stricture of the rectum. 1, anus; 2, rectum; 3, stricture laid open; 4, abscess in cellular tissue opening into rectum above and below stricture, as shown by probes; 5, abscess of ovary. From author's photograph.

Illustrating this same pathology, the following case has been one of great interest to me. The liability of stricture of the rectum to be complicated sooner or later by extensive pelvic abscess and resulting incurable fistula is known to all clinicians; but the course of such a case when left practically to nature has seldom been described.

Eleven years ago a young lady came under my care with a well-marked stricture of the rectum at

the usual level; and by stricture I do not mean any of the hypothetical muscular contractions now so popular and prolific with certain practitioners, but *real* stricture, which we all know without description. It had then existed for years, and the contraction from hypertrophic proctitis was such that

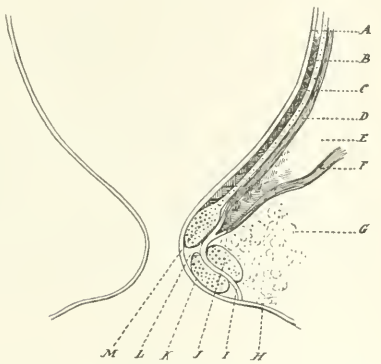

FIG. 2.—Diagram of lower rectum and anus. *A*, mucous membrane; *B*, submucosa; *C*, circular muscular layer; *D*, longitudinal muscular layer; *E*, superior pelvirectal space; *F*, levator ani; *G*, ischiorectal fossa; *H*, skin; *I*, tendinous insertion of longitudinal muscular fibers; *J*, deep portion of external sphincter; *K*, superficial portion of external sphincter; *L*, interval between external and internal sphincters; *M*, internal sphincter.

the finger could not be forced above it. The treatment began in the usual way by mild dilatation, which was both painful and useless, as it always is; and after explaining to her that eventually active surgical interference would be necessary practically all treatment was abandoned and the case left to its own course. I confess I wished to see what that course would be. For about ten years the condition remained almost unchanged. There was little if any increase in the constriction, the bowels moved astonishingly well considering the smallness of the canal, and the general health remained fair, though not up to normal. Then came the always-to-be-expected change, and an abscess and fistula formed on one side, the external orifice well out on the buttocks. From this time on the deterioration was rapid. For one year abscess followed abscess and each left its fistulous track; an opening finally formed between rectum and vagina below the stricture, and a huge abscess in the labium from suppuration of one of Bartholini's glands rendered her willing to submit to curative treatment. This, it is needless to say, consisted in the formation of a permanent artificial anus in the left groin. Three months after the operation she had gained twenty-five pounds; the rectovaginal opening had closed spontaneously, the other openings were closing one after another, and the artificial anus was causing no annoyance, the function of defecation going on normally once a day and attended by the natural premonition.

The case was to me very instructive from many points.

In the case shown in Fig. 1 the sequence of events was never quite clear, though it certainly comes under this class of direct formation of abscess by lymphatic extension from a remote focus; but whether that focus was within the rectum and the extension was to the cellular tissue of the broad ligaments, or *vice versa*, the reader may choose.

The patient was found by me to be in the following condition: A tight stricture of the rectum at the usual site; a fistula leading into the pelvis from the rectum below the point of greatest constriction; another from above the stricture leading in the same direction; a hard mass of old pelvic exudate filling the pelvis; and chronic intestinal obstruction. This was in the early days of my experience as a student of rectal conditions, before I had begun to advocate and practise colostomy; at the time when Senn said he did not believe any surgeon had ever practised the operation or any patient submitted to it who did not regret it; and I regret to say that after using all the futile means of avoiding such a result then known to surgery the woman died, under my care, of intestinal obstruction.

The cut, from a photograph of my own, shows the pathological conditions.

There was a firm, hard stricture of the rectum, which is divided in the illustration between the points marked by 3; 1 and 2 show the normal gut below the stricture, and 4 the normal gut above; 5 is the cavity of an abscess in the broad ligament, and 6 the cavity of another abscess in the ovary. The probes are passed from the fistulous openings in the rectum into the abscess in the pelvic cellular tissue, the one from above the stricture, the other from below.

In this case the focus of suppuration may have been in the pelvic cellular tissue and the stricture of the rectum merely due to the compression of exudate, or the primary condition may have been a chronic hypertrophic proctitis (stricture) and the pelvic suppuration and fistulæ a natural result. The patient could not make the point clear by her account of symptoms, and I was never able to decide.

There are several anatomical points to be borne in mind in considering these perirectal abscesses, as they have much to do in regulating the treatment as well as helping to a clear understanding of the pathology.

The first great distinction to be drawn is between deep and superficial phlegmons. Deep abscesses are arbitrarily described as those situated above the

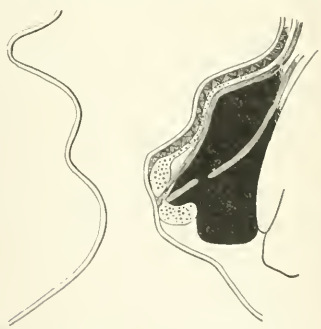

FIG. 3.—Abscess of pelvirectal space perforating levator, and extending into ischiorectal fossa.

levator ani muscle and the pelvic fascia which covers it. Superficial abscesses are those situated below this muscle, and often limited in their upward progress by it. The deep abscesses are often spoken of as abscesses of the superior pelvirectal space.

The superior pelvirectal space is bounded by the levator ani below and the peritoneum above. It is filled with connective tissue varying in amount in different subjects, and this tissue is directly con-

tinuous with that of the broad ligaments in women, and with that surrounding the prostate and neck of the bladder in men. It receives its vascular supply from the hypogastrics. Abscesses in this tissue may therefore be caused by a focus in the rectum, in the prostate or neck of the bladder, or in the uterus and adnexa, and they may assume vast proportions, pointing finally almost anywhere in or near the pelvis. The rectum, bladder or urethra, and the vagina furnish the most frequent outlets, though they may come to the surface over the trochanter or far down the thigh.

An abscess originating above the levator may perforate that barrier and involve the ischiorectal fossa, and *vice versa*. Such a perforation is shown in the cut.

These abscesses are not to be confounded with those in the cellular tissue behind the rectum in the hollow of the sacrum, the retrorectal space shown in Fig. 4. This tissue constitutes the meso rectum, and is supplied by the inferior mesenteric, and phlegmon here is generally due to a focus in the rectum itself or to disease of adjacent bone. Here the pus is in the median line and the cutaneous opening is also apt to be in the median line behind and not far from the anus.

Bearing these anatomical points in mind, we may now discuss each form of abscess in detail, beginning with the deeper and more serious varieties.

Diffuse Pelvic Cellulitis.—In this form of disease we have a diffuse inflammation of all the subperitoneal connective tissue of the pelvis. It is not as common as in former days, thanks to antiseptic methods; but the most careful precautions will not always prevent it, and it is still the most frequent cause of death after extensive operations upon the rectum, such as the removal of cancerous or non-malignant strictures, and I have seen it follow a simple operation for fistula. The only fatal result of excision of cancer in my own practice in the last three years was caused by this; and when I recognized my old enemy and told the nurses that no treatment made much difference, as the patient would certainly die, they were greatly surprised, for to them the man had only had a chill and a sharp rise in temperature, while he seemed to be progressing favorably.

I may say in passing that I have also once seen this unfortunate condition caused by the injection treatment of a pile, but not in my own practice. The substance injected was krameria, but that has never been a matter of any importance to my mind, though the lack of any attempt at asepsis in the operation may have been directly responsible. This infection always shows itself by a chill and high temperature (105° to 106°), and the chills are repeated at intervals. There is acute purulent edema infiltrating all the cellular tissue around the rectum and in the pelvis, and extending rapidly upwards until it may show itself on the abdominal wall, and sometimes extend as high as the axilla. There is also serous effusion into the peritoneum, and there may be acute fatty degeneration of the liver or kidneys. Unless the disease runs a longer course than usual, there will at no time be any distinct collection of pus, and free incisions into the infiltrated area will only cause a slight discharge of serum.

Usually the disease shows itself within the first three days after an operation, by a chill, pain around the site of operation, and a marked change in the appearance of the wound itself, which becomes grayish and begins to secrete fetid serum. There is often diarrhea, which is nature's attempt at eliminating the poison, and there may be pleurisy or bronchopneumonia, and metastatic abscesses. Death generally closes the history in a very few days; but though I have never seen a recovery I have known the case to drag on for a number of weeks, and have seen numerous fistulæ form, generally deep in the pelvis and opening anywhere above or below it. Twice I have seen vesicointestinal fistula result, and once I did colostomy for that condition, simply to relieve pain, though without hope of accomplishing more.

It is a dread disease, and a chill after any operation on the rectum, no matter how trivial, is a source of anxiety always until its cause is evident.

Gangrenous Periproctitis.—Another form of inflammation which is usually fatal in a short time is a diffuse gangrene of the perirectal tissues. Although I have unfortunately seen many cases of the disease last described, I have never but twice encountered this, and it is very rare. In the last case seen only a few weeks ago the patient was suffering from cancer of the rectum and chronic nephritis, which

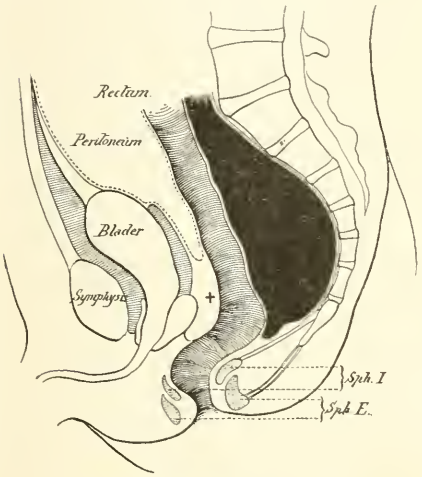

Fig. 4.—Retrorectal space, injected with wax. (Quénu.)

may have been of importance as showing lowered vitality and cachexia. His immediate reason for consulting me, however, was that he had been suffering for two days with severe pain near the anus, and at my first visit an abscess was found in one ischiorectal fossa. There was absolutely nothing to distinguish this from any other similar abscess. It was distinctly limited in area to the size of an egg, red, very painful, and hard; and I promised to see him the next day and operate under laughing gas. Imagine my surprise when in less than twenty-four hours I found the whole fossa and perineum black with gangrene, which was freely incised without causing the least sensation. There was also a distended bladder and retention. On the following day it was evident the process had extended into the pelvis and there was an infiltration above the symphysis. Death came the same night about four days from the onset.

But little is really known of this form of disease, and not much has been added to Jordan's first description in 1879. Sporadic cases have been reported by Gerster and myself in this country, and

it is said to be more common in the hot climates, Peru, Brazil, and Africa, but its etiology is unknown. The case of Quénu, given in full in his book, in which the gangrene extended to the axilla, shows that it is not necessarily fatal, however, as the man, after months of treatment, finally made a good recovery.

It is evidently due to some septic poison of intense virulence, but the exact character of the germ has not as yet been discovered.

Both these forms of phlegmon are marked by the same characteristic, the failure on the part of nature to set up any limiting barrier to the extension of the disease. There is seldom any distinct abscess cavity with its wall. Incisions allow only the escape of fetid serosanguinolent and purulent effusion from between the muscular places and the subcutaneous connective tissue, but they seldom evacuate healthy pus or limit the extension of the inflammation.

Passing now from these diffuse and generally fatal processes to the more ordinary and circumscribed forms, we may consider in detail some of the different causes and varieties.

Disease of the Urinary Organs.—Urinary infiltration from rupture of the urethra or bladder or from rough catheterization is not a very rare cause of severe pelvic suppuration, as may be readily understood by a glance at the anatomy. The sloughing frequently causes perforation into the rectum, and the resulting cutaneous openings, which may be numerous and a long way from the anus, often discharge both urine and fecal matter.

Prostatitis.—Acute inflammation of the prostate or of Cowper's glands, generally due to gonorrhea, is one of the most frequent of all causes of deep pelvic abscess. These tend in the great majority of cases to open spontaneously into the rectum; sometimes, however, they work their way into the urethra or bladder, and opening into both canals they are the most frequent cause of retrourethral fistula.

Necrosis of Pelvic Bones.—The abscesses due to this cause may be found in any part of the pelvis, or even the loin or thigh. They involve the rectum only secondarily, but their openings may exactly resemble those of deep and complicated rectal fistulæ, and even the probe will often fail to detect their real significance.

These abscesses are much more apt to be retrorectal than pelvirectal. The pus will usually be found in the median line behind, and the cutaneous opening, when it is present, also between the anus and the tip of the coccyx.

Disease of the Female Pelvic Organs.—Of this cause of perirectal abscess only a few words need be said. An infectious process starting in the endometrium traverses the tube, attacks its peritoneal investment, extends to the cellular tissue, and, depending upon the degree of infection, leaves only slight traces and subsides spontaneously or results in pyosalpinx and abscess of the superior pelvirectal space.

The abscess, once formed, differs in no essential respect from one in the same location due to an infection from the rectum, into which it not infrequently opens, with the result of establishing a permanent fistula high up in the bowel.

Abscesses Due to Stricture and Cancer of the Rectum.—The tendency to the formation of abscess in both these forms of disease, though well recognized clinically, is not easily explained. Cases of both forms of disease have been given above. In nonmalignant stricture and, in fact, in cancerous disease the point of origin may easily be a perforation of the rectal wall by ulceration and an extravasation of intestinal contents into the cellular tissue. In cases in which no such point of origin can be discovered we are forced to fall back upon a general loss of the power of resistance due to cachexia, and a slighter imperceptible lesion of the mucosa opening up the very profuse lymphatic chain around the bowel.

Superficial Abscess.—Referring to the arbitrary anatomical boundary already marked out which is formed by the pelvic fascia and the levator muscle, we come now to the superficial forms of disease, or those below that line. These may result merely in small subcutaneous tracks, or they may extend to the entire depth of one or both ischiorectal fossæ, but the distinction between them and those of the superior pelvirectal space is both practical and useful.

Abscess of the Ischiorectal Fossa.—These occupy an intermediate place both in location and gravity between the deep phlegmons already described and the superficial ones yet to be mentioned. They may be confined to one or both fossæ, as shown in

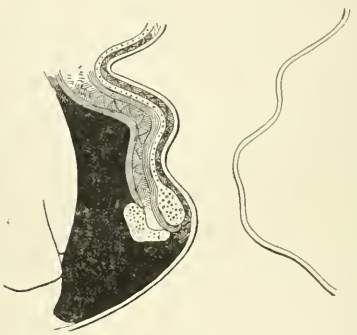

FIG. 5.—Abscess of ischiorectal fossa.

Fig. 5, or they may result from a focus of infection in the pelvirectal space, the pus from which has perforated the pelvic fascia and the levator on its way to the surface (Fig. 3).

This course may also be reversed and an abscess of the fossa resulting from a focus at the mucosa may extend upward and involve the pelvic connective tissue.

These abscesses are not very common, by no means as common as the myriads of more superficial ones which either break and heal spontaneously or are punctured by the family physician; and they are attended by a good deal of pain, fever, and general disturbance. These symptoms may be present for days before there is any superficial hardness or redness to attract attention, and during this stage the diagnosis is only to be made by rectal examination, preferably bimanual. I have known a man to die of unsuspected retention of urine during this stage; and the condition is not without danger to life from sepsis.

When once the inflammation has reached the surface the hard, brawny, painful swelling extending far out upon the buttocks can be mistaken for nothing else.

Left to their own course these abscesses usually burrow extensively, upwards into the superior pelvirectal space, downwards forming horseshoe tracks in front and behind the anus, and laterally. They

may evacuate themselves into the rectum, upon the skin, in fact anywhere, and it is seldom they are limited to one opening. Even when free incisions have been made the extension may go on, as in a case of my own where the patient had been operated upon and had convalesced sufficiently to leave

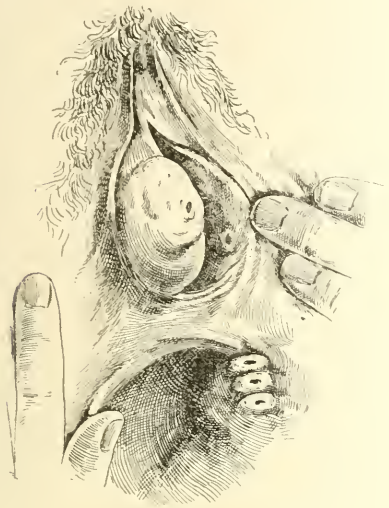

Fig. 6.—Rectolabial fistulæ. Author's photograph.

the hospital and come to my office. There was then, weeks after the incision, a chill, an involvement of the cellular tissues above the levator, and an opening high up in the rectum, which was never cured.

Abscess in Bartholin's Glands.—Inflammation of the glands or ducts of Bartholin is a not infrequent cause of a severe form of abscess which requires more than ordinary skill in its operative treatment to avoid serious damage to the parts. In the case shown in Fig 6 there were three distinct abscesses, one arising in each gland, and one near the anus, unconnected with each other, and only one of them communicating with the gut. Although generally tending to open upon the surface, they may extend deeply into the ischiorectal fossa and open well above the sphincters.

Submuco-Cutaneous Abscesses.—These, by far the most frequent, may be divided into several varieties, according to their location and pathology.

There is, first, the subcutaneous and submucous form, Fig. 7, in which although the pus may be entirely subcutaneous or entirely submucous, it generally extends to both localities.

These "marginal" abscesses, as they are often characterized, are due to infection from the anal canal. When left to their own course they open sometimes on the skin, sometimes on the mucosa just within the sphincter, often at both places; but seldom far above the sphincters. They are marked by severe pain and often some general disturbance. The pain is throbbing in character, defecation is attended by great suffering, the skin is red and swollen, the patient has fever, and takes to his couch to avoid pressure in sitting; and this history lasts till cut short by the surgeon or by spontaneous evacuation.

One peculiarity of these abscesses is their liability to an extension upwards within the wall of the gut, always between the mucosa and the muscularis. This has been described under a distinct name as the *intramural* abscess. It is this upward extension which gives rise to the ascending track, the cause of so much bad and ineffectual surgery in the treatment of fistulæ with internal opening low down, and a blind track running upwards from it under the mucosa.

Follicular Abscess.—This is a variety of subcutaneous abscess originating in the sebaceous follicles. Several follicles may be involved and there may be some little burrowing under the skin, but the disease is trivial.

Thrombotic Abscess is due to the suppuration of an extravasated blood clot at the margin of the anus, which is known as the thrombotic pile. Both of these last forms are attended by more or less pain, but seldom any constitutional disturbance. They break on the cutaneous surface or are punctured; there is seldom any tendency to spread, and they usually heal spontaneously without the formation of fistula.

Treatment.—From the descriptions already given of the extent and location of these phlegmons, it is evident that their treatment covers a wide range of surgery and some of it major surgery. With the deep pelvic abscesses, those of the broad ligaments, and the superior pelvirectal space, in women, laparotomy and removal of the affected organs with drainage through Douglas' pouch is the only cure. Where these collections of pus have opened into the rectum we all know the serious nature of this complication, otherwise the results are good.

The general rule in the treatment of all abscesses of this part is free and early incision. When once

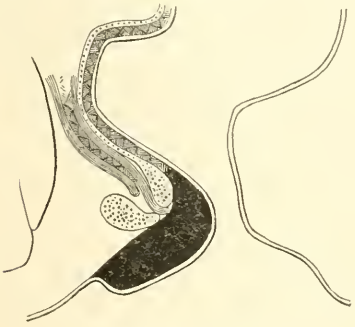

Fig. 7.—Submuco-cutaneous abscess.

the diagnosis of *commencing* abscess has been made incision should follow immediately and as a matter of course. There should be no delay in the hope of resolution and no waiting for fluctuation; the idea is to prevent the burrowing and the production of the fistulæ which constitute the greatest dangers.

To accomplish this most certainly the incision should be large, so that all sinuses and pockets may be opened up with knife or finger and free escape of all contents provided for. The incision shown in the cut has great advantages, the dotted line indicating the extent of the induration.

The long arm of the T should be as nearly parallel with the course of the external sphincter as possible. Slight punctures, which allow only the escape of a little pus, do not accomplish enough to pay for the pain of making them. The opening of any abscess here, except the little cutaneous follicular and

thrombotic ones, is a surgical procedure of no small importance and often of considerable magnitude, and it should be done under general anesthesia, so that it can be done properly and efficiently.

Another cardinal rule is that since abscesses are not actual fistulæ, but only the possible cause of them, they should be treated as abscesses and not as fistulæ and they should *not* be opened into the rectum. It is true that in spite of cutaneous incision many will subsequently perforate the bowel and form complete fistulæ, and thus make division of the wall of the gut and the sphincters a necessity for cure; still this does not constitute a reason for the surgeon doing the same thing with his knife. Often when an ischiorectal abscess has been freely incised on the skin and the finger is introduced to break down sloughing pockets, it will be found that the cavity has approached very near the rectal wall and only a little barrier intervenes between the two cavities. And it may seem as though it were as well to push through this barrier and divide the entire rectum and thus make the fistula and cure it at one sitting. This method of treatment has been advocated by good surgeons, but is not generally accepted, and to my mind is absolutely bad, simply

Fig. 8. Incision for large abscess.

because with free cutaneous opening and proper dressing many abscesses of the deeper variety, which have approached very near the bowels, will close as they do in other parts; and when this can be brought about all injury to the sphincters and all interference with function is avoided. My own rule, therefore, is to operate on abscesses as abscesses, and if fistulæ subsequently form to operate upon them in the usual way.

To make a more definite application of these general principles:

In abscesses of the superior pelvirectal space much good surgery may be shown in securing free evacuation without cutting into the bowel. If the pus is in the anterior portion of the perineum a curved incision in front of the anus will generally be efficient. More often the incision both for these and for the retrorectal variety will need to be posterior and should begin with a free division of the sphincters in the posterior median line. Through this by blunt dissection a way can be made between the levator and the rectum, and the pus cavity on either or both sides thoroughly drained.

Periprostatic abscesses should be opened by the incision for median lithotomy.

Unilateral ischiorectal abscesses should be opened when they are confined to one fossa only by the T incision. When they have spread to both fossæ, the first incision should be through the sphincters posteriorly, and from this free cutaneous incisions forming a V should be made into each fossa.

In subcutaneous or submucous abscesses the incision should be in line with the radiating folds of skin and should lay open the entire cavity whether it be chiefly on the skin, on the mucosa, or equally on both. In this way only will fistula be avoided.

Follicular and thrombotic abscesses do not often form fistula, but they should be incised freely for their entire extent.

THE SURGICAL TREATMENT OF ULCER OF THE STOMACH.*

By OTTO KILIANI, M.D.,

NEW YORK.

Surgeon to the German Hospital.

Until very recently the impression prevailed that ulcers of the stomach warranted or necessitated surgical interference only when they had reached the "accident stage," so to speak, namely, in cases of acute perforation or for uncontrollable hemorrhage. This conception is utterly wrong, in two ways; there are, first, a number of conditions which allow of and necessitate surgical treatment, where the patients are not *in extremis;* and, secondly, the indication for operation in apparently uncontrollable hemorrhage is exceedingly doubtful.

There can, of course, be no question that ulcer of the stomach is a disease which belongs, in most cases, and at most times, entirely in the *rayon* of the medical treatment.

In figuring out the mortality of ulcers, if not operated upon, different authors have reached very different conclusions. Welch says that 3 to 5 per cent. die alone from hemorrhage; Gerhardt says as many die of perforation; Hauser finds that 5 to 6 per cent. become carcinomatous, while Leube gives a 2.4 per cent. mortality of the general death-rate.

Debove and Raymond claim that only 50 per cent. of the ulcers really heal. Mikulicz finds that the real mortality of non-operated ulcers varies between 25 and 39 per cent. This statistic of his includes all the possibilities of fatal ending in ulcers, as hemorrhage or perforation, inanition, the acute development or recurrence of phthisis, and the transition from ulcer into carcinoma.

I want to deal first with those cases which apparently need operation most, namely, those with perforation or hemorrhage. The acute free perforation of an ulcer into the peritoneal cavity, without any formation of adhesions, is extremely rare. The perforation is usually slow, and presents the clinical and anatomical picture of an inflammatory tumor, sometimes of quite large size, so that a differential diagnosis between malignant tumor and perforation would be extremely difficult. Therefore, operation for *indicatio vitalis* hardly ever becomes necessary. Finally, a larger or smaller abscess will form which, in the course of time, may lead to operation.

The question of operation for hemorrhage is an open one, for while it sounds only natural and rational to operate in a case where there is very severe hemorrhage from an ulcer, operation becomes really necessary very rarely, because, even in extreme cases where the hemorrhage is so severe that

*Read before the Medical Association of the Greater City of New York at its stated meeting, October 21, 1907.

it seems as though it must unavoidably lead to death, the bleeding stops just before the crucial point, as soon as the patient passes into deep collapse. And, just in those cases where medication fails, and operation would become necessary and desirable, the surgical treatment fails, too, because the patients cannot stand the shock of the operation, and because quite frequently it is impossible to find the bleeding vessel, or get at it.

The other indications for the operative treatment of ulcer are uncontrollable, violent pain, inflammations with or without pus-forming adhesions, the formation of scar tissue with symptoms of stenosis, and a suspicion of malignant degeneration. The best observers in medical and surgical clinics have finally reached a conclusion that a patient with ulcer, who has been subjected to one or several systematic courses of rational medical treatment, with very little if any improvement, or who suffers from recurrences again and again, ought to be operated upon.

Before entering upon the question of results, prognosis, mortality, and so on, of the operation, I want to mention that the operation κατ'ἐξοχήν is *gastroenterostomy*. Although it does not come within my domain to speak of different methods of operation, and their intended effects, I have to explain briefly why gastroenterostomy is the operation for ulcer. All other forms of operation, as the pyloroplastic, excision, resection, and so on, endeavor to treat the ulcer *per se*, by removing it or otherwise. On the other hand, gastroenterostomy tries to form anatomical conditions which partly overcome mechanical difficulties, partly set the stomach at rest, and give the ulcer a chance to heal. The real *circulus vitiosus* of the ulcer is hyperacidity, dilatation of the stomach, motor insufficiency, pyloric stenosis or spasm, all working into each other's hands, and thus producing the unfortunate clinical picture of violent pain, vomiting, inability to empty the stomach of its contents, difficulty in feeding, inanition, and so on. All these conditions are changed immediately, or, at least, after a very short time, if gastroenterostomy is performed, for this permits of the propulsion of the contents of the stomach into the gut and prevents stagnation, fermentation, and stretching of the walls of the stomach by dilatation and spasm. Vomiting becomes unnecessary, and therefore ceases.

Recent operative experimental work on animals seems to have shown that if a gastroenterostomy is done on a normal stomach, the contents never enter the new way—although it is shorter—but always go through the pylorus. If this would hold true in our operations upon patients who need the operation, that is, in the case of a diseased stomach, no ulcer would be benefited by gastroenterostomy. But experience shows that the great majority of cases of ulcer of the stomach are benefited most strikingly by the above-named operation. Contrariwise, the reason why a number of ulcers are not benefited by the operation is explained by those above-named experiments.

To come now to the prognosis of gastroenterostomy, I have to mention the principal danger, which is *circulus vitiosus* and the peptic post-operative jejunal ulcer. How utterly without any value personal statistics are is shown by the fact that in all my gastroenterostomies (not only for ulcer), I have never seen a single case of the vicious circle. While it cannot be denied that the constant improvement of our methods and technique in the gastroenterostomy operations strives to avoid this calamity, I am convinced that it is greatly luck if a surgeon does not get it in any of his cases.

With regard to the death-rate of gastroenterostomy for ulcer, without going into details, it is safe to assume that the average rate of different operators within the last three years is not more than 3.5 per cent. I, personally, have not lost any patients, but my number is so small that it is of very little account. However, if we consider the fact that only the very worst cases of ulcer come to operation, the mortality of this type of ulcers, if not operated upon, is at least 30 per cent.

It is decidedly more difficult to get at accurate statistics as to the therapeutic result of gastroenterostomy. If the *circulus vitiosus* is avoidable, nearly all cases of ulcer thus operated upon are greatly benefited—usually at once, sometimes only after a while. It is a question if this satisfactory state continues in all cases permanently. It seems that in a number of cases the opening contracts so much that it becomes too small to answer the purpose fully. I personally had to reoperate in one case for this very reason.

This short paper would not be complete if I would not mention briefly two other forms of operation which have come into vogue, so to speak. One of them is resection of the stomach, which a few surgeons have taken up, induced by the marked recent decrease in the death-rate of this serious operation. But to me it seems about as rational to resect the stomach in all cases of ulcer as to amputate the leg for each ulcus cruris.

One of our leaders in surgery, Eiselsberg, advocates jejunostomy as the operation of selection. We all know what a fistula-life, with artificial feeding, means, a condition which I would try to force upon a patient only in especially selected cases. Aside from the great discomfort to the patients connected with this operation, it would seem only rational to set the stomach entirely at rest and at the same time feed the patient properly. But, unfortunately, the death-rate of this operation, in spite of the excellent technique of its advocate, is so appallingly high that the time has, in my opinion, not yet come to accept it.

It may not be entirely superfluous to mention that the diagnosis of ulcer of the stomach is by no means so easy, and in a number of cases is rather uncertain. In the differential diagnosis we have to consider tabes, diseases of the spine, as carcinoma and spondylitis, diseases of the gall-bladder, of the pancreas, aneurysms, epigastric hernia, floating kidney, neurosis, and chronic poisoning, as from lead.

In conclusion, I should like to say that we have seen that, in otherwise intractable cases of ulcer, gastroenterostomy is a safe operation, with generally excellent therapeutic results. It rests with the practitioner to find the indication for such interference, and to educate his clientèle to expect it. Practically the entire field of medicine belongs to-day, in certain phases, to the *Grenzgebiete* of medicine and surgery, and only the constant cooperation of the internist with the surgeon can produce those best results for which we are all striving.

116 East Fifty-seventh Street

Professor Osler Still Pessimistic.—In a recent address to the students of St. Mary's Hospital, Professor Osler is reported as saying: "Be skeptical as to the pharmacopœia as a whole. He is the best doctor who knows the worthlessness of most medicines. Study your fellow-man and fellow-woman and learn to manage them. Remember above all things that you are in this profession as a calling, not as a business. Once get down to a purely business level and your influence is gone and the light of your life goes out."

THE NOSE IN ITS RELATION TO EPILEPSY.*

By W. SOHIER BRYANT, A.M., M.D.

NEW YORK.

CHANCE sent to me a year ago a patient suffering with epilepsy who had marked obstruction and pathological changes in the nose. This accident set me at working out what connection there might be between the nose and epileptic seizures.

I was fortunate enough to have access to a number of segregated cases of epileptic insanity at the Manhattan State Hospital. This group consisted of about sixty women. I made a careful rhinological examination, including the accessory sinuses, in forty-eight cases of this group. All were found to have extensive abnormalities of the nares of nearly every obstructive variety, and many had suppuration and sinusitis. The patients had been subjected to a great variety of treatment, both surgical and medical, in various institutions, extending over many years. Eighteen were selected from the number examined, for observation and treatment of the nasal defects. The cases whose mental deterioration had not rendered them unresponsive, and who had frequent epileptic seizures were chosen. The course of treatment was wholly operative, directed to the prevention of contact of intranasal structures. Five only of the eighteen cases were observed; two of the eighteen passed from observation. The remaining eleven were operated on from two to eight times each.

The rhinological work is not yet completed in any one case, but there is marked nasal improvement in all the patients operated upon thus far. The epileptic results are as yet very meager, but they show a slight decrease in the number of seizures, together with a slight improvement in the general mental and physical condition.

Case No.	Age	Years of Epileptic Seizures	No. of Months Observed Before Commencement of Treatment	No. of Months Observed After Commencement of Treatment	Average Monthly Seizures Before Treatment	Average Monthly Seizures After Treatment
1	27	12	11	2	9	9
2	49	3+	10	3	4	3
3	22	12	11	2	25	22
4	33	6+	11	2	30	26
5	22	3+	9	4	52	17
6	38	10	3	8	38	10
7	36	28	5	1	14	10
8	24	5+	8	2	19	15
9	47	28	7	4	18	9
10	20	5+	9	3	25	17
11	36	5+	8	5	11	7

I have observed at various times that blows upon the head and severe injuries to the upper spinal cord in man and animals often produce epileptiform convulsions. Also that a nasal cause of reflex epilepsy rarely exists in animals, among whom nasal obstruction and its consequences is practically unknown except in serious constitutional disease or where there is parasitic nasal disease.

During the year I made the following conclusions, namely, that the number of seizures increased with increased congestion and obstruction of the nose, and that they decreased when these symptoms diminished. I observed that colds in the head (nasal infection), lack of vasomotor tone, and diminution of out door exercise were often associated with an increased number of epileptic convulsions. I also noticed that the fits did not occur when the Schneiderian membrane was anemic and hard, but that when they occurred the membrane was always congested and more or less distended. The engorged condition of the mucosa was noticeable before the attacks as well as after them. I further noted that in some patients painful manipulation of the nose at once produced seizures, which would recur in rapid succession if the irritation was repeated (three cases). Cotton pledgets or crusts left in the nose increased the frequency of the attacks; nasal bleeding diminished the number of attacks. In a general way, whatever irritated the Schneiderian mucosa and made it congested and tumid was provocative of epileptic seizures; whatever tended to an anemia and contraction of this membrane tended to decrease the frequency of the seizures. The statistics of the Manhattan State Hospital show that epileptic seizures are slightly more frequent during the colder months.

From my observations I concluded that the stimulus for an epileptic seizure was apt to start in the nose. It seemed to me, too, that the epileptic seizures were reflex in character, and that the epileptic reflex was the exaggeration of a normal nerve reaction under certain extreme stimulations.

Literature gives us only fifty-two cases of epilepsy definitely associated with nasal defects or disease. The treatment of these cases was not sufficiently long to justify more than the assertion that it had been a deterrent to attacks; very few have been observed long enough to justify the name of cure. If we look over the literature of the etiology of epilepsy, we find that it is most common in the colder, densely populated countries, and least so in the warm, sparsely settled ones. I also gathered from the literature on epilepsy that overeating, indigestion, menstruation, and mental excitement were exciting causes of increased frequency of seizures, and that these conditions have an important bearing on the circulatory condition of the nose.

A perusal of the literature showed that a small proportion of the reflex epilepsies had their peripheral origin in various parts of the body, while most of the cases noted were due to reflex irritation in or about the cranium, chiefly from the nose through the fifth cranial nerve, and that reflex epilepsies occurred occasionally in animals from various causes, among them nasal disease. In experimental epileptic seizures of cortical origin, the resultant nervous activity appeared to spread over a much larger part of the central nervous system than the area of direct stimulation, which suggested something of a reflex nature.

Severe injuries of the head and spinal cord have caused epilepsies in previously healthy individuals. Literature shows that animals may succumb to epilepsy when the stimulus is excessive; that they may be rendered more susceptible by weakening their resistance through previous experiment, and that they become unprotected against spontaneous epilepsy by experimental nervous lesions. The analogy holds good in man; a normal man becomes epileptic under severe stimulation, and a previous pathological condition, predisposition, or lack of protection is all that is necessary for slight exciting stimuli to produce epileptic seizures. Our conclusion from the literature is that the chief cause of reflex epilepsy in man is nasal irritation; that epilepsies due to the irritation of the cortex, the lower centers, or the cord, are, to a considerable extent, all reflex; that there is no essential difference between reflex epilepsy and essential epilepsy, or idiopathic epilepsy, except that the exciting cause is not obvious in the latter; and, finally, that epileptic seizures represent the exaggerated normal nerve reaction to certain stimuli.

*Read before the American Academy of Ophthalmology and Oto Laryngology, Louisville, Ky., September, 1907.

The conclusions derived from my own observation and from the perusal of the literature are identical. A peculiar fact appears on consideration of the literature and after observation of the selected cases, namely, that epileptic seizures and the nasal condition fluctuate in unison. It appears, both from my own experience and from the clinical and experimental literature, that peripheral irritation of the fifth nerve—especially that portion supplying the nasal membrane—is more frequently the cause of epilepsy than the peripheral irritation of other nerves.

The nasal condition found in this series of cases of epileptic insanity—all long-standing cases of epilepsy, from five years to thirty years, all of whom had exhausted the known treatment of epilepsy—strengthens me in the supposition that in these cases the nasal cause of peripheral epileptic irritation was the most resistant exciting cause and at the same time the constantly acting one.

Reflex disturbances of the higher centers from irritation of the nasal branches of the fifth nerve are anamnesia, aprosexia, vertigo, migraine, hemicrania, and scotoma scintillans, not to mention epilepsy, and of the lower centers, chorea, coughing, sneezing, temporary arrest of the heart beat, asthma, and sexual reflexes. The great disturbances caused by comparatively slight nasal stimuli are worthy of note in this connection. The reason the fifth nerve, which supplies the Schneiderian membrane, is the most frequent conveyor of peripheral stimuli causing considerable central disturbances including epilepsy, is, in the first place, because it is a cranial nerve of large size, with very extensive peripheral and reflex connections—practically the only sensory nerve supplying a region of the body which is, as a rule, pathological in civilized man; secondly, because the central connections of the fifth nerve bring it into peculiarly close relation with the higher and lower centers; and, thirdly, because it is the sensory nerve of a large part of the brain and meninges.

The weight of evidence favors the hypothesis that epilepsy is a reflex nervous symptom. It can be compared to vertigo, nausea, or vomiting, which are caused by overstimulation of the peripheral space organs. These are normal nerve reactions to overstimulation of the peripheral space organ or of its central connection, but become pathological when excited by insufficient or trivial causes.

We explain the large number of cases having origin in intranasal irritation by the scientific hypothesis that, given a predisposition to epilepsy, the exciting peripheral irritation will probably first appear in the nose, not only because that organ is undergoing a retrograde change in civilized man—a condition rarely found in animals, but which, when it does occur, is fraught with the most dire consequences—but also because sensory stimulation of this organ has special effect on the central nervous system.

Epilepsy has always been a very resistant disease, or rather symptom, because its predisposing cause can rarely be removed, and its exciting cause, though occasionally found, is still less frequently removable. It has been overlooked where it most usually occurs and where it is most amenable to treatment, namely, in the nose, and here it has been most reprehensibly neglected.

If our view of epilepsy is correct, that it is a reflex symptom of central overstimulation, and that the cause rendering the patient abnormally susceptible is beyond reach, permanent cure may not follow the removal of the peripheral exciting irritant, because a disturbance in some other part may later again produce the exciting irritation.

I have essayed to treat this series of cases intranasally. I have obtained very slow results, which, however, have not been entirely discouraging, since slight improvement has followed my efforts, and since I have obtained additional proof of a peripheral cause of the seizures.

Conclusions.—1. Epilepsy is a normal symptom consequent on overstimulation of the higher centers of the cord and brain.

2. This overstimulation is largely reflex in its characteristics.

3. The normal nerve reaction may become pathological, even when it is irritated by a comparatively insignificant peripheral stimulation.

4. Epileptic seizures are more often due to reflexes from the Schneiderian membrane through the fifth nerve than to other causes.

5. Appropriate treatment of the intranasal defects may be expected to lessen greatly the number of attacks, and in favorable cases to remove wholly the peripheral irritating cause of the epilepsy, which will allow cessation of the seizures.

6. In the epileptic neurosis, predisposition or weakened resistance of the central nervous system is due to other causes than the slight exciting peripheral irritations which have previously lessened the self-protective power of the higher nerve centers.

Reaction of Central Nervous Substance to Tetanus Toxin.—M. Almagia says that lecithin and cholesterin have the same physical properties toward tetanus toxin as the central nervous substance as a whole. They may be compared to receptors that in the nervous substance fix the tetanus toxins. The author considers these factors of immunity against the toxin for the organism, while antagonistic to the toxin when they are in the circulation, because they seize upon the toxins before they attack the sensitive cells. He experimented as to whether the injection of cholesterin would prevent tetanic intoxication in animals. From many experiments on guinea pigs he concluded that this procedure was valuable, since animals previously injected with cholesterin were not affected by tetanus toxin. He desires that experiments should be made in man.—*La Riforma Medica*

THE INDICATIONS FOR ERGOT ASIDE FROM ITS OBSTETRICAL USES.

By ALFRED T. LIVINGSTON, M.D.,
JAMESTOWN, N. Y.

The general deductions that appear to be warranted, from my personal experience with the therapeutic application of ergot, are

First.—That its direct and specific effect is the contraction of unstriated muscular fiber, or other involuntary contractile tissue.*

Second.—That it does not markedly contract that which is normal in tone; but

Third.—That it is emphatic in its contraction of that which is lacking in tone, and

Fourth.—That it is prompt and striking in such effect, in proportion to the recency of occurrence of the atonic state in such fiber.

Fifth.—That its widest field of usefulness is its application to the muscular coat, or other contractile tissue, of weak and relaxed blood-vessels.

Sixth.—That it there tends to equalize vascular tension; to distribute the blood equably throughout the body; to restore or to promote functional activity of glands and organs generally, and vasomotor centers particularly; to promote sleep; to relieve pain, nervousness, and spasm; to prevent or modify the effects of autotoxins and bacteria; to promote assimilation, absorption of exudates, and elimination of waste; to relieve nausea; to prevent the ill and dangerous effects of anesthesia; to promote the healing of wounds; to prevent or modify inflammation; to arrest capillary hemorrhage; to relieve narcotic poisoning, and to make the work of the heart more easy, and so to prevent its exhaustion or paralysis.

Seventh.—That it is useful to restore tone in the unstriped fiber of the walls of the hollow viscera, stomach, bowels, bladder, uterus, etc.

Eighth.—That the prevalent, popular notion, existing even in the medical profession, that it is a dangerous drug, and likely to produce ergotism, is unfounded as regards the modern pharmacopial preparations, at least as regards such as I have used during the past thirty-four years.

Ninth.—That its local action upon the stomach is often offensive, especially if full doses are given; that its absorption from the stomach is uncertain, both as to promptness and degree, and, therefore,

Tenth.—That its administration should be limited as much as possible to hypodermic injection, which assures immediate effect, admits of exact regulation of dose, and avoids nausea and other ill effects of its administration per os.

The foregoing deductions are wholly founded upon my clinical experience, as I have made no experiments upon animals; but, while it may not be as exact in explaining the rationale of action, clinical experience is the only reliable guide as to the applicability of any therapy to disease.

The indications for ergot, aside from its obstetrical uses, are many, and in the partial relation of them which I shall make, some may appear contradictory to others, but a careful analysis of the ultimate conditions in any individual indication stated will demonstrate the existence of unstriped muscular fiber, or other involuntary contractile tissue, that is lacking in tone; and upon that single thread hang all the manifold indications for ergot, and upon the power of that drug to contract (stimulate and tone) such atonic fiber depends the myriad utilities of ergot in therapeutics.

In detailing indications for ergot I will not attempt to include every variety of condition to which I have applied it, nor can I, in the limit of this paper, enter into the rationale of its application to each of the conditions that will be mentioned; but I shall endeavor to make sufficiently clear the principles involved in the use of ergot that not only may what is left unsaid be implied, but the reader may be prepared to recognize, in his daily practice, many conditions not here mentioned that will be to him indications for the use of this drug.

I will endeavor to classify the indications which I mention, although this cannot be wholly successful because of the complexity of indications that often exists.

Disorders of the Circulation.—No other pathological condition can be mentioned that is more common than too much blood in one or more regions of the circulation, and, therefore, too little in the other regions; witness cold hands and feet, pallor or flushing, the frequency of "colds," the passive or active congestions associated with almost every ill of humanity. If passive it is called "poor circulation;" if active, it is the beginning of "inflammation." Whatever the type or extent of such disorder, the direct cause is a weakness of the contractile coat of some blood-vessels, and this is an indication for ergot.

Disorders of Blood-vessels.—When the walls of blood-vessels are unusually weak or greatly strained they may break, causing hemorrhage. If the vessels are minute (capillary hemorrhage), ergot will contract them and stop the hemorrhage. This applies especially to the various mucous tracts.

Veins, lymphatics, and arteries are subject to inflammation of their walls, and the congested vessels permeating them constitute an indication for ergot.

I have treated successfully with ergot several cases of inflammation of a limited area (or areas) of the abdominal aorta or its greater branches, the location varying from just below the diaphragm to the external iliacs. This inflammation only yielded to ergot with long-continued absolute rest. Besides its action on the congested area, ergot slowed the heart's pulsations and sensibly softened them, thus giving longer periods of rest to the inflamed surface and lessening the friction of the blood-current over it.

Dilatation of veins, as the hemorrhoidal, or the superficial varicosities, is modified by ergot, but it is important to associate gravity or pressure to secure some emptying of the veins, as ergot cannot overcome extreme active resistance to the shortening of the greatly and chronically stretched unstriped fiber.

Atony of the Hollow Viscera.—In this condition, affecting for example the stomach or bladder, it is also important to empty the organs to lessen resistance to the influence of ergot. While ergot seems sometimes marvelously powerful to contract relaxed unstriped fiber, I regard it as so gentle in its action that, to secure its best effect, physical repose should be maintained for half an hour or more after its administration.

Assimilation and Elimination are associated with the minuter circulation. The best performance of these important functions demands a certain caliber of the minute vessels, that the lymph spaces about them may be sufficiently free for the proper circula-

*The claim has been made that there is no unstriated muscular fiber in the vessels of the brain and that ergot, therefore, cannot influence congestive states in that organ. If it be true that there is no unstriated fiber in the cerebral vessels, there must be some other contractile tissue upon which ergot acts in like manner as upon the unstriated muscular fiber since no other effect of ergot has been more positively demonstrated than the relief of congested states in the brain. It is possible that other classes of defective tissue (in process of degeneration) are also normalized by ergot, as is claimed by so careful a student of ultimate pathology as Dr. Homer Wakefield.

tion of that fluid. The waste matter taken up by the lymphatics and passed into the general circulation is thrown out by the secretory glands as the blood passes through their capillary vessels, and this function is also best performed when the vessels are in good tone, not unduly dilated.

Indeed, I think I am warranted in asserting that the performance of function in general, of glands or other organs, including nerve centers, is interfered with by excess of blood, due to a relaxed state of their vascular walls. One indication, then, in *impaired functional activity*, is the contracting of relaxed blood-vessels, which ergot effects

The organ whose disturbed function is the most serious, because the most intimately associated with fatality, is the heart. The disturbance of the heart's function may be due to defects in its own vascular supply; to vascular defects elsewhere, as in the lungs or the kidneys, affecting the quality of the blood; to vascular defects in the nerve centers related to it, or to areas of vascular relaxation somewhere in the general circulation that obstruct the most free action of the heart as a pump.

The effect of these abnormal states is sometimes to diminish the force of the heart's action and sometimes to increase it. The remote defects that unfavorably affect the quality of the blood are also chiefly dependent upon abnormal states of the blood-vessels in those regions, so that the general indication in disturbances of the heart's function is the correcting of vascular relaxations somewhere in the round of the circulation. As prolonged functional disturbance develops organic changes, and as the restoring of normal organic conditions depends upon improvement of the circulation, the preceding statement applies even to organic disorders of the heart.

The above argument applies as well to disordered function of other organs, as the brain, lungs, kidneys, digestive tract, reproductive apparatus, and organs of special sense. I have repeatedly seen marked improvement of sight, hearing, and smell, even in chronic and extreme cases of such defective sense, result from the toning of the circulation.

Ergot is distinctly indicated in disturbances of the *menstrual function*, and in the preparation of subjects for *either climacteric*, a most important matter, generally neglected, such neglect often resulting seriously.

Nervous diseases form an extensive class of indications for ergot. They are too often treated with direct reference to a state of the nervous tissue, when the real cause of the altered function of that tissue is an altered state of the blood-vessels distributed to and about it, as demonstrated by the effective action of ergot in relieving many nervous disorders.

Insomnia is generally conceded to be due to an excess of blood in the vessels of the brain. I have many times recognized in my own person, and observed in my patients, the sleep-determining power of ergot. The sleep resulting from ergot is not a narcotic sleep, but natural in all its phases, having resulted from the same condition that develops natural sleep, a reduction of the amount of blood in the brain.

The state denominated *nervousness* is relieved by ergot, and doubtless in the same way, through vascular change. A patient to whom I have been giving ergot said to me a few minutes ago: "I used to feel that I must be rushing about something all the while; now I take things easy." A great many medical men would be benefited by ergot, since it tends to calmness, steadiness of hand, and clearness of thought. I have prepared, with ergot, the clergyman for his sermons and the lawyer for trying his cases, as well as the teacher for her perplexing and onerous duties. Intense nervousness is illustrated in alcoholic tremor and the reaction due to abstinence in the drug habitués. A further development of this state is manifested in hysteria and hysterical convulsions and the most intensely in hysteroepilepsy, all of which states are quickly dissipated by ergot.

Neurasthenia, the forerunner of insanity, presents a clear indication for ergot in several particulars: to promote calm, thus saving expenditure of force; to promote sleep, thus securing rest, and to promote assimilation, thus restoring vigor of the nerve centers. A recent extreme case, complicated with developing locomotor ataxia, was cured in a few weeks and returned to the duties of an arduous position. The treatment was ergot and electricity.

Spasmodic affections afford indications for ergot. Asthma, chorea, intestinal colic, and spasm of sphincters have all been cured by ergot, and epilepsy has been as much modified by it as I have seen accomplished by the bromides and without the depressant and enervating effects of the salts. Convulsions, due to uremic poisoning, have yielded to ergot.

Paralysis in many instances (hemiplegia, paraplegia, and bulbar) and aphasia have been relieved by ergot, and, in some instances with astonishing promptness.

Stupor or coma and also *delirium* are other indications for ergot; the serous apoplexies occurring in alcoholics are strikingly relieved by ergot, and that drug has in a few minutes dissipated a profound coma from three and a half grains of morphine that had been administered hypodermically to relieve pain.

Pain appears to be largely due to relaxed contractile fiber in blood-vessels, for most kinds of pain are relieved by ergot, and, when it is indicated, it should surely be used in preference to morphine. For many years I have never administered morphine except with ergot, to prevent its congestive effects. Angina pectoris is promptly relieved by ergot, notwithstanding the theory that it is contraindicated. Other nervous affections in which ergot has been effective in curing or modifying, and which are, therefore, indications for that drug, are insanity, general paresis, paralysis agitans, neuritis, neuralgia, inflammations of nervous tissues and of the meninges, including epidemic cerebrospinal meningitis.

Associated with the nervous system, directly or reflexly, but having the element of vacular disturbance in causation or condition, are many *skin diseases;* the vascular element in whatever way related, determining them indications for ergot. I would particularly mention erythema, urticaria, and acne rosacea. I have repeatedly observed a coarse, rough skin become fine-grained and soft after a prolonged use of ergot for some other purpose.

Zymotic, infectious, and *autotoxemic diseases* include an extensive class of indications for ergot, because of the serious and fatal elements which arise from relaxation of vascular walls, or of unstriped fiber elsewhere, as in the bowel.

I have entertained the theory for many years that a relaxed vascular state, general or local, in other words, a state of congestion, is necessary to the active development of bacteria and poisons that determine a febrile state. This was illustrated in a study of appendicitis by Dr. Zwalenburg, recently reported, who found that injecting bacteria into the appendix did not produce appendicitis, but, when a state of congestion of the appendix was produced by mechanically obstructing the circulation in that organ, typical appendicitis was promptly developed by the bacteria ordinarily present.

If a state of congestion is necessary to virulent activity of bacteria, a prompt application of ergot, by contracting the dilated vessels, ought to abort the disease. Ergot has unquestionably aborted appendicitis, pneumonia, and influenza, and I believe that its sufficiently early and thorough application will abort typhoid fever and other diseases of similar origin. I know that it has so markedly modified the course of typhoid fever that the continued high temperature became practically the only distinctive symptom, and when that finally yielded the patients were well, not having the usual prolonged stage of convalescence. Aside from aborting this class of diseases, the indications for ergot are to modify local inflammation; to prevent or modify hemorrhage; to prevent congestive complications; to prevent or modify tympanites or intestinal atony; to promote normal secretion and elimination; to prevent or relieve pain, delirium, or stupor, and to prevent exhaustion of the heart by securing an approximately equable circulation.

The indication for ergot in simple inflammatory affections is too apparent to need more than suggestion. The last class of indications for ergot which I will mention are those connected with

Surgical Cases.—I have positively demonstrated the efficacy of ergot to relieve traumatic shock; to prevent shock from anesthesia or operation; to prepare for prompt operation a subject already shocked; to prevent retching and vomiting from the influence of anesthetics; to relieve or prevent postoperative pain, and to promote the process of healing.

The multiplicity of indications for the application of ergot (which have really been but meagerly suggested in this limited paper) are not likely to be appreciated or credited by those who have been accustomed to regard the drug as applicable only in obstetrics and capillary hemorrhage, until they have developed a truer appreciation of the extent to which a relaxed state of the unstriated or other involuntary contractile fiber enters into the varied conditions of disease. It will then be realized that, after all, there is but a single indication for the use of ergot, the contracting of the weak and relaxed unstriated fiber, or other vital contractile tissue, and that one of the most important duties of the physician, in determining therapy, is considerately and thoroughly to apply this principle to the many indicating cases in his practice.

THE ACTION OF THE RADIANT LIGHT BATH IN NERVOUS DISEASES.*

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.
SUPERINTENDENT WALNUT LODGE HOSPITAL.

During a period of nearly ten years I have used the radiant light bath every day, sometimes giving as many as one hundred baths a week. While the special object sought was the sudorific effects, its tonic and medicinal influence exceeded all expectation.

The effort to make a study of its peculiar action as distinguished from other conditions appears to be difficult because of the character of the patients and the very complex disorders from which they suffered. The purpose of this paper is to indicate some of the clinical conclusions which have been apparent from its action on these persons, together with some possible suggestions for farther and more exact studies.

*Read at the annual meeting of the American Electro-Therapeutic Society at Boston, Mass., September 18, 1907.

The patients upon whom it has been used were all spirit and drug neurotics and psychopaths, suffering from sclerosis, fibrosis, local irritation, and subacute inflammatory states, with deranged metabolism and degenerative conditions. In addition to this there was always present neurosis or profound psychosis with organic and functional derangements. The effort to treat these conditions by any special means is always open to error from faulty observation and conclusions.

Exact measurements of the disability and degeneration present furnish a basis from which to judge the action and influence of remedial measures. The more accurate the studies of these conditions, the clearer the evidence of the effects of remedies; thus measurements of the sensorial conditions, the heart's action, and the arterial tension, give some idea of the present, and the application of means and measures changing these conditions indicate their remedial value. The error is always found in attributing special results to particular means of treatment. In all these drug and drink neurotics the simple withdrawal of the poison is followed by changes which often are ascribed to remedial measures alone. Thus elimination by cathartics and abstinence from food is followed by symptoms which a careless observer might think due to some special remedy.

The action of the radiant light bath is not only eliminative, but something more than that. It is a tonic and stimulant, and apparently has some specific influence on the cells and tissues which is yet to be discovered. For the present purpose I will consider, first, the bath as a powerful sudorific and eliminative; second, its special influence on metabolism, nutrition, and the cutaneous circulation; third, its psychical effects on the nervous system and its influence on the emotions and mind.

As a sudorific the radiant light has a very pronounced uniform action. It is far superior and more active than hot air in its profound influence on the organism. The light rays penetrate to the interior of the body, creating increased activity in both cell and tissue. The circulation on the surface is more intense and rapid, and the amount of water thrown off from the skin exceeds that when hot air is used. An effort made to estimate the perspiration induced by both hot air and radiant light indicated this. In most cases this sudorific action reaches its point of greatest intensity in from ten to fifteen minutes, but to reach that point with the use of hot air requires from twenty to forty minutes.

There is evidently some shock to the cutaneous nerves in the rapid, intense action of the capillaries that react beneficially on the nerve centers, particularly in persons who are suffering from degrees of palsy following the use of spirits and drugs. The rapidity of the sudorific stimulation varies largely in different persons at different times. In some instances six or seven minutes' exposure to the radiant light is followed by a free perspiration. In others double this time is required. In persons under the influence of spirits or drugs two conditions seem to be prominent. In some there is a slow and progressive relaxation culminating in profuse perspiration in a few minutes. In others a temporary blanching of the skin and oppressive feeling of dry heat, followed by a sudden relaxation and profound perspiration.

In many cases states of insomnia and continuous exhilaration for several hours follow the use of the bath. Then a profound sleep with the most restful feeling comes later. In other cases somnolence almost bordering on narcotism continues for a time,

followed by the same restful feeling. It is found by long experience that this condition is the most beneficial, and the efforts to produce sleep and somnolence by this means are usually successful.

Examination of the surface of the body is made before the bath. If the skin is found dry, and the circulation sluggish, warm showers are given with strong soap and brushing. Where the person is unaccustomed to bathe, and has cutaneous disturbances of sensation and a tendency to take on inflammatory action from any internal cause, it is quite necessary to prepare the skin by massage, showers, cold and hot douches, and dry rubbing to secure the best effect of the radiant light.

Persons under the influence of spirits and drugs, and persons suffering from high-tensioned arteries, always do better when the bath is preceded by a warm shower and rubbing. In other instances, after free perspiration of the bath, a shower with gentle massage, a distinct somnolent effect follows, and the patient who has been awake for a long time will fall into a most refreshing slumber.

In some instances in which the action of light on the surface produces a form of cutaneous palsy, blanching the surface for a few minutes, and later followed by intense redness and profuse perspiration, a prolonged shower is valuable to equalize the circulation. Where the stimulating effect is followed by exhilaration and wakefulness for some hours, a warm shower will prevent this. Patients should always recline after a bath for an hour or more in a well-ventilated room. The excellent effects of this light in the ordinary skin disease is a matter of daily observation. This is greatly increased by salines in small doses before the bath, and warm showers.

In drug-takers the effect of the radiant light is almost a specific in overcoming irritations, diminishing nervousness and removing internal states of congestion for the time being. In many instances a prolonged bath is followed by the best results; in others a gentle surface stimulation is all that is required. It has been observed that the free use of baths greatly diminishes the impulse to take spirits and drugs. The desire for relief, for which drugs and spirits are used, is less prominent and intense, and this has led some observers to believe that the Turkish and radiant light baths were capable of effectually removing the morbid impulse for drugs or spirits. A more careful study shows that the baths divert nervous energies and remove sources of irritation, and that it has some special action in restoring the disordered cell and tissue.

The radiant light bath has a marked physiological effect evident from the improvement of the function of the brain and nervous system that is unknown. The second effect of the radiant light bath on nutrition and cutaneous circulation has many unexplainable phenomena. Sometimes the appetite is immensely stimulated, and in nearly all cases the disordered digestion is improved. In some cases a craving for fats and sugars or acid foods is followed by a strong repulsion for other classes of foods.

In certain cases where the action of the light produces profound perspiration, an unusual thirst follows, and not unfrequently a general relaxation of the system is succeeded by great looseness of the bowels and intense renal activity.

In persons who have profound nutrient disturbances experiments have been made by massaging the body before the bath with soap, and then washing in a strong solution of salt and water, the latter not rubbed off. This was followed by a great improvement in indigestion and nutrition. There are many reasons for believing that the skin, saturated with salt water before the bath, becomes more sensitive to the action of light; probably the salt is absorbed, and in this way becomes more of a tonic. It is difficult to explain the marked improvement in neurotic dyspeptics treated by radiant light and the special value due to the salt or its influence on the skin.

Another experiment seemed to indicate the greater potency of drugs, particularly phosphate of sodium, and in other instances vegetable acids, which were given a short time before the baths. There seemed a marked improvement from both.

The same thing was apparent in persons suffering from great irritability and excessive nervousness who were always benefited by large doses of phosphate of sodium and pills of lupulin given a short time before the bath. In the insomnias following the withdrawal of narcotic drugs, the bath is a very valuable remedy given once a day, preceded by hot water douches, soda compounds, and occasionally sulphate of magnesia. The nerve relaxation and rest, with tendency to sleep, is very marked, and comparison in this respect with the hot air baths and the same drugs indicates great superiority of the radiant light. In alcoholics of the epileptic character, the action of the bromides seems to be greatly intensified by the bath. In many instances it was noticed that small doses produced extreme physiological effects when followed by the baths, and the supposition was that the salt was more thoroughly assimilated and distributed to the nerve centers by the action of the light

It has been suggested that the radiant light exercises not only a peculiar cell-stimulating power, but an influence over the mineral constituence of the body, increasing their assimilation and circulation or diminishing their irritative action. With a view to determine this, alkaloids of quinine and opium were given before the bath was taken, and, while the results are very striking, the data are insufficient to draw conclusions.

In morphinism and alcoholism the poison symptoms are always reduced after the bath. In Bright's disease and general dropsical conditions, the drainage of the water to the surface by the radiant light bath is more profound and less exhaustive. In chronic enteritis very marked results have been noted. These are no doubt mechanical as well as physiological effects.

The third effect of the radiant light on the brain and nervous system is one of still greater mystery, and the explanation of the startling changes produced must await future study and demonstration. The mental relief and satisfaction seen in the buoyancy of the mind and the sense of quiet and comfort is a very common condition. When massage is given before or after the bath a pleasing sense of fatigue and desire for sleep follows. States of despondency seem to pass away, and the patient acknowledges relief which before was not recognized.

One very marked effect is the diminution of the arterial tension from five degrees to twenty degrees noted on the Riva-Rocci sphygmomanometer. This may last a long time, and even be permanent. In most instances the tension is lowered by the effects of the bath, and with this the heart's action is steadied, and the disturbances of the senses are all diminished. It is possible to measure these effects with instruments of precision, and show the exact changes that are registered in the heart, arteries, and senses. Comparing this with the effect of the hot air baths, we find it very much greater and more

marked. It is evident that this is not all due to the drainage of the water from the blood, but to some other conditions not very clear. In the hot water bath often the tension is but little influenced, and other organic and functional disturbances are seldom changed.

The radiant light bath, preceded or followed by a static breeze, has a very pronounced effect on the tension of the arteries and the action of the heart. In some instances a marked narcotic action follows. In one case restlessness followed for a short time, then profound sleep for a long time. The static breeze following the bath seems to have a soothing effect, and the combination of the two in certain persons has an almost specific action. In the insomnia following the withdrawal of drugs the baths have a sedative effect in lowering also some psychical influence which antagonizes whatever delusions or derangements may be present.

The intensity of morbid impulses and hallucinations of the senses is changed for a short time at least. In delirium tremens the bath is marked in its effects, and should always be preceded by vigorous massage and showers, and large quantities of mineral water taken internally. This is usually followed by distinct sane intervals. The mind seems to recover its balance for a time, and with it the power of control returns. I have used mechanical massage and vibration before and after these baths with excellent results. In multiple neuritis and many of the local palsies the same results follow. In two cases in which malarious fever complicated the drug-taking, the bath had a very marked effect in cutting short the paroxysm.

The psychical effect of perspiration from light is a very powerful factor in many ways unknown, and should be classed as a distinct form of medication. A degree of confidence and buoyancy is created, which may be termed exhilaration, and yet it is more than this; it is a sense of relief and rest, freedom from pain, and other conditions which for the time have a powerful reaction on the higher brain centers. Nearly all persons who take these baths receive some half-conscious impulse of approach to ideal health that is most helpful, and this should be encouraged, as it is both a physical and a psychical force of the most powerful therapeutic value.

These are some of the daily experiences and suggestions which encourage further study and more exact observation. So far the ordinary incandescent and arc lights have been used. Other forms of light are more powerful and no doubt more pronounced in their effects. There have been no ill effects noted, and increasing experience shows that the best effects from the bath follow when given in surroundings and circumstances adapted to meet the special conditions of each case.

I conclude with the statement that the radiant light bath is a remedial measure of the widest application, and its possibilities as an agent in restoration of diseased cells and tissues is far greater than any present knowledge can explain. Its effects are undoubtedly physiological in draining off water from the system, chemical in its action on metabolism and the salts of the body, and physical in its sudden profound influence over nerve force and energy. The possibility of using it in private practice is more and more assured every year, and the methods of using it will become perfected with increase of knowledge of its influence.

City Children in England.—It appears that fewer children are being born or more are dying in English cities. In the year 1800 the number of children was 33 per cent. of the population. In the year 1900 they were only 23 per cent.

MOTOR PARALYSIS AS AN EARLY SIGN OF TABES DORSALIS.

WITH A REPORT OF TWO CASES.

By CARL D. CAMP, M.D.,

PHILADELPHIA.

INSTRUCTOR IN NEUROPATHOLOGY AND ELECTROTHERAPEUTICS AT THE UNIVERSITY OF PENNSYLVANIA AND INSTRUCTOR IN NERVOUS DISEASES IN THE PHILADELPHIA POLYCLINIC, ASSISTANT NEUROLOGIST TO THE PHILADELPHIA GENERAL HOSPITAL.

Under the heading, "Einige wenig beschriebene Formen der Tabes dorsalis," Lapinsky reports five cases of tabes in which the primary symptoms of the disease involved more the motor than the sensory sphere. A brief outline of these cases, sufficient to show their nature, is as follows:

1. A twenty-three-year-old girl of a neurotic heredity whose father had syphilis and whose two sisters had hystero-neurasthenia developed a paretic condition of the left foot and the right hand. Three months later the right foot also became affected, and an examination showed ataxic gait, Romberg's symptom, hyperesthesia, and hypalgesia of the legs, paresthesia of the feet, girdle sensation, incontinence of urine, inequality of the pupils with a slowing of the reaction to light, diminished knee-jerks, and Achilles-jerks diminished on the one side and lost on the other side. There was an absence of pain or tenderness in the legs.

2. A thirty-seven-year-old male first complained of a tired and weak feeling in the legs. Ten months later there was noted a loss of sexual power and a partial incontinence of urine, which was followed by difficulty in walking in the dark and diplopia. The weakness of the legs was progressive and examination showed that in the left leg all movements thought possible were weak, especially those involving the small muscles of the foot. The right leg was also paretic *in toto,* but the extensors of the foot and toes were paralyzed. Tactile, pain, temperature, and muscle sense were diminished in the legs. The skin reflexes were normal. The knee-jerks, Achilles-jerks, and biceps-jerks were lost on both sides. The right pupil was larger than the left, and neither one reacted to light stimulation. The electrical reactions were normal and the nerve trunks showed no especial tenderness on pressure.

The third, fourth, and fifth are similar cases of tabes dorsalis in which an early or initial symptom was the weakness.

Through the kindness of Dr. William G. Spiller I am enabled to report two cases of similar interest from his service at the Polyclinic Hospital.

Case I.—P. D., aged fifty-five years, and a stonecutter, on his admission to the hospital stated that he had had a chancre about thirty years before, and for the past two or three years had been taking two or three drinks of whisky daily. He had sharp pains in his legs for the past nine years, but had had no incontinence of urine or girdle sensation. Three days before, he had noticed that he could not raise the toes of the right foot from the ground and that the foot felt "dead." There was no pain in the legs. On examination it was found that there was a myosis of both pupils and that they did not react to light but reacted promptly in accommodation. The knee-jerks and Achilles-jerks were lost even on reinforcement. Sensation on the soles of the feet was lessened and plantar irritation caused no movement of the toes. His station was good with his eyes open, but he swayed markedly with them closed. Gait: with his eyes open, he lifted his right leg high with a decided toe-drop, *i.e.* he

had a unilateral steppage gait; with his eyes closed his gait was extremely ataxic and he would have fallen if unsupported. There was no disease of the fundus oculi.

In this case there were present the etiological factors of both tabes dorsalis and alcoholic multiple neuritis, but the first symptom, the sharp pain in the legs, began six or seven years before he began drinking, according to his own statement. As in the cases reported by Lapinsky, the first symptom which compelled him to seek medical advice was a unilateral paresis of the extensors of the foot. The loss of the knee-jerks and the Achilles-jerks, the sensory changes, Romberg's sign, and the myotic pupils with loss of reflex contraction to light point conclusively to the diagnosis of tabes dorsalis.

The absence of pain on pressure over the nerve trunks or muscle masses is against the diagnosis of neuritis as a complication.

Case II.—Geo. H. G. is aged sixty-five years and is a clerk. His family history is negative and his only severe illness was an attack of typhoid fever in 1863. He was a painter for eighteen years, but has not followed that occupation for the past twenty years. He denied ever having had sexual intercourse except with his wife, who has had six healthy children. He positively denied all venereal disease or alcoholism. In the summer of 1905 he first began to notice in both legs and both feet, but especially on the left side, a sensation in the nature of a tingling, heavy feeling, which was accompanied with shooting pains that radiated from the instep to the toes. About March, 1906, he began to notice an increasing weakness of the left ankle, associated with some slight pains in the calf muscles. On examination in June, 1906, it was noted that the loss of power was confined to the dorso-flexors of the left foot. His gait was ataxic and his station was poor. The knee-jerks and the Achilles-jerks were absent even on reinforcement. He had no incontinence of urine and no girdle sensation, but on walking there was a sensation in the soles of the feet as if walking on wool. The finger to nose test showed ataxia on each side. Dr. Wm. C. Posey examined the eyes at this time and reported as follows: "The pupils respond to light, accommodation, and convergence. His optic nerves show slight atrophy. There are numerous round spots of choroidal change about both discs, especially in the right eye, where below the disc there is a large spot of choroidal change. There are no fresh hemorrhages. Vision, O. D. 5/9, O. S. 5/12.

At an examination made September 19, 1906, the etiological factors of a multiple neuritis, as far as possible, were carefully eliminated. He described an illness occurring in 1898 in which he had pain in the bladder and a constant desire to urinate with no urethral discharge. Since then he has had several attacks of "dyspepsia," described as a very severe pain in the stomach, only relieved by morphine, and accompanied by intense nausea and vomiting of a green, acid liquid. There was no obvious cause for these attacks, and they lasted a variable length of time. His gait with his eyes open was a typical steppage; with his eyes closed there was an added ataxia and he would fall. His station was good with his eyes open, but he fell when they were closed. Foot-drop was complete on the left side and partial on the right. There was no atrophy, though both legs were thin below the knees. Pressure on the nerve trunks or on the muscle masses produced no pain. Sensation to touch appeared to be blunted on the soles of the feet, and though he felt a deep pin-prick acutely the sensation appeared to be delayed. With his eyes closed his toes could be moved passively in various directions without his knowledge; there was no loss of the sense of position of the legs. A strong faradic current produced no response in the muscles below the knees; above the knees the irritability was much diminished. There was no palsy of the arms.

In this second case there are none of the recognized etiological factors of either tabes dorsalis or multiple neuritis, for though at one time a painter he had not followed that occupation for twenty years previous to the onset of his symptoms. As in the first case, the first symptom was sharp, shooting pain, which was followed by weakness in the legs and a foot-drop which, in the early stages, was unilateral. The history of vesical and gastric crises, Westphal's symptom, Romberg's symptom, ataxia of all four extremities, sensory changes in the soles of the feet, and the optic atrophy lead to the diagnosis of tabes dorsalis with motor paralysis as an early symptom.

According to Lapinsky,[1] such cases are very rare and there are only a few reported. That the motor nerves of the eyes are very frequently affected in the beginning of a case of tabes is well known, but that other motor nerves, such as those of the legs, may be affected is not so well recognized, although Charcot refers to motor paralysis as present in "exceptional cases" of tabes. Eichorst says that muscular paralysis with tabes is in many patients an early symptom, in which case it is especially often a paralysis of the peroneal or radial nerve. Sometimes it comes on suddenly. Often, but not regularly, there is present the reaction of degeneration, electrically. Sensory changes are not present. Finkelnburg gives to Remak the credit of being the first to report a case of peroneal palsy, occurring in tabes; there was no history of lues or alcoholism; there was a diminution of faradic irritability of the affected muscles and the palsy was entirely recovered from. In a second observation of Remak's the patient had a degenerative paralysis of the tibialis anticus muscle and a year later the symptoms showed it to be undoubtedly a case of tabes. Cases are also reported by Müller (bilateral), Fischer, and Bernhardt. Finkelnburg reported two cases in which he attributed the palsy to traumatism, pressure on the nerve, in the first case from sitting with the legs crossed, and in the second from an arthropathy; in either case the etiology cannot be regarded as proved.

It is interesting and necessary to the understanding of these cases to determine the nature and location of the lesion causing the weakness, and in order to do this it is necessary to first consider the pathogenesis of tabes dorsalis. David Ferrier,[2] who has recently critically reviewed the various theories on this point, adopts finally the hypothesis of Thomas and Hauser, that "the essential lesion of tabes dorsalis is a dystrophy, similar to that induced by certain toxic agents, affecting the sensory protoneurone as a whole, and manifesting itself as a degeneration of both the central and peripheral terminations, of which the intramedullary are the more vulnerable and are usually the first to exhibit anatomical change. The process, however, is not confined to the spinal protoneurone, but may affect, among others, the optic, sympathetic, and certain motor neurones." This conclusion of Ferrier, it will be noted, contains the interesting statement, in this connection, that "certain motor neurones may be affected." Cole,[3] in a histological study of the nerves and spinal cords from three cases of alcoholic multiple neuritis, found a degeneration in

the posterior column similar to that of tabes dorsalis. He refers to Vierordt, Korsakow, Kojewnikow, Pal, Campbell, Soukhanoff, Heilbronner, Wright and Orange, Goldscheider and Moxter, and Marinesco as describing similar findings, and further says that he "could find no record of any case of multiple neuritis in which the spinal cord was examined by the Marchi method in which it is stated that the posterior columns were free from degeneration." Cole arrives at a conclusion concerning the effects of alcohol on the sensory nerves and the spinal cord peculiarly like the hypothesis advocated by Ferrier as to the pathogenesis of tabes dorsalis, viz., "The central and peripheral fiber degeneration are simultaneous manifestations of a single disorder of the whole sensory neurone." Therefore, according to the most recent theories, both alcohol and the hypothetical toxin which is the cause of tabes dorsalis produce a degeneration of the sensory neurone as a whole, while that of tabes affects only certain motor neurones, the effect of alcohol on the motor nerves is usually marked and extended. With such similarity in their effects of the causative toxic substances there is a strong probability that the one will at times produce symptoms usually produced by the other. It may be then that in these cases the tabes toxin has produced an effect, *i.e.* paresis of the dorso-flexors of the feet, such as is usually produced by alcohol.

Another point of interest in these cases is the location of the lesion causing the paralysis. From the foregoing study of the probable pathogenesis of these cases, the lesion would seem likely to be in the peripheral motor nerve, and a neuritis has been found on histological examination in cases of tabes in which there was an atrophy of the muscles (Dejerine,[4] Pitres and Viallard,[5] Oppenheim and Siemerling,[6] Kraus,[7] Jean,[8] Remak,[9] and others). At present, however, there is more evidence to show that the amyatrophy which sometimes occurs in tabes is due to a degeneration of the nerve cells of the anterior horns of the spinal cord. My own studies on this subject[10] confirm the findings of Shaffer[10] and others that such is the case. These changes in the anterior horn cells are regarded as consecutive to the lesion of the posterior roots, and are due to a default of the habitual excitations upon which the vitality of the cells depends. Similar changes in the anterior horn cells occur after experimental section of the posterior nerve roots (Lapinsky, Schaffer). It is well known that experimental section of the posterior nerve roots produces a paralysis or a paresis of the part of the body innervated by these roots, which is sometimes accompanied by atrophy (experiments of Claude Barnard, Mott and Sherrington, and others, quoted by Lapinsky).

The question of the location of the lesion in these cases of early paralysis in tabes dorsalis cannot be regarded as definitely settled. By some it will be held that the lesion is a motor neuritis due to the action of the mysterious toxin that causes tabes, but acting more extensively, and on the motor as well as on the sensory neurone. A second view is that the paralysis is due to an affection of the motor cells of the anterior horns of the spinal cord, not perhaps as severe as those causing the amyatrophies, and due to a propagation of the lesion across the posterior cornua to the motor cells. Whether the lesion were in the motor nerves or in the motor cells, if it were severe the paralysis would be followed by atrophy and changes in the electrical reactions such as occurred in the second case.

THE MISUSE OF THE VOICE AND ITS CURE.

ARTICULATION.

By N. J. POOCK VAN BAGGEN, M.D.,

THE HAGUE, HOLLAND.

When we observe the articulation of the sufferer of the throat disease, described in my article published in the Medical Record of January 5, 1907, we will see that in this respect also many faults are committed, which by continuance have disastrous results for the speaker or singer.

Articulation is effected by the lower jaw, the lips, the tongue, and the soft palate. When we examine the movements of each of these parts when the patient is singing or speaking, we will notice what follows: The mouth is not opened sufficiently because of the laziness of the lower jaw and the inertness or the weakness of the lips. There is no distinct difference in the movements of the lips when pronouncing successively the vowels "ah," "ee," "oo," while the lip consonants are faint. The tip of the tongue fails to do its duty. When the "t" or "d" is pronounced the lower-jaw does more than half of the labor, where the tip of the tongue only should work. Consonants as k, g, j, r are formed with the back of the tongue leaning against the soft palate instead of being articulated in the foremost part of the mouth with the tip or the middle of the tongue against the alveolus or the hard palate. As a result of those faults the back of the tongue is too developed, and rises as a thick and heavy wall between the mouth and the pharynx, which hinders the sound from vibrating freely in the mouth.

With regard to the soft palate, we will see that the action of the palato-glossi and the palato-pharyngei, as well as that of the tensor and the elevator, is stemmed by the swelling of the mucous membrane, which covers the soft palate, and thereby the widening and narrowing of the isthmus of the fauces, and the rising and descending of the soft palate, which is of such great importance in singing more still than in speaking, is incomplete and sluggish.

To cure this imperfect state of the articulation, the patient mus begin by exercising each group of muscles separately.

A very effective exercise for the lips is the following: Project the lips as when saying "oo," then retract them as when saying "ee," repeat this movement in cadence some twenty times.

The exercises for the tongue must tend specially to develop and strengthen the tip of the tongue and to obtain a normal position of it. In a normal position the tongue is concave, the point leans against

the lower teeth and from the point to the back, the tongue inclines slightly downwards.

One of the best exercises for the point of the tongue is as follows: Open the mouth widely, stretch out the tongue and move the tip up and down, touching alternatively the upper and the under lip. The lower jaw remains motionless. The moving up and down must be rhythmical.

To flatten the back of the tongue the pupil may make the following exercise: Fix the tip of the tongue agains the lower teeth, bend the middle of the tongue forward and out of the mouth, then retract the tongue slowly till it has regained its position of rest. Repeat the same movement several times.

The exercises for the tongue must never be prolonged until fatigue ensues. Only after the position of the tongue is corrected, may the soft palate be exercised. The pupil may practise in the following way: Inhale, with open mouth, through the nostrils, exhale through the mouth; then inhale through the mouth and exhale through the nostrils, the mouth always opened widely.

When inhaling or exhaling through the nostrils with open mouth the opening between the mouth and the pharynx will be shut by the back of the tongue, which rises, and the soft palate, which descends. When inhaling or exhaling through the mouth, the contrary movement takes place, that is the soft palate rises and the tongue descends.

When the movement is normal the tongue rises as much as the palate descends. To prevent the back of the tongue from rising too much, which occurs when the action of the soft palate is weakened by catarrh, the pupil must be careful to keep the tip of the tongue fixed against the lower teeth.

Besides the above named exercise there are several other exercises which all tend to improve the movement of the soft palate and to widen the isthmus of the fauces.

When the different groups of articulating muscles have improved sufficiently the vowels and consonants can be practised; the pupil must therefore be told how the vowels and consonants are formed.

After the position of the lower jaw, the lips, the tongue, and the soft palate, the vowels or sounds are divided into three series. The vowels of the first series are front vowels, those of the second series are back vowels, while the vowels of the third series are called mixed vowels.

As the position of the articulating muscles for "ah" is more or less neutral, we use this vowel as the starting point for each series.

The first series comprises: ah, eh, a, ee;

The second series comprises: ah, oh, ow, oo;

The third series comprises: ah, œ (eu, u).

The eu and u do not apear in the English language. These twelve vowels form the following table:

	Ah	
eh	œ	oh
a	(eu)	ow
ee	(u)	oo

which sounds we hear in the words:

father (ah)

pet (eh) nut (œ) box (oh)

same (a) neutre (eu) French pole (ow)

feet (ee) pure (u) French pool (oo)

By "ah" the opening of the mouth is round, the tongue rests, the soft palate rises slightly.

For "eh" the corners of the lips are retracted a little, the cavity of the mouth is only just narrowed by the raising of the center of the tongue and the lower jaw (the pupil must be careful that the lower jaw does not rise too much, preventing by so doing the tongue from rising as much as it has to). The point of the tongue is fixed against the lower teeth; the soft palate is more elevated than by "ah."

When forming "a" the retraction of the lips increases, while at the same time the rising of the lower jaw and of the center of the tongue increases; the soft palate is more elevated.

"Ee" shows us the same position, but still more accentuated. The lips are drawn as far sideways as when we are laughing, the soft palate arches up to its highest position, the point of the tongue is always resting against the lower front teeth, the center of the tongue and the lower jaw, by their rising, still more narrow the cavity of the mouth.

For the second series: ah, oh, ow, oo, the movements of the articulating muscles are altogether different from those by which the first series are formed.

When we pronounce "ah," "oh" successively we observe that for "oh" the lips are projected forward, the root of the tongue descends, the point of the tongue is no more fixed against the lower teeth, but is drawn a little backward by the descending of the root of the tongue, the lower jaw is raised slightly, the soft palate is elevated a little.

By "ow" the labial aperture is more rounded than by "oh." The position of the root of the tongue is lower while that of the soft palate is higher than by the preceding sound.

For "oo" the descending of the root of the tongue, the rising of the lower jaw and of the soft palate is still augmented. However, the soft palate is not elevated as high as by the forming of "ee." The lips protrude as when whistling.

The vowels of the third series: ah, œ (eu, u) are mixed vowels. They are called so because of the lips, the tongue, and the soft palate being in a position relative to that for the first and the second series of vowels.

When we pronounce: ah, œ, eu, u, the lips are more and more protruded as they are when pronouncing ah, oh, ow, oo. On the other hand, we will see the center of the tongue rising as by ah, eh, a, ee. The point of the tongue also remains fixed against the lower front teeth. By ah, œ, eu, u likewise the soft palate gradually arches up, not so much as for the first series but higher than for the second.

To come to a clear understanding of the action of the articulating muscles, when forming the consonants, we classify the consonants in three different ways. By each classification we consider two or more groups of consonants.

1. Consonants are formed by the breath in the cavity of the mouth, which is closed or narrowed. When the cavity of the mouth is closed (by closing the lips or raising the tongue against the hard palate) the breath is stopped a moment and causes a little explosion at the instant that the passage is opened, when the consonant is pronounced. Those consonants are called "explosives."

When the cavity of the mouth is narrowed by the lips or tongue, the passage not being completely closed, the breath continues to issue during the time that the consonant is pronounced. These consonants are called "continuants." Thus in this first case we distinguish two groups:

Explosives: b, d, g, k, p, t.

Continuants: f, j, l, m, n, r, s, v, w, z, th.

2. The second classification is made according to the place where the cavity of the mouth is closed or narrowed by the tongue and the lips. This place or point is called the articulating point. We distinguish five articulating points, and thus this sec-

ond classification also comprises five groups of consonants, which are formed as follows:

(*a*) B. p. m. are formed by closing the lips.

(*b*) F. v. w. are formed by leaning the underlip against the upper teeth.

(*c*) S. z. are formed by closing the teeth; the tip of the tongue is fixed against the lower teeth, the center of the tongue is raised towards the hard palate, leaving but a small aperture in the middle for the breath to pass.

(*d*) L. t. d. n. r. are formed by leaning the tip of the tongue against the upper front alveolus. (Th is formed by leaning the tip of the tongue against the upper teeth.)

(*e*) K. g. j. are formed by raising the center of the tongue against or towards the hard palate.

3. Finally, in the third case, we distinguish two groups of consonants: the breath consonants and the voiced consonants.

Breath consonants are formed by the whistling of the breath in the cavity of the mouth; the vocal cords do not vibrate when we pronounce them, the breath passes the cords without making them sound.

When, on the contrary, we pronounce a voiced consonant the breath strikes the vocal cords and makes them vibrate. We easily can recognize the breath consonants from the voiced consonants when we pronounce them whilst the ears are stopped.

During the formation of a voiced consonant we hear a buzzing noise caused by the vibration of the vocal cords, which noise we do not perceive when forming a breath consonant.

Breath consonants are: p. f. s. t. k. th.

Voiced consonants are: b. m. v. w. z. l. d n. r. g. j. th.

As a rule the vowels offer no great difficulty to the pupil, especially when previously the position of the tongue has been corrected and the lips as well as the soft palate have been trained to work normally and actively. In my complete course of exercises the faults in the formation of the vowels will be amply discussed and exercises mentioned which have in view their correction.

In regard to the consonants we have seen that k, g and r are nearly without exception mispronounced.

The k and g are usually formed with the back of the tongue leaning against the soft palate, a soft and yielding part against which it is impossible to form a sharp and distinct "k" and "g." To correct this faulty formation of those consonants, the teacher will make the pupil see in his mouth, by means of a mirror, where the hard palate ends, which he may feel also with the finger. Then, always controlling himself by means of the mirror, he must press with force the center of the tongue against the hard palate (the tip of the tongue rests against the lower teeth), to relax it suddenly.

By this movement a normal "k" is produced. As the ee is formed with the center of the tongue raised towards the hard palate, this vowel will be of great help for the pupil in studying the k and g; also the first exercises are made in combination with ee, as: eekee, eeka, eekeh, eekah, eekoh, eekow, eekoo.

While by oh, ow, oo, as we have seen before the back of the tongue rises, the correct pronunciation of the k and g combined with one of these vowels offers the most difficulties and must be carefully exercised.

The g must be learnt in the same way as the k, the only difference between those two consonants being that the k is a breath consonant, the g a voiced consonant. As, however, for k the pressure of the center of the tongue against the hard palate is stronger than for g, it is better and easier to study first the k.

The studying of the correct r requires a good deal of patience and energy from the pupil as well as from the teacher. Especially in Germany France, and Holland the r is generally formed by the trilling of the uvula against the back of the tongue. After the wrongly directed breath the thus formed r is one of the principal causes of catarrh, and the correct pronunciation of the r, however difficult, must be learnt and must be especially attended to.

The normal r is pronounced with the point of the tongue, which, by the breath, is made to vibrate against the upper front-alveolus.

Most of the patients are unable to roll the r with the tip of the tongue and, as they have to avoid the r formed by the trilling of the uvula, they must begin by substituting the d for the r.

We use the d because its formation approaches very nearly that of the r. The point of the tongue strikes the root of the upper teeth exactly at the same spot as the r. The only difference between the d and the r is that by the d the point of the tongue strikes but once the root of the upper teeth, while by the *r* it strikes the same spot repeatedly, that means it trills.

To obtain the trilling of the point of the tongue the *d* also is used. Therefore the pupil must pronounce rapidly and as energetically as possible: *d*dddd with a strong accent on the first d and repeat this same *d*dddd till fatigue is felt. For some this exercise can be facilitated by another consonant, especially a plosive, preceding the ddddd. The pupil may pronounce *p*dddd, *b*dddd, *t*dddd, *k*dddd, etc., giving the accent on the preceding consonant. The exercises by which the r is directly studied must be supported by various other exercises, which have in view the strengthening and the flexibility of the point of the tongue. Exercises formed with the other consonants of the fourth articulating point, *l. t. d. n.*, are generally very effective in this case. As the faulty pronunciation of the *k, g,* and *r* is typical by the sufferers of the throat disease caused by the misuse of the voice, I only mentioned those consonants. Of course it occurs that more consonants are mispronounced and in regard to the articulation the patient has to go through a careful examination and when faults are found they must be corrected.

Separate from faults we generally find the articulation of the consonants too weak and sluggish. As this is a reason why the speaker or singer is so badly understood and a reason also why he overstrains his vocal cords, it is expedient to reform this condition and to exercise all the consonants separately and in combination with each other. In a normal state the articulating muscles must support the vocal muscles, instead of the articulation relying on the vocal cords, as is but too often the case.

An effective and at the same time amusing exercise is that which imitates the drumbeating, as:

la, la, la, *la, la,* la, la, la, *la, la,*
la, la, *la,* la, la, *la,* la, la, *la.*

The same exercise can be made with all the consonants and combinations of consonants.

In the very beginning it will be rather difficult for the pupil to remember his breathing when exercising the articulation, yet he must try to apply always the right way of breathing when practising in order to improve the cooperation of the breathing and articulating muscles.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 23, 1907.

ARTIFICIAL PNEUMOTHORAX IN PULMONARY TUBERCULOSIS.

IN 1894 Forlanini reported the history of several patients in whom he had tried to cure one-sided tuberculous processes of the lung by producing an artificial pneumothorax; since then other clinicians have tested the therapeutic value of this procedure, and from all their published results we may conclude that the chances of curing some patients by producing an artificial pneumothorax seem favorable. Recently Karl Lexer has reported four cases in the *Beiträge zur Klinik der Tuberkulose,* Vol. VIII, 1907. He applied the ordinary methods used in producing an artificial pneumothorax, sterile nitrogen being used to compress the lung. The gas passes from a tank into a graduated bottle filled with a one per cent. solution of bichloride of mercury, the latter gradually running into a second bottle as it is supplanted by the gas. A fairly good sized needle is inserted obliquely into the pleural cavity, if possible at a point where there are no pleural adhesions and where the lung is healthy, the gas passing through the needle at a pressure of 100 mm. of water. He considers it unnecessary to cut down upon the pleura before inserting the needle, as this requires an anesthetic, and injury of the lung can usually be avoided if the needle is inserted obliquely, and the gas is permitted to run through it constantly while it is being inserted, the lung thus being pushed away by gas as soon as the pleural cavity is entered. Not more than two to five hundred cubic centimeters of nitrogen is injected at one sitting as larger amounts cause a too rapid displacement of the heart, and as a very rapid compression of the lung is followed by too much coughing and expectoration, thus making an aspiration pneumonia of the other lung possible. A manometer is attached to the apparatus, so that the intrapleural pressure and that of the entering gas can be controlled. When there is an early high intrapleural pressure pleural adhesions probably prevent an increase in the size of the pneumothorax, and when this occurs the needle can be inserted at another point or one may hope to break up the adhesions gradually.

In one of his patients Lexer always penetrated the lung, even after cutting down upon the pleura, for dense adhesions prevented his getting into the pleural cavity. Two other patients were improving when a process in the other lung became active, and it was deemed advisable to stop treatment. His fourth patient, with a lesion at the left apex, and profuse expectoration containing tubercle bacilli, received thirteen injections in five weeks. During the treatment he showed all the physical signs of a pneumothorax, the respiratory sounds were practically absent, and the lung was compressed to one-half its original volume, mainly in the direction of the hilus. The direction of compression depends upon the location of the adhesions, if any are present. The left half of the chest was several centimeters larger in circumference than the right, the intercostal spaces were practically filled out, and the heart was pushed over to the right, all these physical signs being confirmed by the *x*-ray. His patients usually complained only of pain, which was caused by the breaking up of adhesions, and which he could control by morphine. Occasional dyspnea while the gas was being injected, and subcutaneous emphysema after coughing, were noticed, but were usually not marked enough to be of any account. After the thirteenth injection in the one patient marked dyspnea set in, and a physical examination revealed an extensive pneumothorax, while the heart was pushed well to the right and interfered with the function of the right lung; the dyspnea disappeared in a few days, and then injections of gas were necessary only every week or two in order to keep up an efficient pneumothorax.

As regards the good effects on the patient, Lexer's observations agree with those of others; they were immediate, the temperature came down to normal, the expectoration became less in amount and thinner, elastic fibers and tubercle bacilli diminished in number, or could no longer be found, and the general condition improved; all this improvement was undoubtedly caused by putting the lung partially or completely at rest, the degree of the latter depending upon the density of the adhesions. Active processes in both lungs, uncompensated heart lesions, tuberculosis in other parts of the body, causing a poor general condition, an acute tuberculous pneumonia, during which the other lung may suddenly become involved, are all contraindications to this mode of treatment. Lexer believes that the good results justify further trials of this treatment, with a hope of it becoming curative, especially since no harm can be done.

Forlanini reported a case in which the pneumothorax was kept up for four years, and which he considered cured, but neither in this nor in other cases regarded as absolute cures has sufficient time elapsed to confirm this favorable view. Post-mortem examinations in pyopneumothorax cases, however, often reveal extensive cavities in the retracted lung which are surrounded by dense connective tissue, or the lung shows other forms of healed tuberculous lesions, all of which would indicate that in a lung set at rest there is no further increase of a tuberculous process by way of aspiration or of the lymphatics, and that the treatment of tuberculosis of the lung by producing an artificial pneumothorax is therefore rational.

PRESERVATION OF THE PARATHYROIDS IN OPERATIONS UPON THE THYROID GLAND.

OPERATIVE tetany was at one time believed to be due to thyroid privation, and therefore the surgeon feared to remove both lateral lobes of the gland. At

times, however, total excision of the thyroid was survived, and this fact and experiments on dogs led to the belief that the absence of tetany was due to the fact that the parathyroids escaped destruction. This knowledge of the function of the parathyroids, scant as it is, points to the necessity of their preservation, and consequently our plan of operating for various forms of goiter should be modified in conformity with it. With this point in view, Halsted advises a bilateral operation in place of the unilateral operation heretofore practised in cases of colloid or other nonhypertrophic varieties of goiter, while in the hypertrophic varieties he believes the one lobe should be so operated upon that in case of need the other may be subsequently attacked without danger of parathyroid privation. The question then arises how the thyroid lobes may be removed without simultaneous removal of the parathyroids or without destroying the latter. Halsted undertakes to answer this question in the October number of the *Annals of Surgery,* pointing out the necessity of a thorough knowledge of the blood supply and of the location of these little bodies. He states that the glands are usually found near the posterior border of the lateral lobe of the thyroid, more or less in a line with the channel of anastomosis between the superior and inferior thyroid arteries. They are usually situated behind the thyroid, though the superior parathyroid body may be above the upper pole of the thyroid and the inferior in the bony thorax. Each parathyroid is supplied by a special artery, which usually arises from the inferior thyroid, but frequently takes its origin from the anastomosing channel between the inferior and superior thyroid vessels. Few if any direct vascular connections normally exist between the parathyroid glands and the connective tissue envelope of the thyroid.

The best method of removing the thyroid and saving the parathyroids is the operation of ultraligation beyond the origin of the parathyroid arteries. This is often very difficult, for between the point at which the branch giving off the parathyroid artery enters the thyroid lobe and the origin of the latter vessel, there may be hardly room for one fine-pointed artery forceps. If the blood supply must be sacrificed the parathyroid glandule may be transplanted into a remaining piece of thyroid gland. In other respects Halsted's technique does not vary much from that of other operators except that, contrary to the universal custom, he does not suddenly complete the full delivery of the entire gland when the latter is exposed, for fear of causing the rupture of some delicate blood-vessels and consequent staining of the field containing the parathyroid glandules. He prefers to draw the thyroid to the opposite side in order to make ultraligation of the vessels perfectly easy without tearing any of them. He claims that this method requires no more time than any other, and states that in eighty cases of exophthalmic goiter operated upon by him, in only seven instances was one parathyroid removed with the excised lobe.

THE BENZIDIN TEST FOR OCCULT BLOOD.

Since Boas, in 1903, directed the attention of the medical world to the significance of small hemorrhages from the gastrointestinal tract, many methods have been employed to detect the macroscopically invisible blood, among them the Teichmann hemin test, the spectroscopic examination, the guaiac and aloin tests. In 1904, O. and R. Adler described the benzidin test, which was, however, inapplicable for clinical purposes until several modifications were effected. The following method of Schlesinger and Holst seems most practical; feces are ground with distilled water and boiled. While this is cooling a concentrated solution of benzidin is made by using as much benzidin as will go on the end of a knife in about 2 c.c. of glacial acetic acid. About 1 c.c. is poured into a test tube, ten drops of the boiled feces solution added, and the two shaken. To this 1 to 3 c.c. of a 3 per cent. solution of hydrogen dioxide is added and shaken, when, in the presence of blood a green or deep blue color appears. In using this test several precautions must be borne in mind, the benzidin must be pure, and no excess of hydrogen dioxide should be used. Oxidizing ferments (destroyed by boiling), iron salts, potassium iodide, animal charcoal, have given a positive reaction, hence these substances are always previously eliminated before using the test.

In the October number of the *American Journal of the Medical Sciences,* E. H. Goodman publishes the results of a number of experiments made with the benzidin test in Musser's Philadelphia laboratory. In all, he studied 129 specimens of feces, the guaiac, aloin, and benzidin tests being applied to each. The three tests agreed 110 times out of 129. From his studies he concludes that a benzidin test of feces should be made first; if negative we may be sure of the absence of blood, and we need go no further. If, on the other hand, the test is positive, the aloin and guaiac tests should be made, and if these are negative occult blood may be regarded as being absent. A substantiation of the benzidin test is to be regarded as indicating the presence of blood. Hence, a positive benzidin test shows nothing unless corroborated by one or both of the other tests; a negative test, however, is proof of the absence of occult bleeding. In none of his cases was the benzidin test negative and the other tests positive.

After the feces show a positive reaction for blood we can determine whether this is pathological or not by not examining another stool until diet and medication have been regulated; only then can a fair idea of the clinical importance of the test be obtained. Goodman recommends the benzidin test for gastric and urine work as well. Owing to the sensitiveness and simplicity of this test it may well be adopted in every laboratory.

The Absence of the Patellar Reflex.

While one may find in the writings of the older neurologists the statement that the knee jerk may be absent in 1 per cent., or even more, of normal individuals, of late years the technique of eliciting the tendon reflexes by means of such devices as Jendrassik's method, has been so much improved that it is regarded as a matter of the greatest rarity for the knee jerk to be absent in a healthy person. Indeed, so careful an authority as Oppenheim goes so far as to say that the knee jerk is normally always present, and its absence is always of the greatest diagnostic significance. Particular interest attaches therefore to a case reported by Kölpin (*Deutsche*

medizinische Wochenschrift, October 31, 1907), which he describes as one in which this sign was absent in an individual having no organic nervous disease. The patient was a girl of sixteen years, whose heredity was good and whose physical examination was negative except for the fact that the left patellar reflex was absent at all times, while only at some examinations was it possible to get a suggestion of the reflex on the right side. The Achilles reflex, triceps reflex, and plantar reflex were absent, but the conjunctival, pharyngeal, and abdominal reflexes were present in full strength. After a cool bath the plantar reflex could be evoked, but the others remained as before. The patient was examined repeatedly, and every possible care was taken in making the tests to abrogate all inhibitory stimuli. Although she came under observation in order to have her sanity inquired into, as she was accused of incendiarism, no evidences of either nervous or mental disease or of chronic intoxication of any sort were discovered. Kölpin, accordingly, is of the opinion that in some exceedingly rare cases the patellar reflex may be absent without any attending organic disease.

Function of the Pacinian Bodies.

The sensory nerves have several modes of termination, among which are the Pacinian bodies, whose function is variously described in text-books. Some authors claim they are organs for the pressure sense; others deny this, and still others omit saying anything about their function, so that the subject seems to be uncertain. In the *Upsala Läkareförenings-Förhandlingar*, Volume XIII., No. 1, M. Ramström gives us some negative proofs as to their function. He first demonstrated the presence of Pacinian bodies and the course of the nerves in the human parietal peritoneum, and then examined patients on whom a laparotomy had been performed under local anesthesia. He found that the Pacinian bodies did not react to touch or to pressure, no matter whether the latter was light or heavy, whether of short or long duration, and no matter whether the instruments used were hot or cold. He was certain that the nerves leading to the bodies were neither severed nor anesthetized during the operation, and, as large areas were tested, these bodies were surely touched. The only proof that was ever offered of any relation between the pressure sense and the Pacinian bodies was the fact that the latter were found in areas which are sensitive to pressure, but this is certainly no absolute proof, as we experience sensations of pressure in regions of skin free from Pacinian bodies, and, furthermore, we can appreciate pressure by the cornea from which these bodies and dermic organs are absent. These facts and the anatomical findings of Ramström would tend to show that the Pacinian bodies are in no way essential to touch.

The Operative Treatment of Tuberculosis.

Some weeks ago we commented in these columns on a paper by Passler and Seidel, in which these authors discussed the influence of ossification of the cartilage of the upper ribs in the causation of emphysema, and reported several cases in which the operative division of this cartilage had been followed by very satisfactory results. At the same time they showed that the first rib itself was not so difficult of access surgically as had been supposed, and that the operation of dividing it was simple and short enough not to involve any considerable risk. In this connection the authors suggested the possibility of applying the operation to the treatment of early cases of apical tuberculosis, in the etiology of which, according to Freund, Hart, and others, the imperfect aeration due to congenital deformity of the first rib or to ossification of its cartilage plays a considerable part. Hart (*Münchener medizinische Wochenschrift*, October 29, 1907) elaborates this idea and warmly advocates a trial of the operation in suitable cases, even going so far as to suggest that it may be found a serviceable prophylactic measure, though he admits that at present there is considerable difficulty in determining beforehand whether or not the configuration of the first rib or the consistency of its cartilage is such as to predispose to tuberculous infection.

News of the Week.

The Use of the Red Cross Emblem.—Brigadier General Robert M. O'Reilly, Surgeon-General U. S. A., makes public the following resolutions adopted by the Executive Committee of the American National Red Cross at its meeting of October 18: *Whereas*, By international agreement in the Treaty of Geneva, 1864, and the revised Treaty of Geneva, 1906, "the emblem of the Red Cross on a white ground and the words Red Cross or Geneva Cross" were adopted to designate the personnel protected by this convention, and *Whereas*, The Treaty further provides (Art. 23) that "the emblem of the red cross on a white ground and the words Red Cross or Geneva Cross can only be used whether in time of peace or war, to protect or designate sanitary formations and establishments, the personnel and material protected by this convention," and *Whereas*, The American National Red Cross comes under the regulations of this Treaty according to Article 10, "volunteer aid societies, duly recognized and authorized by their respective governments," such recognition and authority having been conferred upon the American National Red Cross in the charter granted by Congress, January 5, 1905, Sec. 2, "The corporation hereby created is designated as the organization which is authorized to act in matters of relief under said Treaty," and, furthermore, *Whereas*, In the Revised Treaty of Geneva, 1906, in Article 27, it is provided that "the signatory powers whose legislation should not now be adequate, engage to take or recommend to their legislatures such measures as may be necessary to prevent the use by private persons or by societies other than those upon which this Convention confers the right thereto of the emblem or name of the Red Cross or Geneva Cross," be it *Resolved*, That the Executive Committee of the American National Red Cross requests that all hospitals, health departments, and like institutions kindly desist from the use of the Red Cross created for the special purpose mentioned above, and suggests that for it should be substituted some other insignia, such as a green St. Andrew's Cross on a white ground, to be named the "Hospital Cross," and used to designate all hospitals (save such as are under the medical departments of the Army and Navy and the authorized volunteer aid society of the Government), all health departments, and like institutions, and, further, be it *Resolved*, That the Executive Committee of the American National Red Cross likewise requests that all individuals or business firms and corporations who employ the Geneva Red Cross for business purposes kindly desist from such use, gradually withdrawing its employment

and substituting some other distinguishing mark. The suggestion is also made that in cases where the name and insignia are used as trademarks, their employment be gradually eliminated within the next three or four years in conformity with the provisions of the Treaty that the prohibition of the use of the emblem and name should be enforced not later than five years after the Treaty becomes effective.

Cigarettes in the Navy.—In his annual report, Surgeon-General of the Navy, Presley M. Rixey, recommends that an order be issued by the Navy Department forbidding the use of cigarettes by all persons in the navy under twenty-one years of age. It is stated that in three months the crew of the battleship *Missouri* (700 men) used 1,500 books of cigarette papers, 1,200 pounds of smoking tobacco, and 37,000 cigarettes. None the less, 48,000 cigarettes and 15,000 pounds of candy, together with 1,000 pounds of navy plug chewing tobacco and 30,000 cigars, have been loaded on the *Culgoa* in the Brooklyn Navy Yard as a part of the canteen supply.

Failure to Register Birth Not a Punitive Offence.—Under instructions from the presiding judge, a jury in the city of Wilkesbarre, Pa., returned a verdict of not guilty in the case of a physician charged with failure to report births under his observation. The defence contended that a busy doctor could not give his time to red tape observances, such as reporting the time of birth, the ancestry of a child, and its name. It was contended that several visits might be required to learn the name of the child, as this is sometimes not decided upon for some time after birth. Besides the act of Assembly provided for no compensation for the registration.

The Use of the Title Doctor.—The Attorney-General of Illinois rendered an opinion November 7, in which he states that an osteopath is not guilty of unprofessional conduct within the meaning of the statute by designating himself "Doctor," and that the Illinois State Board of Health cannot, on this account, revoke his license. The term "unprofessional conduct" is held to mean dishonorable conduct in the practice of one's profession.

A Proposed Cocaine Law in Illinois.—Mr. C. H. Avery of the State Board of Pharmacy of Illinois has introduced a bill in the Legislature to prevent the sale of cocaine to others than physicians. The bill proscribes the illegal sale of cocaine, and also alpha-eucaine and beta-eucaine, and any salt or compound containing any of the foregoing substances or any of their salts or compounds, or derivatives. The only legal sale is on the prescription of a registered physician, which must give the name and address of the person prescribed for and the date the prescription was filled. The prescription can be filled but once, and no copy can be made. Cocaine may be sold at wholesale on the written order of any registered druggist, physician, veterinary surgeon, or dentist, but the package must be plainly marked on the outside, showing what it contains, and the word "poison" must be printed on the package in red ink. The punishment for violation of the law is a fine of not more than one thousand dollars or imprisonment in jail for a term of one year, or both.

Attempted Prohibition in Finland.—The Finnish Legislature, which has nineteen women and eighty social democrats among its two hundred members, has just passed a drastic act for the total prohibition of spirits, wine, beer, and alcohol, which may be kept only for medical and technical purposes, and for the use of Russian troops. Even the use of wine for the communion service is forbidden. No one may keep alcoholic drinks in his house unless he can prove that they were in his possession before the act was passed. The police have full rights of search, and the penalties vary from $20 fine to penal servitude for three years. There is no provision for loss of capital in breweries, distilleries, or private houses. There is said to be no chance for the law to become operative, however, as the Czar's veto is regarded as certain.

An Alcohol Exposition in Munich.—In view of the undoubted value attaching to the tuberculosis exhibitions that are being held in this country, it is interesting to note that an exposition along somewhat similar lines is being conducted in Munich to call attention to the physical and social evils attending the misuse of alcoholic beverages. In addition to plaster casts and pathological specimens illustrating the damage to the internal organs resulting from chronic alcoholism, there are various graphic demonstrations of the alcohol content and relative injuriousness of the different spirituous beverages, as well as charts depicting all sorts of statistics relative to the alcohol question in its bearings on crime, insanity, poverty, disease, accidents, etc.

Reform in China.—On the 15th of the eighth moon there was a burning of opium pipes on the city hill of this city. Several months ago public-spirited citizens formed two societies to aid in suppressing opium smoking. They offered to buy pipes if given up before the seventh moon; offered medicine and services of physicians to those breaking off the habit; opened an industrial school to teach trades to waiters in opium dens; offered to lend four dollars to those who wanted capital for trade. Well, a large number of pipes and other utensils used in smoking were brought in and redeemed, so a day was set for the public burning of these trophies of reform, and a large crowd assembled to witness the sight. First an address was made to the assembly, then a piece of music was performed on an organ, then the fire was applied to the pile of five thousand opium pipes and other utensils, and the services were closed with another address.—Hangchow correspondent of the *Shanghai Mercury*.

Platinum Decomposed?—Dr. Theodore Grosse of Germany is reported as having succeeded, by a combination of heat and electrical discharges, in obtaining from platinum an unknown substance regarded as an element and having none of the properties of platinum.

To Commemorate Army Surgeons of the War of 1812.—Two cannons have been mounted on the site of the battle of Brownstown, near Detroit, occurring on August 5, 1812, and which is now part of the estate of Dr. Hal. C. Wyman. A tablet on the base of one of the cannons has been erected by the Wayne County Medical Society to commemorate Surgeons Roby and Allison, officers in Van Horn's command who were killed in the battle.

Doctor Milliken Honored.—A reception was given on November 8, in St. Louis, by his professional friends to Dr. Kenneth Milliken, former editor of the St. Louis *Medical Review*.

New York Charities Directory.—The seventieth annual issue of this publication shows that there are now in the city 3,500 institutions connected with charitable work. Attention is called to four needs in the field of charity for which it is said no adequate provision has been made as yet, namely,

neighborhood buildings, homes for the aged and infirm, day nurseries, and institutions for the care of consumptives.

Dissatisfaction Among Hawaiian Lepers.—The lepers in the settlement at Molokai and the natives of Honolulu are reported as being very indignant at the action of the health authorities in not permitting the trial of an alleged leprosy cure until its originator has proved his contentions. It is stated that the matter will become an issue between the races at the next election, and that the effort will be made to elect a purely native Legislature.

The Literature of Carcinoma.—The following figures in regard to publications on carcinoma have been prepared by Sticker: Since 1902, 3,395 papers on this subject have appeared. Of these, 1,960 are in German, 607 in English, 549 in French, 113 in Italian, 70 in Russian and Polish, 37 in Norwegian and Swedish, 22 in Spanish, 16 in Dutch, 9 in Hungarian, 7 in Portugese, 3 in Japanese, and 2 in Greek.

Philadelphia Hospital Celebration.—The Association of ex-Resident and Resident Physicians of the Philadelphia Hospital celebrated the twenty-first anniversary of its organization on November 12. In the afternoon the men met in the hospital and were shown over the buildings, and the improvements made in the course of recent years were pointed out. Subsequently an address was delivered in the clinical amphitheater by Dr. L. Chalmers Da Costa, who briefly outlined the history of the institution and related numerous personal reminiscences. This was followed by a reception and collation on the part of the resident staff. In the evening a smoker was held at the University Club.

Jewish Hospital of Brooklyn.—At the meeting of this organization held last week it was announced that since the opening of the hospital on December 17 of last year, there had been 1,544 applicants for admission and 1,112 patients had been admitted. Preparations are under way for the building of an additional wing for a nurses' training school.

St. John's Guild Convalescent Hospital to Close.—Owing to lack of funds, the managers of St. John's Guild have decided to discontinue the convalescent home at the Seaside Hospital, New Dorp, Staten Island.

Mount Maria Hospital.—The cornerstone of the new Mount Maria Hospital, at 138-140 Second street, was laid last week. The hospital will have a capacity of seventy regular beds and ten children's cots. It is expected to be ready to receive patients in a few months.

Medical Inspection of Chicago Schools.—During the months of September and October, 126,790 medical inspections of school children were made by the Chicago Health Department, and of this number 3,335 were excluded from schools; 341 bacterial examinations and 12,803 vaccinations were made.

Quiet Zones in Chicago.—The Chicago City Council recently passed an ordinance, similar to the one passed last spring in this city at the instance of Mrs. Rice, establishing "zones of quietude," extending 250 feet in all directions from each hospital. Within that area "the making, causing, or permiting to be made of any unnecessary noise, or the playing of itinerant musicians on the public streets, avenues, or alleys, that disturbs, or that may tend to disturb the peace or quiet of any of the inmates of the hospital," is declared to be a nuisance. For violation of this ordinance, a fine of from $2 to $50 is provided.

Officers of the Military Tract Medical Association.—The following officers were elected at the sixty-eighth annual session of this Illinois Association, held at Bushnell, October 17 and 18: *President,* Dr. Samuel C. Stremmel McComb; *Vice-President,* Dr. Ernest E. Davis, Avon, and *Secretary-Treasurer,* Dr. Ralph C. Matheny, Galesburg. Peoria was selected as the place of meeting in 1908.

Rolla (Mo.) District Medical Society.—At its meeting held in Rolla on November 9, this organization elected the following officers: *President,* Dr. G. A. Herzog of Cuba; *Vice-President,* Dr. E. L. Hume of Bourbon; *Secretary,* Dr. W. H. Brewer of St. James.

Holyoke (Mass.) Medical Association.—Officers as follows were elected at the meeting of this society held in Holyoke on November 6: *President,* Dr. R. E. Dickson; *Vice-President,* Dr. George L. Taylor; *Secretary and Treasurer,* Dr. H. R. Sackett.

Cheshire Co. (N. H.) Medical Society.—The annual meeting of this society was held in Keene on October 29, and officers for the coming year were elected as follows: *President,* Dr. A. H. Childs of Dublin; *Vice-President,* Dr. A. A. Pratt; *Secretary and Treasurer,* Dr. William Robb.

Obituary Notes.—Dr. Franklin Bonney of Hadley, Mass., died on November 9 at Ashmont, at the age of eighty-five years. Dr. Bonney was born in Hadley, and was sixth in descent from Thomas Bonney who settled in Duxbury in 1634. He received his medical education at Dartmouth College, from which he was graduated in 1847. He at once began to practice in Hadley, and had continued in active work until he retired three years ago on account of advancing years.

Dr. Thos. H. Holgate of this city died on November 14 of lobar pneumonia, in the seventy-seventh year of his age. Dr. Holgate was born in Leeds, England, in 1831, and came to the United States fifty-two years ago. He began the practice of medicine at Cairo, Greene County, N. Y., where he remained for several years, having built up a large country practice. He was licensed by the Greene County Medical Society in 1867. In the year of 1869 he was graduated from Bellevue Medical College and since that time practised his profession in this city. He was physician to the Out-Patient Department of Bellevue Hospital for twenty-three years. At the time of his death he was a member of the Academy of Medicine and of the State and County Medical Societies. One daughter survives him.

Dr. D. M. Parker of Dartmouth, N. S., died on November 5, at the age of eighty-five years. He was a graduate of Edinburgh University, and had practised in Nova Scotia for over fifty years. He was made a member of the Legislative Council in 1879, and continued to hold this office until failing health compelled him to give up his seat about ten years ago. He also occupied many public and professional offices, including the presidency of the Dominion Medical Association.

Dr. George H. McGeer of San Francisco died on October 31, at the age of thirty-three years. He was born in Auburn, N. Y., and after living for some time in Tacoma, Wash., received his medical degree from Cooper Medical College, and began practice in San Francisco.

Dr. Robert Disbrow of Boston died suddenly on November 9, at the age of sixty-five years. He was born in St. John, N. B., and was graduated from Harvard Medical School in 1865. He was assistant surgeon with the 109th U. S. Colored Infantry during the Civil War.

THE HARVEY SOCIETY LECTURE.

The second lecture of the present series given by the Harvey Society was delivered at the Academy of Medicine on Saturday, November 16. The speaker, Prof. James Ewing of this city, took for his subject "The Etiology of Tumors," discussing principally the etiology of cancer.

There were three principal views as to the etiology of malignant tumors, namely the parasitic, the view based on cell autonomy, and the modern biochemical one. He would discuss these in the order named. The advocates of the parasitic view had always spoken much of the contagiousness of cancer, and pointed to so-called cancer houses, to cancer in various members of the same family, etc. There were also the observations on the endemic occurrence of these tumors. It was known that a form of cancer was frequent in aged domestic animals. However, there was no evidence to show that these tumors were really contagious. Thus, working with transplantable mouse tumors, Bashford, who had observed over 30,000 mice, had seen nothing pointing to a cage infection. Attention had also been called to the peculiar tumors affecting fish. In trout, for example, a kind of cancer often affected large numbers of the fish in breeding pools and other ponds. However, it was probable that inbreeding and changes in the composition of the water were at the bottom of the trouble. Other authors had been positive that cancer was largely on the increase in cities, that the disease was water-borne, etc. But careful examination of all these statements had disclosed numerous fallacies. In order to determine whether cancer could be transferred by contact, some French surgeons had even gone to the extent of inoculating themselves with bits of cancer tissue, but with negative results. Inoculation from man to man, spontaneously, probably never occurred. Experiments made to determine whether human cancer was inoculable into lower animals had mostly had negative results. Most alleged successful results did not, as a rule, stand scientific criticism. However, in one or two instances, which the speaker described, there seemed to have been a successful transference from man to rats. The experiments which had been made to inoculate higher monkeys with human cancer had failed. However, it must be remembered that inoculability proved nothing as to etiology of the disease, *i.e.* as to the nature of the infecting agent.

Because of this, a number of observers had sought to demonstrate the cause of cancer directly. And this, the speaker said, was one of the most chaotic chapters of medical research. The number of "cancer bacilli" or other cancer germs, was something astounding. He had compiled a partial list of the various germs described; it began with the bacteria, took in coccidia, sporozoa, blastomyces, mycetozoa, and recently the spirochetes had also been charged with the origin of cancer. One thing stood out in studying these various "cancer germs," and that was the fact that most of the observers had substituted easy credulity for critical common sense. It was curious, too, that a number of the "discoverers" had found eminent biologists to back up their claims. Even Metchnikoff had favored one of the cancer germs. Most of the discoverers in recent years had fixed their attention on certain peculiar cell inclusions. These were of all shapes and sizes, and had long been known. In fact, Virchow had distinctly warned against certain of them being mistaken for parasites. Finally, the upholders of the parasitic nature of these inclusions had pinned their faith on a peculiar type of inclusion. This was the so-called "bird's-eye" form. But this, too, had not been able to withstand scientific criticism, and had been abandoned. Some of the forms of inclusions looked much like plasmodiophora, and attention was thereupon called to the peculiar swellings often found in certain plants. These swellings, which were associated with *Plasmodiophora brassica* were erroneously called tumors. As a matter of fact, there was not an increased number of cells, but merely a distention of certain cells. Hence there was no analogy with cancer. So far as the blastomyces were concerned, it would suffice to say that these were not present in all tumors by any means. Furthermore, the distribution and numbers, when present, did not bear out the belief that they had any causative part. Some years ago, Gaylord and Calkins had found one particular kind of spirochete in ten consecutive cancers in mice. Gaylord believed that the number of the organisms corresponded to the virulence of the tumors. Subsequently, however, the spirochetes were shown to have no etiological significance. Certain of the cancer germs had been found only in cancer and in smallpox. But these diseases were so dissimilar that it was difficult to think that the germs should be very similar. However, despite all the failures in the search for cancer germs, it was not necessary to drop all conceptions as to a connection between neoplasms and microorganisms. The relation, however, should then be regarded as a secondary one, cancer arising for example after an infection with *Spirochæta pallida* as was sometimes seen on the tongue.

The speaker then exhibited lantern pictures illustrating a large number of the "cancer germs." These included the Ruffer and Plimmer bodies, those of Pianese, of Cattle, and of Ross; the club root due to *Plasmodiophora brassica*, the vaccine bodies, measles bodies, and others.

The speaker next discussed the theory of cell autonomy as applied to the development of tumors. It was not a finished theory; not the product of one mind; nor was it popular. It had the great merit, however, of becoming more satisfactory the more it was studied. It was first clearly enunciated by Cohnheim in 1874, who referred tumor formation to misplacement of embryonal cells and their subsequent development. The whole question was one of the mechanics of development. The theory of Cohnheim had its deficiencies, among which was the fact that these misplaced embryonal cells could not be demonstrated. Ribbert modified the theory somewhat, and introduced the idea of tissue-tension. According to him it was not necessary that the cells be embryonal; disturbances of tissue tension sufficed to make the cells lose their restraint and grow wild. In discussing tissue tension, the lecturer said there were four principal forces, of which three were physical. They were (1) mechanical pressure, (2) distribution of nutriment, (3) demands for function, and (4) organization. Under the last named, the speaker gave various examples of regeneration, and also spoke of the interdependence of the tissues, or the "altruism of the tissues," as Councilman had termed it. Then briefly the evidence was reviewed, showing that in the study of tumors the question of the mechanics of growth was involved. To be sure, even if one accepted the theory of cell autonomy, the admission of an external stimulus as a cause for the altered tissue tension would still carry with it the necessity for admitting that this stimulus might come from a cancer parasite. However, this conclusion need not give much concern, for it meant a parasite

which, instead of destroying, stimulated the host cells to enormous growth—certainly a curious phenomenon. The speaker also pointed out a number of other difficulties in the way of acceptance of the parasitic theory.

The past five years had seen an enormous amount of work done on the biochemical study of tumors. The principal names associated with this line of research were Ware, Hanan, Loeb, Jensen, Borel, Ehrlich, Michaelis, and Gaylord. These studies were based largely on the transplantability of tumors in mice. Parenthetically, the speaker would remark that this was not an infection, but a transplantation, and could not therefore be brought forward as evidence of a parasite. In transplantation, initial success was the exception. After a time, however, the tumor seemed to become more virulent, *i.e.* there were more "takes." But this was relative. Ehrlich's highly infected tumors were so only for Berlin mice. Tested on Copenhagen mice, the number of takes was no greater than usual. When the Berlin mice were taken to Denmark and bred there, they became less susceptible to the tumor. This indicated that some factor, perhaps food, played a part in this susceptibility. In the case of mouse tumors some of the animals seemed to recover entirely, and this had been interpreted as an immunity. But the point was not entirely clear. This observation had also led to attempts to increase the immunity by means of "vaccination" treatment. In some of his mice, Ehrlich had observed what he spoke of as "panimmunity." This, however, was a very suspicious phenomenon. It was probable that other factors were here concerned. Michaelis had examined the serum of mice which were immune. Although it was found that the injection of such serum into another animal was followed by the regression of the tumors, the Bordet-Gengou test showed no amboceptors in the serum.

The speaker closed by saying that for the present he saw no reason to discard the theory of cell autonomy. Certainly the other theories offered nothing as a substitute at all comparable with it.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL SERVICE FOR THE TERRITORIAL ARMY—TUBERCULOSIS, MEETINGS AT EDINBURGH AND DUBLIN—THE ROYAL SOCIETY OF MEDICINE, ITS ORGANIZATION, ETC.—HOSPITALS—SANITARY DIFFICULTIES AT THE DOCKS.

London, November 1, 1907

The Director-General of the Army Medical Service, Sir Alfred Keogh, attended a conference in Manchester last Friday for the purpose of considering the medical arrangements for the new territorial army. It is intended to provide general and stationary hospitals with a staff of nurses and to invite the assistance of the staffs of our civil hospitals. Moreover, many medical and sanitary officers will be required for regimental and field work. Dealing with the defects of the present volunteer service, Sir Alfred said there was no provision for the sick, no field ambulances, and no field hospitals worth speaking about. He proposes to consolidate the corps in certain districts and appoint principal medical officers in each. In Manchester and Liverpool territorial army hospitals would be established to which the sick could be taken in case of invasion. He asked medical men to join these hospitals and sanitary officers of the county to join the sanitary department. The meeting approved of the scheme and promised Sir Alfred Keogh all possible support. The subject is also to be submitted to the profession in London, for Sir Alfred will attend a meeting of the Royal College of Physicians to which the staffs of hospitals and volunteer medical officers will be invited to discuss all questions in connection with the medical service of the new territorial force. The president of the college will take the chair, supported by the president of the College of Surgeons. The Director-General has also engaged to read a paper next week at the Society of Medical Officers of Health on disease prevention in the territorial army, when he will no doubt expound his scheme and its relation to these officers. Mr. Haldane, War Secretary, hopes to be present at this meeting.

Mr. Balfour went to Edinburgh on Friday and opened a new wing of the Victoria Hospital for Consumption there which was founded in 1887 as a memorial of the late Queen's jubilee. The professoriate of the universities and leading citizens were fully represented. Mr. Balfour said they could not withhold their wonder at the progress of medical science in this department. What was the essence of Koch's discovery? It showed that like many other diseases tuberculosis was the result of the invasion of a small organism. He supposed they might divide the methods of treatment into three: First, some form of inoculation as so long used against smallpox; second, diminishing the danger of infection; third, taking those attacked and restoring their power of resistance, so that they could shake off the disease. This last was the object of sanatorium treatment, and he thought they would never be able to deal adequately with the matter until they got into the popular mind the distinction between the methods of dealing with the disease, not attempting to do in a sanatorium what could only be done in a hospital, or in a hospital what could only be done in a sanatorium.

The movement in Ireland against tuberculosis is gathering strength and, as Mr. Balfour supported it in Scotland, the Chief Secretary, Mr. Birrell, received a deputation in Dublin from delegates of County Councils to urge that government should contribute towards the maintenance of inmates of a sanatorium and should make notification of the disease compulsory. Mr. Birrell was gratified to find the public bodies devoting attention to the matter. There were some workhouses in isolated healthy places which he thought could be utilized for sanatoria. He approved of notification. He was willing to represent the needs of the case to the treasury, not in the form of a demand on the ground of overtaxation in Ireland, but on the ground of humanity and the necessity of the case. The treasury could not by a stroke of the pen assume the responsibility of providing sanatoria, but would require the local authorities to contribute. He would endeavor to get an extension for the repayment of loans by municipal bodies. He hoped for the aid of all gentlemen of position in Ireland in waging the war begun against the shocking state of things that existed.

The Royal Society of Medicine being, with its sections, now in working order, it may interest your readers to have some particulars of the result of the amalgamation. The arrangements, as finally adopted, are a little complicated, and as many inquiries have been made an official statement has been prepared. The Royal Medical and Chirurgical Society, familiarly known as the Medico-Chi., was founded in 1805, and its "Transactions" are well known to serious students of the progress of medicine during the last century. It is that society which has now incorporated by royal charter (1907) fourteen others which were founded at various dates from 1846 to 1902. These fifteen societies then have united under the name of the "Royal Society of Medicine." It is almost a pity they did not take the name of academy instead of society, which would have brought them into line with so many foreign institutions. But that matter is settled with many others, and it only remains for all to pull together and forget the differences which have rendered the negotiations so protracted. The new society has established already thirteen sections, and it is intended in the near future to add to their number so that every department of medicine may have its separate section.

The thirteen sections, you will understand, represent separate societies which have joined in the amalgamation. These sections are: 1, clinical; 2, dermatological; 3, electrotherapeutical; 4, epidemiological; 5, laryngological; 6, medical; 7, neurological; 8, obstetrical and gynecological; 9, odontological; 10, otological; 11, pathological; 12, surgical; 13, therapeutical and pharmacological.

Each of these sections is autonomous and will hold meetings of its own, but in addition there will be from time to time joint meetings of various sections to discuss subjects which are of less specialized interest or which interest a certain number of sections only. One of these joint sectional meetings has already been held. The society as a whole will meet to discuss matters of general medical importance.

Fellows of the Royal can attend all the meetings of the society or any of the sections and take part in the discussions, but are not to vote in any section to which they have not been elected; they may be elected to any section without additional fee; they are entitled to the "Proceedings" of all sections as issued; they can vote on the busi-

ness of the society, and are eligible for election to the council. But perhaps the most highly prized privilege is the full use of the valuable library, which contains nearly 80,000 volumes and the Fellows can take out books to study at home, which is not the case at any other medical library. The privileges of a member of a section are, besides a full share in his special section, to receive the "Proceedings" of all sections and obtain the use of the library on payment of a guinea a year. The subscription to his section is one guinea and for any additional section half a guinea. The subscription of Fellows is three guineas per annum, including everything. That these arrangements will prove satisfactory on the whole is probable, though there are some misgivings and as you know the amalgamation does not include all our societies. There is a good prospect, however, that the Royal will maintain the premier place.

Dr. A., an enthusiast in favor of the organization, descanted at length to me on the advantage of concentration in a central position, enabling him to attend any meeting that interested him. But Dr. B. retorted, "That is very well for you, as you live within a few doors, but for one living at a distance it is bad, and it takes away the meetings I was able to attend." This is no doubt a reason why the distant societies will be able to hold their own, but it does not apply to two or three which are not far from Hanover Square.

The editors of the "Medical Directory" were at first in a quandary how to deal with the numerous changes necessitated by the amalgamation. They have notified that they will insert abbreviated entries as follows: Fell. Roy. Soc. Med., or Mem. Sect. Roy. Soc. Med. I should have thought further abbreviation or omission desirable, for the bulk of the Directory is always increasing and it has become a very unwieldy volume. But it appears many people think well to parade all their societies—I have noticed some put among their distinctions "Memb. Brit. Med. Ass." They might as well add subscriber to the *Lancet* or MEDICAL RECORD, or member, or better still, "Right Worshipful Master" of the "Odd Fellows," or "Ancient Friends."

Princess Christian presided yesterday at a meeting to promote the project of a new King Edward VII Hospital at Windsor to take the place of the present infirmary. The King will devote the Castle Apartment Fund of £400 and in addition subscribe £100 annually to the building fund. The supporters of the infirmary are in favor of a new hospital and the two committees are ready to amalgamate. It was resolved to proceed with the building forthwith.

Princess Henry of Battenberg opened on the 26th ult. the new children's block of the Rugby Hospital.

"Ye Olde Camberwell Fayre" is now being held in aid of the removal fund of King's College Hospital. It is a revival of the famous fairs held on Camberwell Green which were discontinued in 1855. Old English booths with lattice windows are placed against a background of scenes of the local rural beauty before the advent of trams and other modern enormities. The stall holders are in costume. Interesting relics of old times in the neighborhood have been brought together to stimulate the curiosity of the visitors, who can purchase memorials of a modern kind in "Ye Olde Fayre." The Duke of Connaught accompanied the Duchess to open the Fayre on Tuesday. His Royal Highness, as president of the hospital, declared he was very anxious to see the removal. The people of Southwark had that day sent £108 for the building fund—a happy omen of the spirit in which this effort to promote the fund was met. On Wednesday the Duchess of Somerset and on Thursday Mrs. Kleinworth performed opening ceremonies.

At an inquiry held in consequence of an application by the Port of London authorities for increased sanitary powers, the condition of the docks was referred to. The Medical Officer of Health for the port (Dr. Howard Williams) said he could not enforce necessary improvements at the Albert docks, where the sanitary arrangements were very bad, and the other docks were also in an unsanitary state. His powers were limited by overlapping with borough councils. As an example of his difficulties, he said that on one occasion he asked the master of a vessel to kill a pig which was a mass of sores. He refused to do so until he got out to sea, when he said the crew would have to eat it. Had the port authority possessed the powers now asked for that pig would have died a different death.

Trained Nurses for the Navy.—Surgeon-General Rixey is formulating a plan to improve the facilities for the care of sick sailors in the Navy by increasing the number of trained nurses in the service. Afloat the nurses will be men, but in the navy hospitals ashore these are to be women.

OUR PARIS LETTER.

[From Our Special Correspondent.]

PROSTATIC ABSCESS—URETHRAL POLYPS—COLLOIDAL SILVER—PROSTATECTOMY—ENDOVESICAL TREATMENT OF BLADDER TUMORS—RENAL TUBERCULOSIS—NEPHROLITHIASIS—BIER'S METHOD—AN IMPROVED CYSTOSCOPE.

PARIS, October 15, 1907.

THE eleventh session of the Urological Congress has been held in Paris under the presidency of Escat of Marseilles, owing to Professor Guyon's absence on account of a recent bereavement. The chief subject for discussion was the pathology and treatment of non-tuberculous abscesses of the prostate. The first speaker was Oraison of Bordeaux, who said that prostatic abscesses formed as the result of two principal factors, which were, first, circulatory disturbances, and, second, penetration by pathogenic agents which might effect an entrance into the organ either spontaneously or as the result of traumatism. The urethra was the most frequent source of infection, but this might also occur from the exterior as the result of an injury to the intestine or some other point of the body in consequence of a general infectious disease. The treatment of prostatic abscess should above all be prophylactic, which required an energetic treatment of acute or chronic urethritis, intestinal or bladder affections, and acute or chronic prostatitis. When suppuration had commenced three routes were open to the surgeon, the urethra, the rectum, and the perineum. Evacuation through the urethra deserved special mention; to effect this it was necessary only to massage the prostate and use irrigations once or twice daily. The procedures were simple and should be resorted to in all cases of moderate severity. The rectal route was excellent, as the abscess often pointed in this direction. A speculum should be introduced and the incision be made under ocular control. The perineal method was more difficult and demanded special anatomical knowledge. It involved the danger of perineal fistula and also jeopardized the ejaculatory ducts. The speaker, therefore, preferred the rectal operation and practised the latter only in long standing or complicated cases.

An animated discussion followed the reading of the paper. Albarran was an ardent advocate of the perineal operation as opposed to that through the rectum, preferring it both for the acute abscesses and in cases of less intensity. Hamonic, on the other hand, considered that the rectal operation was much superior.

Nogués then presented a paper on the symptomatology, prognosis, and treatment of urethral polyps. These, he said, might be simply fleshy outgrowths or true papillomas; that is, benign tumors.

Hamonic reported the results he had obtained by the use of colloidal silver in affections of the urinary passages. While these had not been very favorable on injecting the remedy into the urethra and bladder, he had met with much more success in disorders of the testicle, the epididymis, and the prostate. In these cases he injected the colloidal silver directly into the diseased tissue. He described the improvement produced in gonorrheal epididymitis and in tuberculosis of this structure and the prostate. In treating the prostate in this way he placed the patient in the knee-chest position, exposed the anterior wall of the rectum, and punctured the gland at its most diseased point.

Pauchet of Amiens reported on the results obtained by transvesical prostatectomy. He considered Frever's operation the method of choice. He enumerated the complications that might result from this operation; these were orchitis which could be avoided by resection of the vasa deferentia, and fatal general infection which occurred in operating on infected individuals and was best avoided by operating in two stages. This was done as follows: At the first stage cystotomy and resection of the vasa deferentia, and at the second, performed three or four weeks later, the actual prostatectomy could easily be effected.

Georges Luys described the results he had obtained in the treatment of tumors of the bladder by means of his direct vision cystoscope. After having set forth the indications for this method of treatment, which was especially suitable for small vesical papillomas, he pointed out its advantages, which were its freedom from danger and effectiveness. He cited two cases, one that of a man with recurring vesical papilloma and the other that of a woman with a malignant new growth, in both of which excellent results had been obtained by this method. He then pointed out the contraindications to the endovesical treatment of new growths and described in detail the method of carrying it out in suitable cases by means of the direct vision cystoscope of his invention.

Albarran reported the results of his experience with lesions of the kidney of the opposite side in unilateral

tuberculosis. He said that in these cases the disorder was nearly always the simple albuminuria of the tuberculous. It was a common observation to discover that the urine of the kidney on the side opposite to the tuberculous organ was heavily loaded with albumin. After the diseased organ had been removed the albuminuria usually disappeared within three or four months, provided that it had not been too pronounced before the operation. In some cases, however, severe albuminuria persisted for years. In spite of this the kidney had good functional capacity and the patients did well. In brief, the tuberculous kidney might influence the organ of the opposite side through reflex action, through the excessive amount of work it was called upon to do, through its microorganisms, and through its bacterial toxins. Simple albuminuria in the second kidney did not contraindicate nephrectomy. The prompt extirpation of the focus of renal infection was the best safeguard for the other kidney.

Legueu spoke on bilateral nephrolithiasis. He said that in nearly all of these cases the diagnosis was made by radiography. If the bilateral character of the affection had been established it was necessary to operate on both sides, but at different times. The better kidney should be treated first, in the first place because the operation protected it, and secondly, when operating on the second organ at a later date it was possible to carry out any procedure that might seem desirable, even nephrectomy.

Arcelin and Raffin of Lyons presented the results they had obtained in nephrolithiasis by means of radiography. The statistics obtained in cases operated on under *x*-ray control showed that the results were intimately connected with two conditions, the asepsis or infection of the kidney and the bilateral nature of the lesion.

Frank of Berlin spoke on Bier's method of treatment with suction cups and said that it gave excellent results in the treatment of inguinal adenitis. Very remarkable results had also been obtained in cases of genitourinary tuberculosis. He also described an ingenious improvement in the prism cystoscope. It is well known that the ordinary Nitze cystoscope has the drawback of inverting the image, but Frank has overcome this difficulty and with his instrument the picture is seen right side up. By improving the optical equipment he has also succeeded in increasing the field of vision and rendering it more brilliant.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 7, 1907.

Experience with Opsonins and Bacterial Vaccines in the Treatment of Tuberculous and Nontuberculous Arthritis.—The experience of C. F. Painter is based on nineteen cases, detailed in the paper, and selected from a larger number treated. The results of treatment were rather discouraging. He notes that it has not always been possible to carry out some of the conditions imposed by laboratory investigators. It may be that cases have been treated with vaccines made from organisms having no possible kinship to the organisms originally present in the patient, though the opsonic findings have pointed that way. Again it may be possible that some of the conditions treated were not originally caused by an infective agent. These and many other obstacles stand in the way of drawing conclusions from the results of the first year's clinical experience. A good many more cases were treated and tested than have been recorded here, but those selected for report were chosen because they covered the types of cases most satisfactorily. It would have been possible to select a group, perhaps an equally large one, where the conformity of the opsonic and clinical findings would have been entirely favorable to this new method of study. So in the matter of treatment, typical opsonic charts might have been exhibited corresponding to remarkable degrees of clinical improvement. The writer believes the danger of expecting too much from an untried method is greater than that of expecting too little, and is desirous of encouraging the continuance of trials now going on in the laboratory provided they can be checked by unbiased clinical observation.

Serum Treatment of Exophthalmic Goiter.—F. S. Bardeen gives a careful review of the literature of this subject and reports one personal case in which the serum gave very doubtful results. In this case, goiter slight or absent, tachycardia and tremor well marked, exophthalmos absent, and the other symptoms those usual in such cases. The thyroid was palpable and visible, but at the same time was no larger than is common in many healthy women. Thyroidectin was used in increasing doses. For a time it seemed to be of some benefit, but this effect was soon lost, in fact, it seemed to aggravate the symptoms. Later, Moebius' serum was tried with practically the same results. Quinine hydrobromate was used for about five months, in doses just under that necessary to produce cinchonism. It seemed to give positive results. The author notes that in the majority of reported cases not enough details are given to enable the reader to judge of the probability of cure or permanency of results. He sees no certainty of even the palliative action of the serum. The assertion has been made that the sera occupy the same relation to exophthalmic goiter that thyroid extract does to myxedema, but we can hardly accept this statement on the basis of the evidence furnished.

New York Medical Journal, November 9, 1907.

Modern Lithotrity.—In a series of paragraphs numbered from one to fifty-eight, J. W. S. Gonley reviews the literature of lithotrity and the development of the crushing operations for vesical stone. The indications for this operation are that the stone be free, frangible, and of small or medium size. Plurality of stones is no contraindication. Urethral stricture is no contraindication provided the canal can be freely dilated or even enlarged by internal incision. A narrow resilient stricture in the perineum, especially if of traumatic origin, demands external section. Lithotrity may be done in multiple short sittings, in one or two sittings, or one prolonged sitting. Each case must be decided on its own merits in this respect. The modern operation requires an irrigation apparatus, flat-bladed, fenestrated and spoon lithotrites, apparatus for detritus aspiration, special combined crusher, and evacuating catheter, and alligator-jawed forceps. The author details the various steps of the operation and calls special attention to the fact that the surgeon's work is not finished with the evacuation of the last fragment of the stone. The consequences of the operation must be remedied and such active measures taken as are required to prevent a recurrence of the calculous disease. In a general way the author has not employed any form of anesthesia in his operations. In children under ten years, perineal lithotomy is the safer operation. The various paragraphs of the paper contain many practical suggestions which cannot well be abstracted.

Tuberculotherapy in Tuberculosis.—F. W. Forbes-Ross presents as the main proposition of his paper the following: "To deliberately and wilfully procure and use as an article of diet for tuberculous persons the raw flesh (beef) of animals known to be affected by tuberculosis, with the object of bringing about artificially that which I firmly believe occurs unobserved in native and in actual daily life among healthy persons." In other words, on such a diet a patient manufactures in his own body those substances which so fortify his system as to oppose the ravages of tuberculous disease. Ross believes that raw or undercooked meat contains the toxins and antitoxins of the animal, in proportion as their blood serum has had the power, and the muscular tissue and blood serum of a tuberculous animal are the main sources of that animal's resistance, and so their flesh possesses immunizing qualities, hitherto not deliberately used to cure the disease. Under present circumstances of meat supply in England, says the author, most persons from time to time partake of meat from a tuberculous animal, and so the habitual meat eaters (underdone) obtain toxins and antitoxins, and so keep up their opsonic index for tubercle and remain immune to both bovine and human tubercle on the vaccinia principle. This is the analogue of feeding with raw thyroid gland for myxedema. The milk-consuming infant, on the other hand, does not obtain in milk anything else than milk, pus organisms, and their toxins, and tubercle bacilli galore. Milk is a secretory degenerative compound derived from mammary cells. Secreting glands have not been shown to produce or contain antitoxin. Milk feeding then confers no acquired immunity from bovine tubercle and so on to immunity from human tubercle. The raw, or partially cooked, meat eater obtains a maximum of stable nutrient nitrogenous food and antitoxin, protective bodies and a minimum of tubercle bacilli; but the milk consuming infant and old person obtains only a nitrogenous food of less nutritive value, together with a maximum of tubercle bacilli (that is, if both meat and milk are partaken and derived from a tuberculous animal), and no antitoxin or protective bodies. Healthy meat eating adults can (and do) with impunity, moreover, partake of unsterilized tuberculous milk from all sources carelessly; whereas infants run a great risk of tuberculous infection from the same milk. It is far better to feed a phthisical patient on raw meat from tuberculous cattle than on pure milk absolutely sterilized and free from tubercle bacilli.

Asphyxia Neonatorum.—A general description of this condition is given by I. L. Hill, who follows the procedure herewith laid down: As soon as the head is born, swab out the pharynx with the finger wrapped with gauze

and squeeze the contents from the nose. After delivery invert the child. Slap its buttocks and back briskly a few times, dash a little cold water upon it and blow into its face. Perform Prochownik's compression of the chest for a half minute. Suck out the mucus from the pharynx of the child with a catheter having a pipette. Blow into the child's mouth, compressing the trachea and pressing gently on the stomach. Now ligate or clamp the cord and cut it. Transfer the child at once to a large tub containing eight inches of water at 108° F. Listen to the heart beat so that improvement or retardation later may be estimated. Perform Byrd's method of artificial respiration without inverting the child at the end of expiration. From time to time mucus should be wiped from the nose and mouth as squeezed out from the air passages. While Byrd's method is being done an assistant if present should make rhythmic traction on the tongue. This can be done readily without interrupting the Byrd treatment. The operator can readily pass the index finger of the left hand into the rectum and from time to time this should be done. After four minutes, if previous injury does not contraindicate, remove the child from the tub and perform Schultze's method for a minute, giving ten swings in that time. By this time, unless the case is a very bad one, some signs of restoration of breathing are usually present. If the infant has improved in color and started breathing, however weakly, return it to the hot water, massaging its breasts, and watch the efforts at breathing. If this is shallow, plunge the child into a tub of cold water for a second. If the breathing improves, the case is doing well and Byrd's method in the tub with an occasional reflex stimulation by stretching of the anus will soon bring about satisfactory breathing. All the reflexes now being good, a dip into cold water and a few slaps will probably cause a genuine cry. Continue the Byrd method, however, timing the movements of inspiration and expiration with the child's until both sides of the chest expand well. Hypodermics of brandy may be necessary. Care must be taken to keep the child uniformly warm after it has once begun to breathe. If atalectasis is present, injury to the vasomotor or respiratory centers, intracranial hemorrhage, or anomalies of circulation due to persistent fetal features, death may result in spite of every care.

Treatment of Snake-Bites as Seen in the Jungle.—Speaking of his personal experience in Siam, C. S. Braddock, Jr., says that his usual course was to cut deep into the tissues, causing free bleeding. A tourniquet between the bite and the trunk of the body, some distance away from the bite, keeping it on tightly for an hour at least. Pure crystals of potassium permanganate were rubbed into the wound, and the wound packed with the same. A ring of punctures was made around the wound with a hypodermic needle and a strong solution of permanganate was forced into the tissues all around the wound at a distance of an inch or so, so as to make a dam to counteract any poison partly absorbed. Then the wound was washed out freely with a strong permanganate solution. Nitroglycerine and digitalis were given in heroic doses, as in a few minutes the pulse falls rapidly, also brandy and whisky in half pint doses and strychnine hypodermically in large doses. With these remedies close at hand, he was very successful in saving life.

Journal of the American Medical Association, November 16, 1907.

The Criminal Responsibility of the Insane.—Morton Prince discusses the subject of the criminal responsibility of the insane, pointing out that the law in this matter, as it exists in this country, is still largely the common law. He gives the history of the famous answers of the English judges which still form the basis of the law in this country and Great Britain, analyzes them and shows their incompleteness and defects. When the defense of insanity is set up, the most sensible procedure would be to commit the accused to an asylum, still under the control of the court, for observation. If found insane and there still remained a question as to his responsibility, he would have the full observations of those who have carefully followed the case in the asylum submitted to the jury and this should be allowed to determine the question for itself. Or the California plan of statutory exclusion or responsibility in proven insanity could be adopted. In the vast majority of cases, Prince holds, those who are found clinically insane will also be found morally irresponsible.

Alcoholic Insanities.—A. Gordon comes to the conclusion that the so-called alcoholic mania, melancholia, paranoia, etc., do not exist, and that even the delusions of marital infidelity, considered characteristic of a type of insanity due to alcoholism, were found by him in only a comparatively few cases. His conclusions are stated substantially as follows: Alcoholic insanity presents certain special characteristic features that usually distinguish it from other analogous conditions. Acute cerebral alcoholism presents three states: delirious, confusional, and stuporous, the intensity of which varies according as we have to deal with a subacute form or with delirium tremens. The chronic alcoholic insanity tends inevitably to dementia, and may or may not be attended in its course by delusions, hallucinations, and illusions. If the latter symptoms sometimes suggest other psychoses, the resemblance is only apparent, as will be demonstrated by closer observation. If the special symptoms of cerebral alcoholism occur in individuals affected with other psychoses who happen to commit excesses this must not mislead us to suppose their existing insanity is due to such excesses. The conception of alcoholic mania, melancholia, paranoia, or paresis is unscientific and not based on accurate observations.

Intravenous Treatment of Syphilis.—G. F. Lydston reports his experience in ten cases with the intravenous mercurial injections which give him a very favorable opinion of the method in the treatment of syphilis. While he does not claim that it should be used in a routine way, in all the cases in which he employed it, its action was superior to any other method in his experience. In malignant cases and those seriously menacing the integrity of the nervous system or viscera, its advantages, he thinks, are manifest. The speedy mercurialization of the blood and prompt systemic action, the relatively large doses permitted, the comparative freedom from pain, and, in general, the absence of gastrointestinal disturbances are special recommendations. Bowel disturbances seem to be exceptional and there was no apparent tendency to sudden severe salivation, though in some cases the mouth reacted promptly. With care, accidents should be infrequent and he is convinced that when the entire dose is put within the lumen of the vein no reaction will occur. The median basilic or median cephalic are suitable for the injections, but any prominent accessible vein will answer.

Prophylaxis in Epidemic Cerebrospinal Meningitis.—A. Seibert reports that he has used a solution of equal parts of resorcin and alcohol to disinfect the nasopharynx. The alcohol should be heated before adding the resorcin. A properly shaped applicator wound with a plug of absorbent cotton well soaked with the solution is introduced once for a couple of seconds on each side of the uvula. The stomach should be empty. The contractions of the soft palate press the fluid out of the cotton and into the folds of the mucous membrane, and the alcohol penetrates deep into the mucosa with the resorcin and destroys all organisms with which it comes in contact. The applications are best repeated every forty-eight hours and six treatments usually suffice for an ordinary chronic case of postnasal pharyngitis. He has also used this method with good results in destroying streptococci in scarlatinous pharyngitis, and also as a disinfectant after pneumonia, diphtheria, tonsillitis, influenza, and measles. Before proposing it as a prophylactic measure in cerebrospinal meningitis, he had some bacteriologic tests made which showed its efficacy against the meningococcus. In every test the number of bacteria in the nasopharynx was notably diminished and in some of the tests the sterilization was almost complete. He recommends it, therefore, to be used in the nasopharynx of the patient in cases of cerebrospinal meningitis to prevent absorption and expectoration of meningococci, and in all persons coming in contact with the patient, especially when postnasal catarrh exists.

Dermatitis Exfoliativa Neonatorum.—W. M. Brown reports seven cases of this rather rare affection (also known as Ritter's disease). It occurs in infants from one week to one month old, usually appearing first about the mouth as a diffuse erythema and spreading over the body, followed by separation of the epidermis, with intense irritation and more or less fever. After scaling there is a furuncular eruption of varying severity. The acute trouble lasts about ten days, leaving a papular eruption that may become eczematous. All the cases but one were in females, the mothers in every case were in single rooms, no cases occurring in the wards. Each case was under the care of a different physician. Five of the seven mothers had a definite puerperal infection of greater or less severity. At the same time forty-one children were born in the hospital, all in the same room and cared for by the

same nurses as the babies with the disease, but not one whose mother was in the ward became infected.

The Lancet, November 2, 1907.

Ruptured Bladder: Operation Forty-two Hours After the Accident: Recovery.—The patient of B. H. Lang was a male cook aged 49 years who after alcoholic indulgence was thrown out of a wagon. He had passed urine one hour before the accident. The immediate symptom from his fall was severe abdominal pain. The next morning he was unable to pass water in spite of frequent desire, and his pain was intense. It was necessary to transport him a long distance in a motor-car before he could reach a hospital. On admission he presented a very bad appearance, with frequent vomiting of a dark fluid, pale face, rapid and weak pulse, and distended abdomen with dullness in the flanks. Catheter drew off a few ounces of deeply blood-stained urine. Diagnosis was made of ruptured bladder and the usual median subumbilical incision was made. A large rent was found in the posterior wall of the bladder. This was closed with iodine catgut, the incision with silk-worm gut, and a large rubber drain left in the lower angle of the wound to drain the pelvis, while a strip of gauze was passed down beside the tube to the site of the sutured wound in the bladder. A catheter was passed and tied into the bladder. The patient's condition was desperately low, but on the fourth day he rallied and began to gain headway. Catheter was removed on the fourth day and the patient passed urine himself. The wound drained well and there was no leakage of urine till the seventh day when a urinary fistula developed. This finally closed, and in six weeks the man was perfectly well.

The Growth of Malignant Disease in Man and the Lower Animals.—E. Goldman considers this question with special reference to the vascular system. His first point concerns the responsibility of the system for the dissemination of malignant growths. This is a very large and important factor. The connective tissue and vasa vasorum of the vessel within the tumor area begin to proliferate and finally vein and artery alike are permeated by numerous vascular channels. Such vessels are naturally more likely to harbor tumor cells than are healthy ones. The author assumes the existence of an intimate relation between the blood and lymphatic channels. The lymphatic glands do not always serve as filters, but permit the transmission of infectious material. What are the general conditions of the circulation in malignant growths? The latter disturb the regular distribution of the vessels, but the new formation of vessels depends upon the general powers of the individual patient and the physiological condition of blood supply in the invaded tissues. The virulence of the cells in a given growth can be measured by the extent of the necrosis found in it. Finally, the new vascular formation serves not merely for nutrition of the morbid growth, but also as a means of defense against it. The body's first line of defense is established on the boundary of the invading growth. An operation in long-growing tumors is sometimes harmful, for the knife in removing the growth has removed the barrier which the body has carefully raised up during the long continuance of the growth.

British Medical Journal, November 2, 1907.

Clinical Observations on Spring Catarrh.—This paper is an analysis by H. Herbert of thirty nine cases seen by him in Bombay in the course of about two and a half years. Only seven of the patients were females. Cases were seen in adults up to forty years. The cases at the more advanced ages were mild and not very characteristic, and some of them gave only short histories. In one youth aged twenty one years vision had become much reduced through invasion of the cornea, the disease having begun in early childhood. The patients were of all races, including Europeans. Seasonal variation in Bombay is not marked. The patients had little information to give in this respect. But on looking up the dates on which the patients first applied for relief, May, the hottest month, was the only month without any cases, and most occurred in July, the wettest month. The author notes that many of these cases are liable to be mistaken for trachoma or chronic simple conjunctivitis. The tarsal conjunctiva may present only infection, fine papillary roughness, slight thickening or loss of translucency. Itching and rubbing of the lids are frequent. In spring catarrh there is usually no discharge to be seen, but if the upper lid be everted for a moment and then be released, there soon appears a scanty thin slimy exudate on the tarsal conjunctiva. Blood examinations were made in twenty-two of the cases, but there did not appear to be any general correspondence between any abnormality of the blood and the degree of conjunctival proliferation. Concerning treatment the author notes that a trial was given to salol, a saturated solution in almond oil, instilled six times a day. It was commonly used in one eye and adrenalin in the fellow eye. The results were not uniform. Sometimes one eye improved the faster, and sometimes the other, and in other cases neither medicament did any good. Failure is perhaps to be anticipated in the cases in which the eye affection was only part of a more diffused malady.

Treatment of Delayed Resolution after Pneumonia.—W. M. Crofton reports one case in which intramuscular injections of fibrolysin were given. This substance is a double compound of thiosinamin and salicylate of soda. The patient was a man of thirty-two years with the history of a pneumonia in the left lung two years previously and with an intermittent cough since. He was attacked with the typical seizure of a pneumonia in the left lower lobe and the crisis came on the ninth day. For the following month there was no change in the local condition. He was up and outdoors, but extremely weak. He had a distressing cough with scanty yellow viscid sputa. So he went on for ten weeks, appearing to be doomed to fibrosis of the lung. Knowing that thiosinamin had the power of dissolving pathological fibrous tissue, the author determined to use it in intramuscular injection in the form of fibrolysin. The morning after the first injection he brought up a large quantity of greenish-yellow sputum, and continued to do so during the treatment in gradually decreasing amount. He received an injection (2.3 c.c.) every second morning and had eighteen in all. His lung has completely cleared up; his cough has almost disappeared; the sputum is reduced to a small quantity in the morning, and he is steadily increasing in weight, as much as three pounds a week.

The Cancer Problem—A Suggestion.—F. B. Skerrett notes that the essential characteristic of the cancer cell is its apparently unlimited power of multiplication. The nucleus determines the division of the cells. Is it possible, asks the author, to so act upon the nucleus as to rob it of its abnormal power of proliferation? Chemically it consists of nuclein. Cancerous growths are particularly rich in this substance. Certain leucocytes may perhaps supply the stimulus and provide the nourishment for cancer cells. If the nuclein is so important for rapid mitosis, may this process not be considerably modified by its withdrawal from the food altogether or by such chemical action upon it as to alter its functional activity? From a chemical point of view, nuclein is remarkable among organic bodies for its high percentage of phosphorus. Can we substitute for phosphorus a chemical having somewhat similar affinities? The author suggests the substitution for phosphorus in the nuclein molecule, of the heavier metals of the group to which it belongs and advances the following propositions: 1. The action on carcinomatous tumors of a diet free from nuclein and its progenitor—nucleoproteid. Such a diet in the case of man would correspond somewhat with the purin-free diet suggested for gout and its manifestations—and by the way, any observed associations between this disease and cancer would be extremely interesting. Cancer has much greater incidence among those taking a mixed diet than among vegetarians, and a vegetarian as well as a restricted nitrogenous diet has been extolled as beneficial in both external and internal cancer. This plan, "the nuclein-free diet," could also be tried in conjunction with the internal administration of arsenic or other member of its periodic group. 2. The action of a "phosphorus-free diet" with or without the internal administration of arsenic, etc., might be tried. Seeing, however, that phosphorus is such an important element in the nervous system of vertebrates, it is doubtful whether the living organism could withstand its entire withdrawal from the food, and it is possible a cancerous growth might still draw its necessary phosphorus from the nervous system, thus producing mental depression or other nervous state. 3. The production artificially of extensive inflammatory conditions far away from a cancerous growth with a view to withdrawing the leucocytes thereto and noticing the effect, if any, might prove interesting if of no practical importance.

Berliner klinische Wochenschrift, October 28, 1907.

Congenital Occlusion of the Lower Part of the Ileum.—Kersten in discussing this subject says that mechanical, inflammatory, and developmental factors have been adduced in explanation of the abnormality. Among the mechanical factors are torsion of the intestine about its axis, incarceration of a loop of gut in openings of the mesentery, and compression by tumors or enlarged organs, for example, the liver. Fetal peritonitis, either general or circumscribed, may also give rise to adhesions or thickening or contraction of the mesentery, which may lead to

interference with the permeability of the intestine. Among the embryological theories that of Krenter, whose experiments have recently been verified by Forsener, seem most worthy of acceptance. As the result of his investigations on human and animal embryos he reaches the conclusion that during the fifth to the tenth week of development temporary obliterations of the intestinal lumen may occur, but are normally corrected through metaplasia of the proliferating epithelial cells. If this goes on to an incomplete degree stenosis results, or in pronounced cases, atresia. The author reports a case in which the intestine was found replaced by a connective tissue strand about 2 mm. in diameter and 1 cm. in length, about 2 cm. from the ileocecal valve. The diagnosis was made early and an artificial anus successfully formed, but the child died on the sixth day after birth. The pathological findings in this case, as recounted by the author, are thought by him to corroborate Krenter's theory.

The Guaiac Test for Blood.—Schroeder has made a series of tests with different modifications of the guaiac method and states that although previous authors have emphasized the fact that the oil of turpentine used should be old and the tincture of guaiac fresh, they have laid no stress on the strength of the latter. He finds that this factor is of considerable importance and that strong solutions of blood for an optimum reaction require strong solutions of the resin, and *vice versa*. If the blood solution is very weak a strong solution of the resin may completely obscure the reaction. He recommends that three test tubes of guaiac solution be used. The first contains 1 c.c. of absolute alcohol, with about 60 mg. of resin of guaiac; the second tube receives a drop or two from the first and 1 c.c. of absolute alcohol, and the third a drop or two from the second tube and 1 c.c. of absolute alcohol. Equal quantities of turpentine and the acetic acid ether extract (usually 1 c.c. of each) are added to each tube. In the presence of blood the characteristic blue color due to oxidation of the guaiac is produced.

Münchener medizinische Wochenschrift, October 20, 1907.

Delirium Tremens Following Abstinence from Alcohol.—Hosch says that although the question was long in doubt, it is now generally recognized that delirium tremens may be evoked by the sudden cessation of the use of alcohol. Most writers on the subject also state that the administration of alcohol after the delirium has once begun has little or no effect on the duration and course of the illness. While the alcohol has little or no value as a remedy, the fact that abstinence delirium occurs indicates that the use of the agent as a prophylactic, in the sense of a gradual reduction in its administration, rather than a sudden breaking off, is to be recommended. The author reports an instance in which delirium set in promptly on cutting off stimulants, though the case is somewhat complicated by the fact that the onset of the delirium was preceded by an epileptic convulsion. This, the author believes, was also predisposed to by the abrupt alteration in metabolism attending the sudden abstinence from alcohol.

Pulmonary Edema and Bronchial Asthma.—Hoesslin says that the most potent cause of edema of the lungs lies in a failure of cardiac power, particularly of the left ventricle. This produces undue pressure in the pulmonary circulation, since the right ventricle continues to force blood into the pulmonary vessels, while the left ventricle does not empty itself satisfactorily. The condition may also result from primary vascular lesions, such as those that accompany acute and chronic renal diseases. A third cause that has been suggested consists in a paralysis of the vasomotor nerves, inducing a condition similar to that of angioneurotic edema. Frequently it is difficult to determine whether the pulmonary edema depends on a pulmonary or a cardiac cause, and the two often work together in a vicious circle. The complication of bronchial asthma with pulmonary edema is rather rare and the author reports a case occurring in a woman of thirty-two years. In addition to the pulmonary manifestations marked albuminuria was observed and after the acute stage of the illness was over the patient developed a pneumonia. Hoesslin considers that the repeated attacks of asthma had already caused considerable damage to the lungs and that both the pulmonary vessels and the heart were already involved. In the attack in question the heart was unable to fulfill the demands put upon it by the increased pressure in the pulmonary circulation, and in consequence transudation took place through the capillary walls and the alveolar epithelium.

Deutsche medizinische Wochenschrift, October 31, 1907.

The Treatment of Syphilis with Suppositories of Mercury.—Hoehne says that the method of treatment of syphilis suggested by Audry, which consists in the administration of the mercury by rectum, has much to recommend it, particularly on the score of ease of application and the ability for the patient to keep his ailment secret from those about him, which is hardly possible when inunctions are used. The method is superior to the administration by injection, owing to the pain that the latter frequently causes, and seems to be less likely to give rise to stomatitis or enteritis than when the drug is given by mouth. Unfortunately, however, it does not appear that Audry's claims for the effectiveness of the method are justified by the facts. Hoehne tested the plan in twenty-two cases; the suppositories being made of cacao butter and 40 per cent. gray oil. Each suppository contained from 25 to 400 mg. of the oil. While no complications attended the treatment, which apparently possessed all the points of convenience claimed for it by its originator, the therapeutic effect was so inadequate and uncertain that the method was soon abandoned. Lesions already present were influenced very slowly or not at all and relapses appeared promptly on ceasing the treatment, so that the author considers that it is not suited for routine use and should be employed only when for one reason or another the usual plans of administration cannot be resorted to.

The Absence of Glycogen from the Leucocytes in Myelogenous Leukemia.—Wolff-Eisner says that whereas glycogen is normally present in the leucocytes and can be demonstrated by the use of iodine, in lymphatic leukemia the leucocytes do not give this reaction. They are therefore different in composition from normal leucocytes and this fact furnishes an argument against those who oppose the phagocytic theory of immunity. It is alleged that this theory cannot hold good, since in myelogenous leukemia, where the blood is flooded with granular cells, no particular resistance to infection is observed. By demonstrating the fact that the leucocytes in this disease differ in composition from those normally present, the author considers that the likelihood is shown that these cells also differ in function from the normal ones and are not necessarily to be looked upon as capable of resisting infection. Although he presents this argument, he is not an adherent of the phagocytic theory and points out that it has not yet been explained by the believers in this why it is that in lymphatic leukemia, when the body is very deficient in granular cells, infections do not always occur very early in the disease, and for the same reason why death does not regularly occur early in pernicious anemia, which also is usually accompanied by leucopenia.

French and Italian Journals.

Intestinal Autointoxication in Relation to Feeding of Infants.—Antonio Longo has experimented as to the fecal and urinary toxicity and the intestinal putrefaction in infants fed on milk alone, or on the commonly used farinaceous foods. Their ages varied from twenty-one to twenty-three months. He finds that a certain amount of incompletely assimilated proteids are in the circulation of these infants. There is also a large amount of albuminous material separated by the metabolism of tissues. The different grades of toxemia observed in different infants depending on the food they take, and not solely on a greater or less production of these poisons in the intestine, but also on the chemical activity of the cells. The children experimented on could sustain life without loss of weight on prepared infant foods, tapioca, etc., and without any bad effects. These foods produce a polyuria. There is very little intestinal putrefaction under this diet. Urinary toxicity is greatest on a milk diet, much less on a farinaceous diet.—*Rivista di Clinica Pediatrica*, September, 1907.

Dystocia by Progressive Deformity of the Pelvis in Mountainous Countries.—Dresch believes that in mountainous countries, where the women are obliged to mount steep inclines burdened with heavy loads there is a gradual progressive deformity of the pelvis that is not accompanied by any symptoms of osteomalacia. He draws this conclusion from the occurrence in his practice of a number of deliveries in contracted pelvis which he has observed in women who had not had any pregnancy for a number of years, and who had previously been delivered without operation of one or more normal sized children. There was no disease and no evidence of deformed metabolism to account for the narrowed pelvis. He believes that in these cases the pelvis was at first of normal diameter, and that it had gradually changed its shape and diameters as a result of altered physical relations.—*Gazette Médicale de Paris, August* 15, 1907.

Book Reviews.

A Dictionary of Medical Diagnosis. A Treatise on the Signs and Symptoms Observed in Diseased Conditions. For the use of medical practitioners and students. By Henry Lawrence McKisack, M.D., M.R.C.P. London, Physician to the Royal Victoria Hospital, Belfast. New York: William Wood & Company. 1897.

In this excellent work the author has placed before medical readers an invaluable adjunct to the modern treatises on the practice of medicine. The book is not intended as a text-book on medicine, but merely as a means of ready reference for the student and practitioner. Arranged as it is alphabetically, the signs and symptoms of disease as they present in physical examination can be conveniently and instantly referred to, and the author may be congratulated upon the ingenuity displayed in the plan of his work. The various clinical methods of examination are clearly described with sufficient minuteness to enable any intelligent student to put them into practice. The illustrations and diagrams are extremely instructive, and beside the alphabetical arrangement which itself permits of quick reference, the work is carefully and fully indexed. A number of comparative tables showing, for instance, comparative symptoms in diseases of the urinary organs, diseases of the stomach, etc., add greatly to the value of the work. In the preparation of the book the author has had the cooperation and assistance of a number of eminent colleagues.

Human Anatomy, Including Structure and Development and Practical Considerations. By Thomas Dwight, M.D., LL.D., Parkman Professor of Anatomy in Harvard University; Charles A. Hamann, M.D., Professor of Anatomy in Western Reserve University; J. Playfair McMurrich, Ph.D., Professor of Anatomy in the University of Michigan; George A. Piersol, M.D., Sc.D., Professor of Anatomy in the University of Pennsylvania, and J. William White, M.D., Ph.D., LL.D., John Rhea Barton Professor of Surgery in the University of Pennsylvania. With 1,734 illustrations, of which 1,522 are Original and Largely from Dissections by John C. Heisler, M.D., Professor of Anatomy in the Medico-Chirurgical College. Edited by George Piersol. Philadelphia and London: J. B. Lippincott Company.

Of all sciences that of anatomy, apart from histological details, would seem to be the most fixed and the one least calling for new treatises expounding it, yet within the past decade there have been eight or ten original works or translations from the German published in this country, not to mention numerous compends and dissection manuals. Without disparagement of any of these works, their multiplication does appear to be rather unnecessary. One is sufficient for the needs of the student, and none but the specialist would ever dream of burdening his library with more than one.

In the present work the limits of descriptive and topographical anatomy have been passed, and an attempt has been made, in the sections entitled "practical application," to point out the relation of anatomy to morbid conditions—those in the province of the internist as well as the surgeon. A special treatise, in which the practical application of the facts of anatomy to diagnosis and treatment were expounded at length, would be serviceable and cover a rather neglected field, but the wisdom of incorporating such in a work on anatomy for the student's use is questionable. Anatomy is one of the elementary branches in the medical curriculum, and the first year student has enough to do in mastering its details without burdening his mind with a study of its relations to disease of which he knows nothing, and should know nothing until a solid foundation of the elements is laid. To the third or fourth year student such information would be of service, but he could better get it from a monograph such as we have suggested than by picking out what he needs from a two thousand-page work on anatomy.

The book, partly because of the inclusion of the extraneous matter to which we have just referred, is too large for the student. It contains 2,088 pages and is far too bulky and unwieldy to be transported to the dissection room, or even to be held in the hands or the lap for study. The print is too fine for continuous study by artificial light, and the binding is not such as to insure a long life for the book, if used as a treatise on anatomy should be.

We have pointed out the defects of the work first, because they are the most striking. It is a pity that they exist, for they render the book unfit for the use of the student and bar the possessor from a utilization of the many and great excellencies which characterize it. The descriptive text is admirable—clear, well put, and not quickly to be forgotten. In reading it one practically sees the anatomical subject before him, and, with the aid of the beautifully executed illustrations, could almost dispense with dissection in acquiring a knowledge of the construction of the human body. One commendable feature is the retention of the familiar anatomical nomenclature, and a relegation of the terminology of the Berne Congress [BNA] to footnotes. The latter is far from perfect, and equally far from being euphonious, and we see no advantage in imposing it upon the student in place of the anglicized terms with which everyone is familiar and which one will always use in daily converse. If the publishers would issue this treatise in three or four substantially bound volumes, one of which would contain the "practical applications," the work would be really useful and one to be welcomed even to the already overcrowded ranks of anatomical text-books.

Lateral Curvature of the Spine and Round Shoulders. By Robert W. Lovett, M.D., Boston, Associate Surgeon to the Children's Hospital; Instructor in Orthopedic Surgery, Harvard Medical School, etc. With 154 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

It is only within the past two decades that any signal advances have been made in the corrective treatment of lateral curvature of the spine, and this is due to the fact that hitherto the therapeutic measures employed have been largely empirical and not sufficiently correlated to the pathology of the condition and the mechanism of the resulting displacements. The progress which has recently been made is based on experimental and clinical work, the records of which are scattered through the medical literature. Dr. Lovett has endeavored to bring together this literature in the book here noted and in addition has enriched it by his own views based on an extended experience. The result is to be commended. The book presents a clear account of the treatment of what was formerly regarded as a practically incurable condition, and this feature is emphasized because the majority of text-books fail in the particular mentioned. After several introductory chapters on the spinal anatomy and movements and the clinical features of scoliosis, the author takes up in great detail the examination of the patient, the etiology and the pathology of this deformity, so that the rationale of the treatment now advocated becomes evident. The importance of proper posture and proper exercise in school children is insisted on, and likewise the early recognition of the condition. The treatment depends on whether the deformity is postural or functional and organic or structural. The systems of exercises which have lately been worked out are carefully explained and this constitutes a feature of the book which is most valuable to the practitioner as showing what can be done with care and patience. The numerous forms of apparatus which have been devised are also illustrated and described. The text is concise and satisfactorily arranged for ready reference and the work may be ranked on an equally high plane with the author's previous contributions to the literature of orthopedic surgery.

Postoperative Treatment. By Nathan Clark Morse, A.B., M.D., Surgeon-in-Chief to "Emergency Hospital," Eldora, Indiana; District Surgeon, Chicago & Northwestern and Iowa Central Railways, etc. Second Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1907.

It is a pleasure to repeat the good opinion of the first edition of Dr. Morse's book, on the occasion of the appearance of this revised and enlarged new edition, which contains an account of all the recent advances which are worthy of being incorporated in a work of this kind. The writer's purpose in bringing out his book has been to correct the lack of information on this important subject and particularly in such form that it is readily accessible to either the student or the practitioner. The modern text-books on surgery are lamentably deficient or conflicting and therefore of little assistance in elucidating the after-treatment of operative cases, the care of which is often left to others. Morse's book furnishes us with an epitome, not too condensed, of the various methods used by modern surgeons, together with comments by the author based on personal experience. The scope of the book is quite extensive; beginning with the preparation of the patient and the care of operative wounds, he takes up in detail the special points relating to the various operations. The after-treatment of fractures, amputations, arthrectomies, and the different bone diseases is also carefully considered and is very up to date. There is an excellent chapter on the use of the *x*-rays in post-operative treatment, which has its indications but should never, according to the writer, be subordinated to surgical treatment proper. The section on dietetics seems rather brief considering the detailed presentation of the subject-matter in the remainder of the book and could have with advantage received more consideration. Only seven pages are devoted to this most important subject, an imperfect knowledge of which works more havoc with patients than any other feature of post-operative technique. The book as a whole, however, can be commended as a most valuable addition to the practitioner's working library.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 7, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Nomination of Officers.—The following officers were nominated: *Vice-President* to serve three years, Dr. Simon Flexner; *Trustee* to serve for five years, Dr. A. M. Jacobus; *Member of the Committee on Admissions* to serve for five years, Dr. Charles H. Richardson; *Member of the Committee on Library* to serve for five years, Dr. Haven Emerson.

Report on the Serum Treatment of Epidemic Cerebrospinal Meningitis.—Drs. SIMON FLEXNER and J. W. JOBLING presented this communication. It seemed desirable to recapitulate the salient points brought out by the different reports, it being understood that they did not represent conclusions, but only statements of observed facts or obvious deductions from them. The records of the cases used in the paper covered 47 cases of epidemic cerebrospinal meningitis treated with the antiserum, of which 34 (72.3 per cent.) recovered and 13 (27.6 per cent.) died. Of the 13 patients who died four were either fulminant cases in which death took place 24 or 36 hours after the first appearance of the meningeal symptoms, or the patients' conditions were such that death occurred within a few hours of the injection of the serum. If, therefore, they subtracted these, there would be a total of 43 cases, of which 34 recovered (79.9 per cent.) and 9 died (20.1 per cent.). Excluding the fulminant cases, those who were injected in the first three days of illness numbered 18, of which 16 recovered (88.9 per cent.) and 2 died (11.1 per cent.). In order that the figures might have any value they were obliged to know with what degree of severity the epidemic prevailed at the time and the place at which the serum was used. Eighteen cases of epidemic meningitis occurred at Castalia within a few weeks. Of these 12 patients died and six recovered. Of the six patients who recovered, three received the serum injections, and no patient receiving the serum died. The report from Akron covered 20 cases of epidemic meningitis. Of these patients nine were not treated with the serum; eight died and one recovered. The remaining 11 patients were treated with the serum; three died and eight recovered. Of the three fatal cases, two were of the fulminant type. The records of the cases that recovered had been full enough to enable them to make out the manner of termination of the disease, and they found that in 13 the disease terminated by lysis and in 12 by crisis. In a number of the cases the abrupt termination of the disease, after an acute and violent onset, within about forty-eight hours of the serum injection, was very striking and impressive. In several cases the serum was injected as early as twelve hours after the onset of severe symptoms with prompt arrest of the disease. Their choice of mode of introducing the antiserum into the body, namely, the spinal canal, should be justified. They were led to this manner of employment by two considerations: First, the theoretical advantage of bringing the serum in direct contact with the focus of infection and inflammation, to support which one possessed data based on experiments on animals; second, the consideration that the elimination of colloids, and even of crystalloids, into the cerebrospinal fluid was a slow and uncertain process in health and probably little better in inflamed states of the membranes. The cases reported in the paper were treated by intradural injection. They possessed evidence that the direct effect of the antiserum upon the diplococci present in the exudate in the spinal membranes was to bring about rapid degeneration and arrest of free multiplication. They had noted remarkable reductions in number and marked evidence of degeneration of the diplococci and loss of power of growth twenty-four hours after the first injection of the serum. Striking changes in the character of the exudate had also followed the serum injections; in twenty four hours they had seen a seropurulent exudate converted into a faintly turbid exudate. The cases in which the exudate was really purulent or fibrino-purulent would seem to be less favorable to the action of the serum. It was clear, once they accepted the abortive and abruptly terminating cases as being caused by the serum, that early injection of the serum was to be sedulously sought. The figures, small as they were, also pointed to better results in those cases which were injected during the first three days as compared to those injected at later periods of the disease. On the other hand, several favorable results had been recorded in cases treated in the fourth, fifth and eighth weeks of the disease. One might suppose that as long as living and multiplying diplococci remained in the membranes and their fluid, the serum might be of value. It was clearly of no avail in the treatment of symptoms resulting from chronic obstructive lesions of the membranes. They believed that the data at hand warranted a wider use of the serum, especially as no other and better means were at hand for combating the disease. It would, however, be calamitous just at present to use the serum indiscriminately and without proper and bacteriological control of the case.

Dr. HENRY HEIMAN reported his own experience with Dr. Flexner's serum. The first case was that of a child one year old, admitted on the twenty-second day of the disease. A lumbar puncture was performed on the day of admission, yielding a fluid in which meningococci were readily found in smears and on cultures. The next day, the twenty-third day of the disease, 32 c.c. of cerebrospinal fluid was withdrawn and 12 c.c. of serum injected, this being all that was available to him at that time. A puncture performed on the next day yielded only a few meningococci, which failed to grow on the usual media. During the next two days, 30 c.c. and 15 c.c. respectively of serum were injected after the withdrawal of only 10 c.c. of cerebrospinal fluid, previous to each injection. In these fluids meningococci could not be demonstrated in smears or on cultures. The child died on the thirty-first day of the disease with fuly developed symptoms of posterior basic meningitis. The second case was a patient one year old and was admitted to the hospital on the fifteenth day of the disease with a temperature of 104°. The next day 35 c.c. of cerebrospinal fluid was withdrawn and 35 c.c. of serum injected. Spreads and cultures yielded meningococci. No subsequent puncture was made, as it was not considered indicated. The temperature dropped to normal within twelve hours after the injection of the serum, at which level it remained during the subsequent course of the disease. The patient was discharged cured twenty-three days after admission. These cases were instructive from several points of view. First, the injection of antimeningitic serum was apparently followed by no harmful results. Second, the apparently bactericidal effect of the serum. Third, the harmlessness of injecting more serum than the cerebrospinal fluid withdrawn. As in the case of any curative serum early injections were desirable.

Dr. MORRIS MANGES said that there had been one case at the hospital which was of special interest and which he would report in full at some later meeting. The patient was a diabetic woman with typical cerebrospinal meningitis who made a complete recovery under the serum treatment.

The Recent Epidemic of Poliomyelitis.—Dr. V. P. GIBNEY and Dr. CARLETON WALLACE presented this communication. The occurrence of the epidemic during the summer months suggested a mode of infection through the intestinal tract. In getting the histories, it not uncommonly appeared that the paralyses were preceded by diarrhea or dysentery. They were able to get accurate data in 100 cases. It was found that diarrhea and vomiting occurred in 10, vomiting and constipation in 11, diarrhea

alone in 11, constipation alone in 11, and vomiting alone in 11, making 63 that were at least the objects of suspicion. At the Hospital for Ruptured and Crippled the cases were admitted during 1900 as follows: In June 4 cases, in July 3 cases, in August 7 cases, in September 11 cases, in October 14 cases, making a total of 39 cases. During 1907 there were admitted in June 17 cases; in July 24 cases, in August 86 cases, in September 138 cases, in October 122 cases, making a total of 387 cases, or nearly ten times the number that came under observation in the summer and fall of 1906. A point of interest was the comparative statement of the ages. For instance, during 1907 there were 36 cases that developed during the first year of life, while in 1906 there was only one. There were 105 during the second year this summer, and 14 last. Cases developing during during the third year numbered 97 in 1907, 12 in 1906. During the fourth year, 60 this summer, 5 last. Between five and eight years, 18 this summer, none last, and there were 4 who developed the disease after the twelfth year in this epidemic, while there were none last summer. This showed pretty conclusively that the present epidemic included children beyond the infantile period of life. Whether this had any bearing on milk as an etiological factor they were unable to say. Their treatment would be, so soon as the diagnosis was established, about as follows: Protect the limb or limbs from strain at the joints by means of a trough, either of wire or wood or light steel, well padded with cotton batting; the feet should be kept at right angles with the legs, and the knees should be kept in slight flexion or very nearly straight, and the thighs on a line with the long axis of the body. In other words, they should aim to prevent any deformities which would arise by the false positions into which the child placed the limb to prevent strain. The limb in these false positions became fixed sometimes by contractions and then contractures, and so long as the opposing muscles might be more or less completely palsied, deformity was easily induced. Massage or electricity or any excitants of the muscles or nerves should not be resorted to until one felt very sure that all inflammatory changes had undergone resolution in the cerebrospinal axis. They should avoid straining the capsule or ligaments of the joint because, when they were weakened, the muscles were called upon to still greater effort. As a further remedial measure in these early cases they recommended artificial hyperemia of the parts in the neighborhood of the cord, such as cupping in young children, the Paquelin cautery in older ones, iodine, and other forms of counterirritation, if more vigorous ones could not be employed. They had treated six or eight cases at the hospital over a period of six or eight weeks, and practically no treatment had been employed other than rest in bed.

Previous Epidemics of Poliomyelitis.—Dr. L. Emmett Holt said that twenty-nine epidemics of poliomyelitis had been reported prior to the present year, and these epidemics were widely separated as to time. The first one reported was in Louisiana in 1841, and they had been reported from all over the civilized world. The most extensive ones occurred in Norway and Sweden. During the decade ending in 1881 six epidemics were reported; during the present decade nine. In fifteen epidemics the number of cases was less than twenty; in seven, twenty-five; in only four were there over one hundred cases. In Australia in 1904, 168 cases were reported; in the epidemic at Rutland, Vt., 108 cases; in Norway, 268 cases. By comparison the present epidemic in New York City was much the largest on record. In the present epidemic cases occurred simultaneously or at short intervals in the same family. There were several instances in which two children in the same family were affected. There were two such instances in Elizabeth, N. J. The occurrence of the epidemic in the hot months, July, August, and September, was strikingly uniform; the epidemic terminated in October. With regard to its association with other diseases, the range was wide, and included whooping cough, measles, diarrheal diseases, etc., and no deductions could be drawn from the association of poliomyelitis with other diseases. In regard to the topographical location, area, and surroundings, it seemed to occur more during a small or little rainfall, when the streams were low. The sanitary surroundings were good in five, and bad in two epidemics, and the disease affected all classes of society. The majority of the patients were under four years of age. In the Rutland, Vt., epidemic one patient was seventy years old. The highest mortality was forty-one deaths among 210 cases. In the Norway epidemic of 1904, there were six deaths among 41 cases. In ten epidemics with 541 cases, there were 60 deaths. During 1905 and 1906 in Norway there were 1,053 cases and 145 deaths, a mortality of over 13 per cent. The question was raised whether this epidemic was likely to be followed by an increase in the number of sporadic cases. With regard to the etiology, no conclusions as yet were warrantable.

Dr. A. Jacobi said that the question of the existence of poliomyelitis had come up many, many years ago, and 100 years ago symptoms were described which undoubtedly pointed to this disease. Fifty years ago Dr. Jacobi had had the opportunity of seeing some cases in New York City and neighborhood. They were generally the chronic cases and gave a history something as follows: The child felt well, was put to bed, slept well, but was taken up the next morning paralyzed. Or a child was taken ill and it was thought it had pneumonia, scarlet fever, or acute rheumatism. When the child was moved it was noted that he was paralyzed on one side. Fifty years ago poliomyelitis was not considered a "feverish" disease at all. It was found that almost invariably the child would be taken suddenly sick, and became paralyzed in one or two limbs; if in two, one would recover soon, and the other would remain paralyzed. Sometimes an arm would become paralyzed on the fourth, fifth or sixth day. They might begin to improve on the fifth or sixth day; or they might improve for a few weeks and then come to a complete standstill with atrophies and deformities finally. In 1840 a large number of cases were reported and in 1860, 150 cases were reported by orthopedists; they saw these cases of a chronic character and, therefore, never saw a fatal issue. It had been shown that not only the spinal cord, but the brain and medulla were affected in a large number of the cases, and Clark's column particularly. A great deal of pain had been complained of by many showing that not only the anterior horns were involved but also other portions of the cord. There had also been noted a large number of isolated hemorrhages in the tissues of the cord, brain, and medulla. In some instances the first symptoms noted were, not the paralyses, but somnolence, mental apathy, etc., showing that they were dealing with not only a poliomyelitis but also a polioencephalitis. That was why the medulla reflexes were not extinct all at once, and it took longer for the paralyses to develop than if they had been cases of poliomyelitis exclusively. In the Stockholm epidemic thirteen years ago, 44 cases were reported; of these 44 cases there were three patients with paralysis of the facial nerve on one side only; there was one that began with facial paralysis only; and there were five that had facial paralysis together with a number of other symptoms. There were five other cases in which there was a paralysis of the abducens; and in some other cases paralysis of the hypoglossus. This proved that not only did the disease affect the spinal cord, but the brain as well. Most of the literature on the subject during the past few years came from Norway and Sweden. Anatomically they were understanding the disease, but pathologically little had been told. We knew a great deal about the anatomy which proved that they were beginning to learn something about the disease.

Dr. Henry Koplik said that poliomyelitis was a term covering a symptom complex; the composite picture of the

disease was something to-day that he had never seen before in New York. Clinically, he said he had been impressed with a few facts. One was that there were three distinct sets of cases in the present epidemic: First, those cases beginning with cerebral symptoms. For the first few days there would be a slight fever, a little rigidity, and symptoms of so-called meningism, but not a meningitis. The children would lie almost completely paralyzed. Some of these cases would awaken from a dream and after three or four days there would be a marked paralysis. There were cases which impressed him as being bulbar cases; cases in which a fatal issue resulted. In some the attack would begin with cerebral symptoms and paralysis of four extremities. In some cases the paralysis affected the muscles of respiration and the children passed away with bulbar symptoms. Second, the neuritic cases, cases that were taken for acute infectious neuritis. The pains in the joints would keep the child awake at night. Some of these would be accompanied by cerebral symptoms at first. Third, the typical classical cases of poliomyelitis. The child would go to bed and awake with paralysis of one or more extremities. In this epidemic there were some remarkable and striking recoveries, in some instances, recovery occurring in a few days. Another point of interest was the rapid atrophy of the muscles, as well as the rapid contractures. Some cases showed a paralysis of the facial muscles; some gave a history of tonsillitis; some came on with symptoms of what one saw following diphtheria, a paralysis of the facial, the ocular, or faucial muscles.

Dr. Henry Heiman said that during the recent epidemic he had had an opportunity to study forty cases of anterior poliomyelitis. There were 23 females and 17 males. The most common age was two years (11 cases). The youngest patient was seven weeks old, the oldest nine years old. The onset was sudden in 34 cases, and gradual in six cases. The two most prominent features of this epidemic were, the not infrequent onset of the disease with symptoms of meningeal irritation, and the occasional occurrence of bulbar symptoms. These cases resembled so closely cerebrospinal meningitis that in the early period of the epidemic an erroneous diagnosis of meningitis was occasionally made. Seven of the 40 cases presented bulbar symptoms. In some of these there were present dyspnea, stertorous breathing, cyanosis, inequality of the pupils, strabismus, tremor of the eyelids and tongue, facial paralysis, dysphagia, rigidity of the neck, and twitching of the extremities. Three types of these cases could be distinguished. First, those with bulbar symptoms alone. Second, those beginning with bulbar symptoms and followed by paralysis of the extremities. Third, those beginning with paralysis of the extremities followed by bulbar symptoms. Blood cultures were made in five cases with negative results. Lumbar puncture was performed in six cases. In one epidemic of cerebrospinal fluid 30 per cent. polynuclears were found: in another the sugar reaction was faint. In the remaining four nothing abnormal was found. White blood counts were made in nine cases. The minimum count was 5,000, the maximum, 23,000, the average being 13,000. Four of the seven bulbar cases ended fatally. Autopsies were obtained in three cases. The macroscopical appearance was as follows: There was marked congestion of the gray matter of the cord in certain places. In these areas small hemorrhages were also seen. The white matter was diffusely edematous.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting Held Monday, October 21, 1907.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Successful Operation for the Formation of a Nasal Septum.—Dr. Chas. J. Proben presented a man, 32 years old, who had apparently innocently contracted an initial lesion on the tongue from intercourse with a woman who had been infected four or five years ago. Any abnormal practice was denied, nor had there been any genital infection. There was no doubt as to the syphilitic character of the lesion, for secondaries rapidly followed, for which he received constant treatment. About four months ago the nasal septum began to ulcerate, and the cartilaginous portion completely disappeared, leaving a direct communication between the anterior nares. One large aperture where two normally should have been caused a rather striking deformity, in consequence of which the man lost his position. The case was referred to Dr. Proben for operation two months ago. A large broad flap was taken from the upper lip extending down to the vermilion border and without penetrating the mucous surface. After freshening a surface inside of the nose in the median line, the flap was turned up into it and anchored by through-and-through sutures. The flap was then covered with skin grafts, which were held in place by winding catgut around them, and the wound in the lip was closed. The wounds healed without trouble and a very satisfactory cosmetic effect was obtained. A good, thick septum, allowing a little for future shrinkage, was visible; the breathing capacity was normal and the pharyngeal irritation had been relieved. The result was eminently satisfactory and the appearance of the patient was practically normal at a distance.

The Origin and Destination of Hydrochloric Acid.—Dr. William H. Porter said that in working out a logical theory for the formation of hydrochloric acid in the stomach a few fundamental facts must be recognized. First, the proteid molecule left the body by a process of oxidation reduction. Second, it had been shown that the cells of the gastric mucous membrane could produce sulphuric acid. Third, the hydrochloric acid was generally admitted to depend upon or come from the decomposition of the sodium chloride of the food. Fourth, the intake and output of sodium chloride was always equal. Fifth, the output of sodium sulphate was always greater than the intake. Sixth, the food contained an abundance of alkaline sodium phosphate, and very little neutral sodium phosphate. Seventh, the blood contained a considerable amount of the neutral phosphate. Eighth, the urine was rendered acid by the acid phosphate of soda. With these facts before us, we could work out easily a theory that fitted all the known data. The proteid molecule was drawn with oxygen into the protoplasm of the gastric epithelial cells, and there, by a process of oxidation reduction, sulphur and hydrogen were split off with the formation of sulphuric acid, which was discharged into the cavity of the stomach from the free surface of the cells. The sulphuric acid here attacked the sodium chloride, forming hydrochloric acid and sodium sulphate, thus increasing the sodium sulphate to be eliminated from the system. After the hydrochloric acid had served its purpose in the digestive tract, it reacted upon the sodium phosphate in the intestinal tract, restoring the sodium chloride lost in the stomach and producing the neutral phosphate for the blood. The neutral phosphate, escaping from the blood through the Malpighian tufts, came in contact in the uriniferous lobules with the uric acid, thus forming the acid phosphate and a urate. Considered in this light, the complete utilization of 150 grams of proteid material daily, after deducting the amount of sulphur required to form the taurochloric acid, left sufficient sulphur to produce 5.78 grams of sulphuric acid. This amount of sulphuric acid, acting upon the requisite amount of sodium chloride, would yield 4.29 grams of hydrochloric acid and 8.37 grams of sodium sulphate. The utilization of a smaller or larger amount of proteid material would naturally decrease or increase the production of the acids. Dr. Porter said the practical deduction to be drawn from this method of forming the acids was that when there was an increased pro-

duction of hydrochloric acid the individual was utilizing more than the 150 grams of proteid material, or there was a decreased production of taurochloric acid, or, estimating the production for a short time, as was commonly done, it might indicate a temporary increased oxidation reduction. Until some method was devised by which the total daily output of the acids could be practically estimated, all deductions were largely speculative.

Lack of Gastric Mucus and Its Relation to Hyperacidity and Gastric Ulcer.—Dr. J. KAUFMANN said he wished to report some observations which showed that the secretion of gastric mucus was a necessary function, and that lack of mucus led to serious disturbances. The presence of mucus was recognized by its most characteristic quality, its coherency. The presence or absence of mucus should be corroborated by the microscopical findings, which were very characteristic. When no mucus was present, no myelin drops could be seen; the field was absolutely clear everywhere, and the different elements, such as starch globules, gluten, yeast, etc., instead of being bound together by the coherent mucus into smaller or larger clumps, appeared singly and sharply outlined. Under normal conditions a moderate amount of mucus was present in the test breakfast; under pathological conditions the mucus was either increased, decreased, or absent. The amount of mucus did not go hand in hand with the amount of gastric juice. Lack of mucus might be due to different causes. There was either insufficient secretion or the secreted mucus was digested or it was dissolved by the action of bacteria, as in cases of bronchoblenorrhea. A certain amount of mucus was possibly digested by an active gastric juice. No matter what the cause of the lack of mucus, we were justified in concluding that the lining of the stomach was not well covered with mucus when we found none in the gastric contents after a test breakfast. It was at once obvious what this meant. The mucus was the protective agent of the gastric mucosa. In cases where no gastric juice or gastric juice of low acidity was secreted, it might not be of great importance whether the mucosa was covered by a thick or a thin layer of mucus. This was altogether different in cases with an active gastric juice, especially when it was of high acidity, because it was the layer of mucus which protected the mucosa against the action of the acid secretion. We were all familiar with the various subjective symptoms which occurred in patients who suffered from hyperacidity. The speaker said an analysis of a great many histories had convinced him that these symptoms were most pronounced in those cases where the stomach contents were found entirely free from mucus. No treatment removed more quickly all the so-called hyperacidity symptoms than the application by lavage of solutions of silver nitrate. In such cases distinct quantities of mucus were found in the stomach contents after the treatment with silver nitrate, whereas the examination made before the treatment had revealed no mucus at all. The effect of insufficient covering of the mucosa might lead to more serious disturbances than mere discomfort and pain. Experiments had shown that the layer of mucus protected the mucosa against mechanical, thermic, and chemical insults, and we might also assume that it was the best protection of the gastric mucosa against the action and invasion of bacteria. When once injured, even though slightly, the damaged part became more prone to the invasion of bacteria and to the digestive action of the gastric juice. Thus we saw that the lack of mucus also played a rôle in bringing about the first lesion of the gastric mucous membrane. That in such cases the first superficial lesion might gradually grow and become deeper became clear when we considered the chronic nature of gastritis, which at the same time caused both the lack of mucus and the hyperacidity. The persistency of both of these disturbances explained the development of gastric ulcer and also its chronic character. Treatment which brought about an increase of gastric mucus helped to cure the ulcer. An increase of mucus, although apparently pathological, might often prove to be nothing but a more active manifestation of a useful function, which served to protect the mucous membrane. Lack of mucus, however, should be considered as an unfavorable symptom.

The Surgical Treatment of Gastric Ulcer.—By Dr. OTTO G. T. KILIANI. (See page 846.)

Modern Methods in the Treatment of Gastric Diseases.—Dr. A. ROSE said that a rational therapy in the treatment of affections of the stomach presupposed an exact diagnosis. In order to arrive at an exact diagnosis in gastric as well as other diseases, it was necessary to take the general conditions into consideration, notably of the circulatory and respiratory apparatus and the nervous system. Physical and dietetic methods of treatment had more and more asserted themselves in modern times, not only in therapeutic measures generally, but also in the treatment of gastric and intestinal disorders in particular. Physiologico-chemical exploration of the stomach and examination of its contents was indispensable in many cases, but the opinion entertained for some length of time that neither a correct diagnosis nor a rational therapy was possible without an examination of the contents of the stomach had proved an unfounded exaggeration. It was not so very long ago that almost every conceivable case of gastric disorder was irrigated. The conditions had now been exactly defined where irrigation of the stomach was indicated, where it was superfluous, and where it was harmful. In the treatment of affections of the digestive tract, diet, of course, played the most important part. In the two affections of hyperchlorhydria and achylia gastrica, dietetic measures formed in most cases the exclusive treatment. The palmy days of the manufacturers of all kinds of pepsin and pancreatin preparations, etc., would probably soon be over, as soon as the causes of the anomalies of gastric secretion had become better understood. The axiom was gaining ground that the replacement of deficient gastric juice by the artificial article could not constitute the scientific remedy. The fact that hyperchlorhydria depended on anomalous nervous conditions had been established by the experiments of Pawlow. The relaxation of the abdominal muscles might be the cause of many nervous disorders which in turn produced gastric symptoms or anomalies of gastric secretion, and if we did not consider this mechanical cause of the gastric affections and remove it first of all, our purely medicamental treatment would be unscientific. Atony and dilatation were identical, a relaxed muscle fiber being at the same time elongated. Modern gastrotherapy was to be based, so far as anomalies of gastric secretion were concerned, on the consideration of nervous and mechanical conditions.

Modern Methods in the Surgical Treatment of Gastric Diseases.—Dr. FRANZ TOREK said the technique of gastric surgery had come more prominently into the foreground since physicians had begun to understand that many cases diagnosticated as chronic gastritis were in reality cases of malignant tumor or of congestion due to mechanical obstruction by an open ulcer or its resulting cicatrix. Unless a distinct cause for gastritis could be traced, such as alcoholism, errors in diet, etc., the other possibilities should be kept in mind and proper measures should at once be taken for making a correct diagnosis. Many cases would then be found to be not chronic gastritis, but some malady requiring surgical treatment. Of the operations upon the stomach, the most important were gastroenterostomy and resection; the former for ulcer and for pyloric obstruction from whatever cause, the latter occasionally for ulcer, but more particularly for the removal of operable cancer. After describing in detail the various gastric operations, and demonstrating the steps in their technique by means of diagrams, Dr. Torek said that when we

looked over the progress that had been made in the surgery of the stomach during the past few years we found that it consisted mainly in an elaboration of certain details in the technique, including improvement in the construction of certain instruments. Improved technique helped us to guard our asepsis still more strictly, and also enabled us to employ the suture much more frequently, where formerly we preferred mechanical appliances, like the button. It was therefore in this branch of surgery, the same as in all other branches, the attention to minute details which was responsible for a great part of the progress made in the art and the improvement in the results achieved.

Dr. Willy Meyer referred to the great difficulty experienced by surgeons in getting cases with carcinoma of the stomach under their care early. He emphasized the importance of the fact that the earlier an exploratory operation was performed in a suspicious case of cancer of the stomach, the better. Unfortunately the virulence of carcinoma was extremely varying. A large malignant gastric tumor, diagnosed late and extirpated, might never return, whereas a small sized cancer of the pylorus, diagnosed by exploratory incision and operated at once, would take the patient's life by multiple metastasis within a very short time. Regarding benign troubles, he would only refer to neurosis of the stomach, a clinical entity, the diagnosis of which would usually be made from the history of the case and its wonderful obstinacy to all kinds of treatment offered by internal medicine. There were cases of pure gastric neurosis in which all the symptoms pointed to a gastric ulcer, and yet nothing whatever was found on operation. If the surgeon resorted to a gastroenterostomy in such a case, the result was usually disastrous, whereas a simple exploratory incision for thorough inspection and palpation effected a cure. The speaker urged that any case of neurosis of the stomach that resisted medical treatment should be submitted to an exploratory operation.

Dr. Robert T. Morris said that he not infrequently had cases referred to him for supposed ulcer of the stomach which were not proper cases for operation at all. Upon investigation they proved to be cases of neurosis of the stomach, due either to a neurotic inheritance or precipitated by some peripheral irritation, such as an eye strain. These cases must be eliminated at the outset. The speaker said he had recently operated on a case that gave all the typical symptoms of gastric ulcer, *i.e.* epigastric pain, with vomiting of blood and mucus. Upon opening the abdomen he found a band of adhesions extending from the stomach to the bile tract; there was no infiltration nor induration. Upon dividing the adhesions the vomiting and pain ceased, and the patient had since remained well. Dr. Rose had stated that atony and dilatation were synonymous, and the speaker said he could distinctly recall a few cases in which there was dilatation due to adhesions, with muscular hypertrophy of the walls of the stomach. In operating on the stomach Dr. Morris said he had discarded the various mechanical devices and had come back to the suture. He now favored a single suture with a large needle, for the reason that fine suture material frequently cut through the tissues. To save time he did not as a rule suture the mucosa unless there was a good deal of hemorrhage. He had also discarded the use of the various ingenious forceps, preferring to rely upon the fingers and the aid of a good assistant. He emphasized the fact that in the past surgeons had been too much afraid of sepsis in these operations, ignoring the fact that in the presence of an ulcer or a malignant lesion the local phagocytosis was such that it was almost impossible to get up a sepsis if we used a reasonable amount of care.

Dr. Richard Ward Westbrook of Brooklyn, N. Y., said he was particularly interested in Dr. Kaufmann's last contribution to the etiology of gastric ulcer. In regard to the surgical treatment of gastric ulcer, the speaker said he was in entire accord with the views expressed by Dr. Kiliani. He favored gastroenterostomy by the posterior method, and in a certain class of cases of ulcer, where one could not tell macroscopically whether he was dealing with ulcer or beginning malignant disease, he thought a resection was indicated. He had never seen a case of gastric hemorrhage, due either to ulcer or cancer, in which the bleeding did not cease spontaneously, and he was decidedly opposed to operating in the acute stage. In dealing with the complications of gastric ulcer, too much should not be expected from gastroenterostomy, and Dr. Westbrook said he could recall especially bad results in cases where there were widespread adhesions about the stomach. In dealing with such extensive adhesions, he did not think they could be relieved either by the operation of Mayo Robson (gastrolysis) or a gastroenterostomy. The speaker said he had never had the misfortune to open the abdomen for the relief of a neurosis, and he thought such an accident could be avoided by careful observation of the patient, combined with great care in the taking of the history. On the other hand, he had had excellent results with gastroenterostomy where a typical history of chronic ulcer could be elicited, but where no lesion could be demonstrated at operation.

Dr. Jonathan G. Wells said the lack of gastric mucus and its relation to hyperacidity and gastric ulcer, which Dr. Kaufmann had discussed in his paper, was a subject that had been scarcely touched upon in the literature. In cases of hyperchlorhydria he had been often struck by the fact that the gastric juice was very fluid and free from mucus. He had noticed an increase of mucus in ulcers which were healing. Although this is not a positive sign, we are getting good results, as it is possible to have an ulcer persist with large amounts of mucus. Dr. Kaufmann's theory that the lack of mucus, by not giving the mucous membrane its proper protection, makes it more subject to injury followed by ulcer, seems to be reasonable and will probably account for a large proportion of the ulcers. Among 30,000 deaths recorded by one of our large insurance companies there were only 135 deaths due to ulcer. This either shows that the general practitioner is poor at diagnosis or that deaths from ulcer are very rare. Dr. Kiliani's paper dealt with the surgical treatment of ulcer most admirably and much less radically than is the tendency at the present time.

Dr. Robert Coleman Kemp, in discussing Dr. Kiliani's paper on the surgical treatment of gastric ulcer, said that many physicians were inclined to keep these patients under their observation for too long a time before turning them over to the surgeon. After referring to the value of the rest cure in certain instances, the speaker said that his own point of view was that all cases of gastric ulcer, especially in patients who were self-supporting, that did not show improvement after a fair course of treatment, should be turned over to the surgeon. This particularly applied to cases in which there was constant hemorrhage and loss of weight, and especially where there was stenosis of the pylorus, as evidenced by the clinical symptoms.

Dr. Max Einhorn said he had frequently noted a lack of mucus secretion in achylia gastrica. There were a distinct class of cases of gastric ulcer that were amenable to surgical intervention, and those were the ones where the ulcer was near the pyloric orifice. The length of time during which a patient had been under treatment was no criterion as to whether he should or should not be operated upon; the important point was, how had he been treated? We could not always assure these patients that an operation would relieve them.

Urethral Growths.—Fungating tumors of the urethra are best removed with a sharp curette whose handle furnishes a continuous irrigation of a bactericide.—*American Journal of Dermatology.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 28, 1907.

THE PRESIDENT, DR. WALTER LESTER CARR, IN THE CHAIR.

Executive Session.—After the nomination of officers, censors, and delegates to be elected at the one hundred and second annual meeting to be held November 25, the scientific program was entered upon. This program was arranged by the Committee on Public Health.

The Prevention and Disposal of Dust.—Dr. WALTER BENSEL, Commissioner of Street Cleaning, made a report of the work of his department, of the difficulties encountered, and illustrated his remarks with lantern slides, showing pictures of various phases of the departmental work, of the working men, of their tools, their wagons, stables, sprinkling carts, flushing outfits, incinerators, etc.

Concerning the Effects of Dust on the Human Organism.—Dr. HARLOW BROOKS read this paper, in which he discussed certain of the more obvious problems. Dust entered the body through practically all its chief channels. Upon the skin it acted indirectly as a disease producer. It entered the digestive tract and was relatively important as bacterial and protozoal infections might be induced, and as early decomposition of food products was so favored. There was no doubt but that typhoid fever was largely disseminated in this manner. But except for certain of these intestinal diseases, among which might be included bacterial and amebic dysentery, dust played but a minor part in the production of infections by this route. Dust was an exciter of ophthalmic disease, especially during epidemics of conjunctivitis. The tract most frequently and seriously diseased as the result of dust was the respiratory, and the most serious lesions produced by the inhalation of dust occurred in the pulmonary parenchyma. Statistical data showed definitely that patients the subjects of pneumokoniosis were especially prone to attacks of acute bronchitis, to pneumonia, and all other forms of pulmonary infection, and especially to pulmonary tuberculosis, as stated by many observers, notable among whom was Merkel. Added to these changes in the lung tissue, which have at the same time decreased its functional possibilities and lowered its resistance against secondary processes, there were great deposits of dust in the lymph nodes. They found these nodes increased in size and black with the dust contained therein. When one considered the important rôle which these glands played in the protection of the body from pathogenic organism which entered through the respiratory tract, one could well appreciate the reason why in these cases lymphoid tuberculosis was the rule. He had found tuberculous lesions almost universally present when pneumokoniosis had brought about this condition in the lymph nodes, and in New York City they might be looked upon as constantly associated lesions. It seemed that the dangerous quality of inhaled dust lay chiefly in two characteristics, one on the physical character of the dust, the other on its organic nature. With very finely comminuted and light dust the resultant lesions of the lungs were much more innocent and secondary pulmonary diseases were much less frequent as a result. On the contrary, dust which contained sharp pointed and jagged particles, inflammatory and irritative changes were much more constant and diffuse and secondary infections, as with tuberculosis, were much more frequent. Dust which was chiefly injurious on account of its organic character was such as contained organisms or organic material which were prone to excite disease in the body, as the dried sputa of tuberculous subjects. Other infections so transmitted were those of anthrax, glanders, diphtheria, actinomycosis, and bubonic plague. Obviously the dust which was most detrimental of all to the human body was one which combined the characteristics of both classes. Pneumokoniosis was practically a universal condition in all adults who had lived in New York City for any considerable length of time; and associated with this was a pulmonary fibrosis of greater or less degree, with a practically constant more or less active bronchitis. In some 80 per cent. of instances tuberculous lesions, which were undoubtedly associated in origin with the primary lesions, were also found. More or less anthracosis, fibrosis, and necrosis of the adjacent lymph nodes was also persistently present. In practically every case the plexus of nodes at the tracheal bifurcation was chiefly involved, and in over 90 per cent. of these it was associated with tuberculous and fibrotic foci. Even a cursory microscopic examination of the composition of New York dust showed a truly wonderful array of pathogenic factors. Dr. Brooks offered the following conclusions: (1) Dust in itself was productive of serious disease conditions, particularly of the respiratory and digestive tracts. (2) These primary conditions predisposed to secondary lesions, particularly to pulmonary and lymphatic tuberculosis. (3) Many contagious and infectious diseases were transmitted through the agency of dust. (4) In a city the size of New York the production of large quantities of dust, often of a highly dangerous character, could not be prevented. (5) Dust could in most instances be relatively and economically collected and disposed of and the production of unnecessary dust could be and should be prevented by properly framed and enforced regulations.

The Mortality of Dusty Trades.—Mr. FREDERIC HOFFMAN, statistician of the Prudential Insurance Company, read this paper by invitation. His conclusions were that in its final analysis labor efficiency depended primarily upon the health, strength, and long life of the individual workman. As long as the present waste of health and life in industry continued our industrial efficiency as a nation must fall lamentably short of the attainable maximum. It was evident that dusty trades in particular exacted a heavy toll in human life at a period when such lives had their highest economic value. The loss to the nation could not be even approximately estimated upon the fragmentary data available, while the suffering and sorrow of the class affected was equally incalculable. Far-reaching changes and improvements were necessary in factory construction and in the sanitary conditions under which labor in dusty trades was carried on. Much had been done, it was true, but as yet the conditions as to air, ventilation, and light were very often far from satisfactory, and efforts tending in this direction were not as promising of good results as would be desirable. The danger of a dust-laden atmosphere required to be better understood and the facts brought home to the individual workman by a more rational system of education. The problem of effective ventilation in workshops required to be more scientifically studied, with a due regard to the best conditions under which industry could be carried on. Factory inspection should be made to rest upon a medical basis, and the periodical physical examination of persons employed in dusty and other health-injurious trades required to be provided for whether upon a voluntary basis or by statutory enactments. The vital statistics of different trades required to be collected with more care and their analysis demanded more qualified treatment. The education of students in medicine should be made to include a course in industrial hygiene, with special reference to the pathology of dust inhalation. The microscopy of the configuration of dust required to be more thoroughly investigated along with more qualified observations upon the medical aspects of the relation of dust disease. There was also need of a higher grade of microphotographs illustrating the different forms of dust to which working people in various trades were continuously exposed and in which an admirable beginning had been made in Dr. Migerkas' monograph on "Dust Varieties," with textual explanations. This work, published in Ger-

man, had not, so far as he knew, been reproduced in English, but many of the illustrations had been reproduced in Oliver's "Dangerous Trades." A more general recognition of dust as a cause of disease would gradually result in much needed improvements, including a more intelligent disposal of the dust and refuse of homes and municipalities. The most important fact disclosed by investigations into the mortality of men employed in dusty trades, however, was the extraordinary proportion of deaths from lung diseases at ages from twenty-five to forty-four. Only by a qualified, periodical medical examination of workmen engaged in such trades could the early symptoms of disease be recognized at a time when proper treatment would with practical certainty produce a cure. The best advice which could be given to workmen in such circumstances was the emphatic suggestion for an early and complete change of employment. Since fibroid phthisis was of much slower growth than the typical form of pulmonary tuberculosis the symptoms were less easily recognized, but the prognosis was more certain when the facts of occupation were taken into account. This suggested a repetition of the remark by Ramazzini more than two hundred years ago, that the physician should inquire into the trade followed by the patient, for, as he said, a just regard to the fact of employment "would be of greater service in facilitating the cure." Even the most radical factory legislation, resting upon a medical basis and carried out by medical inspectors, could not hope to reach a large number of persons individually employed under conditions of continuous exposure to a dust-laden atmosphere. The general practitioner in such cases was the only hope of the afflicted patient, and sensible advice resting upon a thorough knowledge of the facts of industrial diseases would no doubt, in many cases, be followed and prove productive of excellent results. The distinction between fibroid phthisis and ordinary tuberculous disease, whether acute or chronic, was vital. Fibroid phthisis was a specific trade disease affecting chiefly persons employed in dusty occupations. The workman should be made to realize the difference and the more hopeful outlook for relief and cure where the symptoms clearly indicated the case to be one of fibroid phthisis, and in such cases no better advice could be given than that of the Department Committee, that if the workman left the dusty employment for work in agriculture, or in some other occupation in air free from irritating particles, the disease might be practically arrested. No class of persons was entitled to more sympathetic consideration than those who, at the risk of life and health, ministered to the wants and needs of others, and whatever could be done to improve the conditions under which industry was carried on was the imperative duty of every employer of labor and the State. Not, however, until the facts of occupation, mortality, and in particular of dusty trades, were better understood and more intelligently used was there much hope for a material reduction in the waste of life and health in many industries and employments as carried on at the present time, and he could only hope that what he had said might contribute, however slightly, to this end.

Dr. William H. Park said it was difficult to find any bacteria in the dirt of the streets or houses. No pathogenic bacteria had been found, except when one went around the subway stairs, or elevated stations, or other places where people expectorated. The diseases caused were practically only those from street expectorations. If more care was taken only a moderate amount of bacteria would be cast off in this way. Bacteria in the sputum were protected by the mucus. On the higher places, as the high window sills or walls, no pathogenic bacteria would be found; they would be found at street crossings, but no higher up. Personally he did not think the street dirt was such a great factor in carrying infection, but if a child went out on the street on a dusty day one would expect him to be more likely to contract diphtheria or other contagious disease. Dust indirectly might be the cause. He thought that dust was, in a way, like sewer gas; it predisposed to disease. He related an experience he had some years ago in a small town in which a severe wind storm occurred. The day before there were but two cases of diphtheria; but two days following this wind storm thirty-two cases developed. While Dr. Park did not want to belittle the importance of what had been brought out, he could not believe that it was the dust which brought various diseases directly to us; it merely predisposed to them. He cautioned against laying too much or improper stress upon one side only; there were various agencies which together made up the causes of disease.

College of Physicians of Philadelphia.

At a stated meeting held November 6, Dr. John K. Mitchell exhibited "A Patient with Unusual Bony Growths." The patient was a young man who, following an attack of typhoid fever, presented tumorous excrescences upon a number of the long bones of the body which, while a source of inconvenience in movement, caused no discomfort. The condition exhibited a certain crude symmetry in distribution, and it was unyielding to all forms of treatment. Dr. Robert Le Conte presented a communication entitled "A Case of Retroperitoneal Undescended Testis Strangulated by a Twist." Successful removal was effected by surgical means, and the specimen was exhibited. A discussion was entered upon as to the causes of undescended testicle and the dangers arising from such a displacement, as well as the measures to be employed for their relief. Dr. Morris Jastrow, Jr., read a paper entitled "The Liver in Antiquity." He pointed out that the priests were the first physicians, but that gradually there came a separation of the two pursuits. Medicine is thus an offshoot of religion. In ancient times it was the practice to study the livers of sacrificial animals for divinations and auguries. The position of the gall-bladder and of the biliary ducts and the markings on the surface of the liver were accepted as indications of the outcome of various undertakings. The liver was thought to be the seat of the soul and the higher emotions, until the progress of anatomy demonstrated the importance of the heart as the center of circulation. At a later period a compromise was made by making the brain and the heart the seats of the nobler emotions and the liver the seat of the lower. Dr. Astley P. C. Ashhurst read a paper entitled "A Case of Perforation of the Gall-bladder During Typhoid Fever." He reported two cases, in one of which intestinal perforation was suspected, abdominal section was made, and, the patient dying, a perforation of the gall-bladder was found on post-mortem examination. In a second case a diagnosis of perforation of the gall-bladder was made and operation was undertaken within a few hours after the onset of the acute symptoms. The gall-bladder was removed and the patient made a perfect recovery and he was exhibited. Dr. G. E. de Schweinitz and Dr. T. D. Holloway presented a communication entitled "Pulsating Exophthalmos." They discussed the conditions of aneurysm and arteriovenous communication on which the affection commonly depends, and they considered at especial length the various methods of treatment. Traumatism is at times an etiological factor, the affection generally developing on the side injured, although occasionally it develops on the opposite side. Spontaneous recovery sometimes occurs. Compression has been employed, also ligation of the large arteries of the neck, but the best results have been secured from direct attack upon the vessels at fault in the orbit or back of the orbit. A man was exhibited who developed pulsating exophthalmos following a gunshot wound of the head and in whom temporary improvement only followed upon ligation first of the one and then of the other carotid artery. Permanent recovery, however, followed a blow over the eye.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Diseases of the Skin. By Arthur Van Harlingen, Ph.B. (Yale), M.D. Large 8vo, 482 pages, muslin, illustrated, $3.00 net. P. Blakiston's Son & Co., Philadelphia.

Trypanosomes and Trypanosomiases. By A. Laveran and F. Mesnil. 4to, muslin, 540 pages, illustrated, $3.50 net. W. T. Keener & Co., Chicago.

Volume XVI, Nos. 401-61 and 459 Sammlung klinischer Vorträge. By O. Hildebrand, Friedrich Müller and Franz von Winckel. 4to, 96 pages and 104 pages, paper. Druck und Verlag von Breitkopf & Hartel in Leipzig.

Manual of Physiological and Clinical Chemistry. By Elias H. Bartley, B.S., M.D., Ph.G. 8vo, 202 pages, illustrated, $1.00 net, muslin. P. Blakiston's Son & Co., Philadelphia.

State of New York State Commission in Lunacy, Eighteenth Annual Report. Large 8vo, 1290 pages, half morocco. J. B. Lyon Company, Albany.

The Chemistry of Commerce. By Robert Kennedy Duncan. 293 pages, 8vo, half morocco, illustrated. Harper & Bros., New York.

Ueber das Tasten normaler Magenteile. By Dr. Theodor Hausman. Large 8vo, 38 pages, paper. Verlag Von S. Karger, Berlin.

The Quarterly Journal of Medicine. Edited by William Osler, J. Rose Bradford, R. Hutchison, A. E. Garrod, H. D. Rolleston, and W. Hale White. 4to, 106 pages, paper, illustrated. The Clarendon Press, Oxford.

Die Krankheiten des Verdauungskanals. By Dr. Paul Cohnheim. 4to, 252 pages, paper. Verlag Von S. Karger, Berlin.

Jahresbericht über die Verwaltung des Medizinal Wesens die Krankenanstalten und die öffentlichen Gesundheitsverhältnisse der Stadt Frankfurt A. M. Herausgegeben von dem Ärztlichen Verein. Mahlu and Waldschmidt, 1907.

Report on Advancements of Pharmaceutical Chemistry and Therapeutics. Vol. XX, 1906. E. Merck, Darmstadt, May, 1907.

The Pancreas, Its Surgery and Pathology. By A. W. Mayo Robson, D.Sc. (Leeds), F.R.C.S. (Eng.), and P. J. Cammidge, M.B. (Lond.), D.P.H. (Camb.). Large 8vo, 540 pages, illustrated, $5.00 net, cloth. W. B. Saunders Co., Philadelphia and London.

Proceedings of the American Medico-Psychological Association at the Sixty-second Annual Meeting. 8vo, 585 pages, ilustrated. American Medico-Psychological Association.

Practice of Medicine. By James Magoffin French, A.M., M.D. Large 8vo, 1252 pages, cloth, illustrated. William Wood & Company, New York.

Transactions of the American Otological Society. Large 8vo, 594 pages, paper, Mercury Pub. Co.

Transactions of the Maine Medical Association. 8vo, 176 pages, paper. Stephen Berry Co., Portland.

Tropical Diseases. By Sir Patrick Manson, K.C.M.G., LL.D. (Aberd.). 12mo, 876 pages, cloth, illustrated. William Wood & Company, New York.

Immunochemistry. By Svante Arrhenius. 12mo, 300 pages, cloth. The Macmillan Company, New York. $1.60 net

Primary Nursing Technique for First Year Pupil Nurses. By Isabel McIsaacs. 12mo, 107 pages, cloth, $1.25 net. The Macmillan Company, New York.

Clinical Therapeutics. By Alfred C. Croftan. 4to, 626 pages, muslin, $5.00. Cleveland Press, Chicago.

The Internal Secretions and the Principles of Medicine. By Charles E. de M. Sajous, M.D. 8vo, 1873 pages, illustrated, muslin. F. A. Davis Co., Philadelphia.

Diseases of Women. By Harry Sturgeon Crossen, M.D. Large 8vo, 800 pages, illustrated, muslin. C. V. Mosby Med. Book and Pub. Co., St. Louis.

Traite de l'Arthritisme. Par le Dr. D. Ds Grandmaison. 8vo, 496 pages, paper. A. Maloine, Paris.

Medical Ethics. By Robert Saundby, Edin. Large 8vo, 144 pages, muslin. J. B. Lippincott Co., Philadelphia.

Par l'Hyperemie. Par M. le Dr. Tuffier. 8vo, 46 pages, paper. Vigot Frères, Paris.

The Development of the Human Body. By J. Playfair McMurrich, A.M., Ph.D. 8vo, 528 pages, illustrated, $3 net. P. Blakiston's Son & Co., Philadelphia.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

Baltimore, June 18-21, 1907.

ANATOMY.

1. Describe the frontal bone, including its articulations and sinus.
2. Name the branches and give the relations of the external carotid artery.
3. Give relations of liver. Name lobes of liver.
4. Name structures severed by amputation through middle of leg.
5. Name and locate ventricles of brain.
6. Name the forms of inguinal hernia and give the difference between them.

SURGERY.

1. Give the cause and treatment of external hemorrhoids—(a) palliative, (b) one operative method.
2. What are the indications for operative treatment in any form of hernia?
3. What are the signs and symptoms and what is the surgical treatment of a purulent effusion into the knee joint?
4. Give in detail the treatment of a recent compound fracture of the middle third of the tibia.
5. Give the differential diagnosis between acute inflammation of the middle ear and mastoiditis.
6. Give the evidences and treatment of a wound penetrating the bladder.

PATHOLOGY.

1. Name the organisms most frequently associated with each type of pleurisy and give in detail the method of staining of each organism.
2. Define thrombosis, embolism and infarction, and name the organs in which infarction most frequently occurs.
3. Define sarcoma and carcinoma. Give the various types and the chief avenues of extension of each, and name the sarcomata in the order of their malignancy.
4. Define the term general anasarca and give a gross pathological description of the lesion which usually gives rise to it.
5. Name the varieties of meningitis from a bacteriological standpoint and describe the elements you would expect to find in the fluid from a case of the epidemic variety.
6. Give the gross pathology of amebic dysentery. Describe the organism giving rise to it and name the pathological condition of the liver often associated with it.

OBSTETRICS AND GYNECOLOGY.

1. Give treatment for case of placenta previa
2. How would you manage a twin labor, one foot of each child presenting?
3. Diagnosis and treatment of ovarian cyst.
4. How would you treat a case of gonorrheal conjunctivitis in an infant?
5. What treatment would you adopt in a case of umbilical hernia in an infant?
6. How would you manage a posterior shoulder presentation?

PRACTICE.

1. Define (a) myxedema, (b) chlorosis, (c) tinea circinata, (d) enteritis, (e) tabes dorsalis.
2. Differential diagnosis between (a) hysteria and epilepsy, (b) cancer and ulcer of the stomach.
3. Give signs of arteriosclerosis.
4. Give symptoms of Graves' or Basedow's disease.
5. Give differential diagnosis between varicella and varioloid.
6. Give treatment of (a) uremia, (b) empyema, (c) pertussis.

CHEMISTRY.

1. Define the terms dialysis, osmosis, crystalloid and colloid.
2. Give the chemical name for cooking (baking) soda and washing soda, respectively, and state the general properties of each.
3. What, chemically, is glycerine? Give its chemical composition (formula). State its usual source and give its general properties.
4. Give in detail two reliable dissimilar tests for the detection of sugar in the urine.
5. Give the chemical composition (formula) of urea;

state the usual amount excreted in 24 hours, and give in detail a reliable method for its quantitative estimation.

6. Give in detail a reliable test for the estimation of the total acidity of a specimen of gastric contents.

MATERIA MEDICA.

1. Name the mineral acids and give the dose of each.
2. What are the preparations of the phosphates and their doses?
3. What are the official preparations and doses of iodine and the iodides?
4. What are the official preparations of ergot and their doses?
5. Give the official preparations and doses of nux vomica and its alkaloids.
6. What are the principal direct and indirect emmenagogues?

THERAPEUTICS.

1. What are the physiological effects and therapeutic uses of hyoscyamus and its alkaloids?
2. Give the physiological action of nitroglycerine, indications and contraindications for its use.
3. What do we understand by the term alterative, and name the principal drugs of this kind.
4. Describe in detail the treatment for tapeworm.
5. How do disinfectants act? Name the principal ones.
6. Define local and general anesthesia. Name means and method of producing and sources of danger.

PHYSIOLOGY.

1. What portion of the gastrointestinal tract accomplishes the greatest amount of absorption? (b) State what class of substances are absorbed in the stomach, small and large intestines.
2. What are the sources of oxygen and carbonic acid gas in the system? (b) What is the effect of each upon the blood? (c) What is the average quantity of oxygen in venous and arterial blood? (d) What are the symptoms of insufficient oxygen in the blood?
3. Explain the effect of muscular activity upon amount and character of metabolism of body, and the influence upon this metabolism of variation in the composition of the diet.
4. What are ptyalin, pepsin, and pancreatin, and in about what proportion are pepsin and pancreatin found?
5. Describe the condition known as apnea.
6. What becomes of the biliary salts which are constantly poured into the upper part of the intestinal canal? Give test for biliary salts.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

Baltimore, June 18-21, 1907.

ANATOMY.

4. The structures severed by amputation through the middle of the leg are: The skin; cutaneous vessels and nerves; aponeurosis; tibialis anticus, extensor longus digitorum, extensor proprius hallucis, peroneus brevis, peroneus longus, flexor longus hallucis, soleus, gastrocnemius, plantaris, flexor longus digitorum, and tibialis posticus muscles; anterior tibial artery veins and nerve; posterior tibial artery, veins and nerve; peroneal artery and veins; tibia, fibula, and interosseous membrane.

6. The forms of inguinal hernia are:
   (1) *The Direct*, in which the hernia does not occupy the inguinal canal, but leaves the abdomen to the inner side of the deep epigastric artery, through the space known as Hesselbach's triangle. There are two forms of this variety: (*a*) the hernia may escape between the epigastric artery and the obliterated hypogastric artery; (*b*) or it may escape between the obliterated hypogastric artery and the outer edge of the rectus muscle.
   (2) *The Indirect* or *Oblique*, in which the hernia occupies, wholly or in part, the inguinal canal. An *oblique inguinal* hernia may pass into the scrotum or labium majus, when it is called *complete;* or may be retained in the inguinal canal, when it is called *incomplete*, or a *bubonocele*. Other varieties are the *congenital*, *infantile*, and *encysted*.

SURGERY.

2. The indications for operative treatment in hernia are: In all forms of *femoral* hernia; in *inguinal* hernia when strangulated, irreducible, when a truss is unsatisfactory, or very painful, when obstruction occurs, or when taxis fails; in *umbilical* hernia, in the *infantile* form if persisting till puberty, and in *adults* if strangulated, and in other conditions if the patient is in a suitable condition for operation.

PATHOLOGY.

1. In *acute pleurisy* there may be found the tubercle bacillus, the pneumococcus, and the *Streptococcus pyogenes;* varieties of the *Staphylococcus pyogenes*, the typhoid bacillus, Friedlander's bacillus, and the diphtheria bacillus have also been found in cases of acute pleurisy.

In *purulent pleurisy* (*empyema*) there may be found the *Streptococcus pyogenes*, pneumococcus, tubercle bacillus, *Staphylococcus pyogenes, Micrococcus lanceolatus.*

In *tuberculous pleurisy* the tubercle bacillus may be found.

2. *Thrombosis* is the coagulation of the blood within the vessels during life.

Embolism is the plugging of a blood-vessel by a foreign body.

Infarction is the plugging of a terminal artery. It most frequently occurs in the kidneys, spleen, lungs, base of brain, retina, and heart.

3. A *sarcoma* is a malignant tumor of the connective tissue type, in which there is abundant cell formation with very scanty intercellular substance.

Sarcomata are classified:

I. According to the *form of the cell* which predominates, as Round-cell, Spindle-cell, and Mixed-cell Sarcomata.

II. According to the *stroma*, as Myxosarcoma, Chondrosarcoma, Fibrosarcoma, and Osteosarcoma.

III. According to the *secondary changes* which they may undergo, as Liposarcoma, Chloroma, Melanosarcoma, and Calcifying Sarcoma.

Sarcoma extends by the circulation.

The round-celled, the large spindle-celled, and the melanotic sarcomata are the most malignant; the giant-celled and the fibrosarcomata are among the least malignant.

A *carcinoma* is a tumor composed of epithelial cells with a tendency to proliferation and a stroma of connective tissue. The cells are atypical in their appearance, arrangement, division, and proliferation.

Carcinomata are classified as follows: I. Epithelial carcinoma or epithelioma, which may be (*a*) squamous, (*b*) cylindrical celled, (*c*) tubulated; II. glandular carcinoma, which may be (*a*) scirrhus, (*b*) encephaloid.

Carcinoma extends as a rule by the lymphatics, occasionally by the blood-vessels.

5. (1) *Cerebrospinal meningitis*, caused by the *Diplococcus intracellularis meningitidis.*

(2) *Tuberculous meningitis*, caused by the tubercle bacillus.

(3) *Pneumococcic meningitis*, caused by the pneumococcus.

(4) *Pyogenic meningitis*, caused by the *Streptococcus pyogenes*, and the *Staphylococcus pyogenes albus* and *aureus.*

(5) A meningitis may be associated with some of the acute infectious diseases; in such cases the typhoid bacillus, the bacillus of diphtheria, or the gonococcus may be present.

The fluid from a case of the epidemic variety might be expected to contain endothelial cells, leucocytes, some fibrinous material, and the *Diplococcus intracellularis meningitidis*, with some of the other bacteria mentioned above.

6. In amebic dysentery the mucosa of the large intestine is edematous and infiltrated, and finally ulcerated. These ulcers have undermined edges, and several of them may coalesce or connect by means of sinuses; the mouth of the ulcer is comparatively small. Much of the mucosa may be necrosed and slough, and the ulceration may extend down to the muscular coat or even to the serous coat of the intestine. Occasionally the lower portion of the ileum is involved as well as the large intestine. Perforation is rare.

The condition is due to the *Ameba dysenteriæ* or *Ameba coli*, an ameboid body, three or four times as large as a red blood corpuscle, granular in the center and clear at the margin, nucleated, and containing vacuoles, sometimes also containing pigment, bacteria, or other foreign matter.

Abscess of the liver is often associated with this condition.

OBSTETRICS AND GYNECOLOGY.

2. The foot of one child should be pushed up; and the foot of the other child should be pulled down, so as to secure a breech presentation.

3. An ovarian cyst is generally accompanied by menorrhagia or metrorrhagia, sterility, bearing down pain in the pelvis, which may radiate to the back or thighs, hemor-

rhoids or constipation, frequent micturition, and various other pressure symptoms of the digestive or respiratory apparatus if the cyst becomes sufficiently large. Later on there may be the *facies ovariana*, general impairment of health, and ascites. There are no pathognomonic symptoms. The diagnosis is made by bimanual palpation and (sometimes) exploratory incision. The condition is to be particularly differentiated from pregnancy and ascites.

The *treatment* is ovariotomy.

4. Treatment of gonorrheal conjunctivitis in an infant. Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

5. Treatment of umbilical hernia in an infant: "A round disk of wood, a coin, or a button is wrapped in lint or some soft material, and kept in position over the umbilicus with a light elastic bandage or with strips of adhesive plaster, these appliances to be removed for cleansing purposes and replaced. Recovery occurs with subsequent closure of the ring. A much more serious form of umbilical hernia *rarely* occurs, with imperfect development of the abdominal wall, in which *large* protrusions of intestine and other abdominal organs take place. These require a plastic surgical operation." (King's *Manual of Obstetrics.*)

6. In cases of posterior shoulder presentation, if seen before labor, version should be performed to correct the malpresentation; in case of impaction a cesarean section is indicated; sometimes decapitation or embryotomy has been performed, but a cesarean section is preferable. Cases of shoulder presentation have been known to terminate spontaneously, but it is not advisable to rely on this possibility.

PRACTICE.

1. *Myxedema* is a condition characterized by atrophy of the thyroid gland, mental dullness, sluggish movements, and thick speech.

Chlorosis is a form of anemia characterized by a marked diminution in the amount of hemoglobin.

Tinea circinata is ringworm of the body.

Enteritis is a condition characterized by inflammation of the small intestine.

Tabes dorsalis is a condition in which the posterior columns and nerve roots of the spinal cord are degenerated; and which is characterized by incoordination, loss of deep reflexes, and various disturbances of sensation and nutrition.

2. (*a*) In *epilepsy* there will be a brief aura, sudden and complete loss of consciousness, pupils dilated and rigid, the tongue will be bitten (unless prevented), the sphincters may be relaxed, there may be a slight rise of temperature.

In *hysteria* there may be an aura of considerable duration, the onset is gradual, and consciousness is either retained or only partially lost, the pupils are generally mobile and active, the tongue is not apt to be bitten nor the sphincters relaxed, the temperature is generally normal. Hysteria is apt to be preceded by some emotional disturbance.

(*b*) *Cancer of the stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

Ulcer of the stomach is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

3. The *signs of arteriosclerosis* are: A slow pulse of high tension, rigidity of the blood vessels, enlargement of the left ventricle, displacement of the apex beat to the left, the second sound of the heart is accentuated, harsh, and ringing.

4. In *Graves' or Basedow's disease*, the symptoms are: Rapid pulse, protrusion of the eyeballs, enlargement of the thyroid, and a fine muscular tremor.

5. In *varicella* the symptoms come on gradually; there is no prodromal fever; no pain in the back; the eruption appears on the first day, comes in crops, disappears on stretching the skin, and is not shotty.

In *variola* the symptoms come on very suddenly; there is fever; severe pain in the back, and headache; the eruption appears on the third or fourth day, as papules, becoming in turn vesicles and pustules.

CHEMISTRY.

1. *Dialysis* is the process of separating substances from a mixture by placing the latter in a vessel with porous walls and immersing it in water, when the more diffusible substance passes through the porous wall. This latter process is called *osmosis*. Substances which readily pass through this porous membrane are called *crystalloids;* those which do not are called *colloids*.

2. Cooking or baking soda is sodium bicarbonate, $NaHCO_3$.

Washing soda is sodium carbonate, Na_2Co_3+10 Aq.

The former is a white crystalline powder, with a slightly saline taste and a mildly alkaline reaction; it is anhydrous and quite soluble in water.

The latter forms large rhombic crystals, is decidedly alkaline, is efflorescent, and slightly soluble in water.

3. Chemically, glycerine is a triatomic alcohol. Its formula is:

$$\begin{array}{l} CH_2OH \\ \\ CHOH, \text{ or } C_3H_5(OH)_3 \\ \\ CH_2OH \end{array}$$

It is usually obtained as a by-product in the manufacture of soaps and of stearin candles.

Its *general properties* are: It is a colorless, odorless, syrupy liquid, with a sweetish taste; it is soluble in water and in alcohol, insoluble in ether and in chloroform; it is not ordinarily volatile; it is a good solvent for several substances.

4. Two reliable dissimilar tests for the detection of sugar in the urine: The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test*: Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Boettger's test*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

5. The formula of urea is $CO(NH_2)_2$.

The usual amount excreted in twenty-four hours is from thirty to thirty five grams, or about an ounce to an ounce and a half.

A comparatively easy test is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7701 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely." (Witthaus' *Manual of Chemistry.*)

6. To estimate the total acidity of a specimen of gastric contents: Take 10 c.c. of the unfiltered gastric contents, obtained after a test-meal. Titrate this with a decinormal NaHO solution, using phenol phthalein as an indicator. As each c.c. of the NaHO solution corresponds to 0.00365 grams of HCl, the number of c.c. of the sodium hydroxide solution used, multiplied by 0.0365, gives the percentage of total acidity expressed in terms of HCl.

MATERIA MEDICA.

1. Mineral acids, with their doses: Dilute sulphuric acid, 30 minims; aromatic sulphuric acid, 15 minims; dilute nitric acid, 30 minims; nitrohydrochloric acid, 3 minims; dilute nitrohydrochloric acid, 15 minims; dilute hydrochloric acid, 15 minims; dilute phosphoric acid, 30 minims; sulphurous acid, 30 minims; boric acid, 7 grains.

2. The official preparations of the phosphates and their doses are: Codeine phosphate, one-half to two grains; soluble phosphate of iron, two to five grains; soluble pyrophosphate of iron, two to five grains; syrup of the phosphates of iron, quinine, and strychnine, one dram; elixir of the phosphates of iron, quinine, and strychnine, one dram; sodium phosphate, one-half to two drams; effervescing sodium phosphate, two to four drams; dried sodium phosphate, one-half to one dram; solution of sodium phosphate, one-half to two drams.

3. The official preparations and doses of iodine and the iodides are: Iodine, one-tenth of a grain; compound solution of iodine, three minims; tincture of iodine, one and a half minims; potassium iodide, seven and a half grains; sodium iodide, seven and a half grains; ammonium iodide, four grains; strontium iodide, seven and a half grains; zinc iodide, one grain; diluted hydriodic acid, fifteen minims; syrup of hydriodic acid, one dram.

4. The official preparations of ergot and their doses are: Ergot, thirty grains; extract of ergot, seven and a half grains; fluid extract of ergot, thirty minims; wine of ergot, two drams.

5. The official preparations and doses of nux vomica and its alkaloids are: Nux vomica, one grain; extract of nux vomica, one-quarter of a grain; fluid extract of nux vomica, one minim; tincture of nux vomica, ten minims; strychnine, one-sixty-fourth of a grain; strychnine sulphate, one-sixty-fourth of a grain; strychnine nitrate, one sixty-fourth of a grain.

6. The principal *direct emmenagogues* are: Apiol, cantharides, permanganate of potassium, ergot, rue, savine, tansy, pennyroyal, and guaiacum.

The principal *indirect emmenagogues* are: Iron, arsenic, manganese, quinine, strychnine, and aloes.

THERAPEUTICS.

2. *Nitroglycerin* causes a dilatation of the blood-vessels, fullness in the head, giddiness, buzzing in the ear, the heart beat increases in rate and force, arterial tension decreases; it is a cardiac and nerve depressant, respiration is first stimulated and then depressed, it produces frontal headache.

It is *indicated* in angina pectoris, cardiac dyspnea, chronic nephritis, with high tension pulse, vomiting, epilepsy, hiccough, sea-sickness, asthma, and other spasmodic disorders.

3. An *alterative* is a remedy which, in some way that is not understood, alters the course of morbid conditions

The principal alteratives are: Arsenic, mercury, iodine, sulphur, cod liver oil, phosphorus, colchicum.

4. The patient should be starved for from twelve to twenty-four hours, and early in the morning should take a capsule containing three or four grains of pelletierine, the active principle of pomegranate; in place of the pelletierine, one-half dram or one dram of the oleoresina aspidii may be given. This is to be followed by a calomel purge and Epsom salts. A rectal injection of salt and water will dislodge any segments of the tapeworm that may remain in the rectum after the purgative action of the calomel and saline.

5. *Disinfectants* act: (1) By destroying the bacteria and their products; (2) by acting as strong oxidizing or reducing agents; (3) by combining with the protoplasm of the bacteria and forming insoluble compounds; (4) by modifying the chemical reaction of the media in which the bacteria live.

The principal ones are: Heat, sulphur dioxide, chlorine, carbolic acid, formaldehyde, mercuric chloride, potassium permanganate, iodine, bromine, zinc chloride, creolin, hydrogen dioxide, chlorinated lime.

6. *Local anesthesia* is the condition in which there is loss of sensibility of the tissues over a limited area, due to the application of certain agents, such as cold, ethylene chloride, ether, cocaine, eucaine, or the infiltration of water, or a solution of salt, or of salt, cocaine, and morphine.

General anesthesia is a condition in which there is unconsciousness as well as abolition of sensation; it may be induced by the inhalation of ether, chloroform, nitrous oxide gas, chloride of ethyl, or a combination of certain of these agents.

PHYSIOLOGY.

1. (*a*) The small intestine is the portion of the gastro intestinal tract from which the greatest amount of absorption takes place.

(*b*) In *the stomach*, sugars and peptones are absorbed, fats, not at all; water, slightly or not at all; alcohol, readily; salts, slightly.

In the *small intestine*, sugars, proteoses, peptones, fats, water, and salts are all absorbed.

In the *large intestine*, water, salt, sugars, proteids, and fats are all absorbed.

2. (*a*) The *sources of oxygen* in the system are: (1) The oxygen inhaled in the atmospheric air; (2) the chemical decomposition substances in the body.

The *sources of carbonic acid gas* in the system are: (1) It is formed in the cells of the body; (2) the chemical decomposition or analysis of organic substances in the body.

(*b*) The *effect of oxygen on the blood* is to enter into loose chemical combination with the hemoglobin of the red corpuscles and to make the blood red in color.

The *effect of carbonic acid gas on the blood* is to enter into combination with sodium in the liquor sanguinis and in small quantities with the red corpuscles; it makes the blood of a purple color.

(*c*) The average quantity of oxygen in *venous* blood is from eight to twelve volumes in a hundred; in *arterial* blood, about twenty volumes in a hundred.

(*d*) The *symptoms of insufficient oxygen in the blood* are: The respirations are more frequent, and the inspiratory efforts are particularly vigorous; the dyspnea is severe, and lasts a long time before death ensues; the blood pressure is increased; there are various motor disturbances.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 7
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Jan. 14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan. 7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 10
Delaware	J. H. Wilson, Dover	Dover	Dec. 10
Dist. of Col'bia.	W. C. Woodward, Washington	Washington	Jan. 9
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	J. L. Conant, Jr., Genesee	Boise	April 7
Illinois	J. A. Egan, Springfield	Chicago	Jan. —
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May 26
Iowa	Louis A. Thomas, Des Moines	Des Moines	Dec. —
Kansas	T. E. Raines, Concordia	Topeka	Feb. 11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April 28
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 21
Maine	Wm J. Maybury, Saco	Portland	March 17
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 3
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 10
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Detroit	June 9
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Jan. 7
Mississippi	J. F. Hunter, Jackson	Jackson	May 12
Missouri	J. A. B. Adcock, Warrensburg	St. Louis	
Montana*	Wm. C. Riddell, Helena	Helena	April 7
Nebraska	J. E. Sward, Oakland	Lincoln	
Nevada	S. L. Lee, Carson City	Carson City	Feb. 3
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	Jan. 14
New Jersey	J. W. Bennett, Long Branch	Trenton	June 16
New Mexico	B. D. Black, Las Vegas	Santa Fe	Dec. 2
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb. 4
N. Carolina*	G. T. Sikes, Grissom	Winston, Salem	May —
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Jan. 7
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 10
Oklahoma*	J. W. Baker, Enid	Guthrie	Dec. —
Oregon	B. E. Miller, Portland	Portland	Jan. 8
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	Dec. 3
Rhode Island	G. T. Swartz, Providence	Providence	Jan. 2
S. Carolina	W. M. Lester, Columbia	Columbia	June 9
S. Dakota	H. E. McNutt, Aberdeen	Mitchell	Jan. 8
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville	May —
Texas	G. B. Foscue, Waco	Waco	June 16
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	Jan. 6
Vermont	W. Scott Nay, Underhill	Montpelier	Jan. 14
Virginia	R. S. Martin, Stuart	Staunton	Dec. 10
Washington*	C. W. Sharples, Seattle	Spokane	Jan. 7

Wisconsin	J. V. Stevens, Jefferson	Milwaukee	Jan. 14
Wyoming	S. B. Miller, Laramie	Laramie	Feb. 12

* No Reciprocity recognized by these States

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Surgical Suggestions.

Anesthesia.—Johnston says that when there is obvious and extensive nasal obstruction, the mouth must be propped so that the patient may receive enough of the anesthetic, with proper admixture of air, to produce smooth anesthesia. In partial obstruction he uses small rectal tubes, cut six or seven inches long, passed through the nares to the nasopharynx. These, well vaselined, should be placed in position after the patient has been partially anesthetized, and joined with a safety-pin in front, so that they will not slip beyond reach. This is a most excellent method with stout patients, whose tongues swell or fall back.—*Canadian Practitioner and Review.*

Traumatic Gangrene.—Knott recommends the following method of procedure: A circular amputation is made of the soft parts and bones all of the same level, the arteries are ligated and a wet dressing is applied. Later, when the wound is seen to be clean and there is no extension of gangrenous process, a second operation will make a good stump. Reasons: Trimming flaps and suturing both tend to lessen circulation and tend to sloughing, also some infected material may be enclosed if sutured at time of operation. He reports nine cases with only one death. —*Journal of the American Medical Association.*

Ivy Poisoning.—Experiments have lately shown that permanganate of potassium solution (one per cent. and stronger, according to the delicacy of the skin) is the best antidote for ivy poisoning. It acts promptly and thoroughly, but must be freely and well applied and acts much better in a solution as hot as can be borne and kept hot for a half hour or so.—*Clinical Review.*

Eventration and Enucleation of the Eyeball Under Local Anesthesia.—Siegrist employs a glass syringe holding 2.0 gm. with a slightly bent needle. The conjunctiva is thoroughly anesthetized with 3 drops of a 2 per cent. cocain solution to which a few drops of adrenalin have been added. Now he grasps the conjunctiva, together with the capsule, by a forceps or the bent needle with the concavity directed towards the eyeball, and inserts the needle into the folds of mucous membrane; the point of the needle is then pushed between the orbital wall towards the entrance of the optic and ciliary nerves; 0.75 gr. of a 2 per cent. novocain solution, to which also some adrenalin has been added, is now injected into the upper, lower, temporal and nasal sides of the bulb. The enucleation or eventration may be commenced from one to two minutes after the injection, and the patient will experience absolutely no pain.—*Ophthalmology.*

Empyema.—Mann in discussing the treatment of empyema says of aspiration that: 1. Aspiration may be used for diagnostic purposes, but repeated aspiration as a means of treatment is time worse than wasted. 2. In large empyemas it may be used as a preliminary step a short time before operation to relieve the pressure on the lungs, heart, and blood-vessels, and so lessen the shock of the operation. 3. In double empyemas, after operation on one side, aspiration may be used on the second side as a preliminary step to a later operation, though the double operation has been successfully performed at one sitting. 4. It should be used as a palliative measure in empyema before the resolution of a pneumonia. 5. It may sometimes be used as a palliative treatment in cases with advanced tuberculosis, though most cases with accompanying tuberculosis improve, and many are cured by drainage. 6. A tentative aspiration is called for often in the pleurisies of children on account of the frequency and the obscurity of their empyemas; however, aspiration should not be used as a method of treatment even in the pneumococcus pneumonias of children, because, though some of them recover under this treatment, most of them do not. Practically all of them recover if properly drained before they are exhausted. The same statement is probably true of the more rare condition of typhoid empyema in the adult.—*Surgery, Gynecology, and Obstetrics.*

Rectal Diseases.—Patients who have trouble about the rectum should, as a rule, evacuate their bowels at night. Then they have eight to ten hours in the horizontal position, and the bowel has time to readjust itself by the time of rising. This is particularly applicable to those who have to leave home at a certain time every morning.—MR. CHRISTOPHER HEATH.

Paget's Disease, frequently diagnosed as eczema, would appear from the literature to attack not only the nipple, but almost any other part of the body. Clinically it runs a chronic slowly progressive course extending over many years. It appears as a "florid, intensely red, raw surface, very finely granular, as if nearly the whole thickness of the epidermis were removed."—*Southern Medicine and Surgery.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 16, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	364	145
Diphtheria	331	27
Measles	261	5
Scarlet Fever	252	15
Smallpox	1	..
Varicella	162	..

INFANTILE SPASTIC PARALYSIS, AND ITS TREATMENT.

BY E. MUIRHEAD LITTLE, F.R.C.S.,

LONDON.

SENIOR SURGEON TO THE ROYAL NATIONAL ORTHOPEDIC HOSPITAL

THE clinical picture produced by the group of symptoms to which the above name has been given was first accurately described and attention called to its importance by the writer's father, the late Dr. W. J. Little of London. In his lectures on deformities which were delivered at the Royal Orthopedic Hospital and reported in *The Lancet* in the year 1843, and published in volume form in 1853, a clear description of the chief clinical characteristics of the affection was given, and in 1862 the details of fifty-two cases were published in a paper read before the Obstetrical Society of London in the previous year, entitled "On the Influence of Abnormal Parturition, Difficult Labors, Premature Birth and Asphyxia Neonatorum on the Mental and Physical Condition of the Child, Especially in Relation to Deformities."

It is no doubt owing to these publications that on the Continent of Europe the name of "Little's disease" was soon attached to the malady, as a short and convenient title. Its use is now generally restricted to those cases of congenital origin in which labor has been premature or difficult, and in which both lower limbs are affected, but not the upper, although Dr. Little himself did not specially mark out this group, but included in his fifty-two cases of spastic rigidity twenty-two in which the upper extremity was affected as well as the lower. From the point of view of treatment this inclusion has been amply justified, for the experience of half a century has not enabled surgeons to differentiate the principles of treatment of hemiplegic and diplegic from those of paraplegic cases. A wider knowledge of pathology, however, has shown that asphyxia neonatorum does not play as important a part in the causation of the disease as W. J. Little thought, but in justice to him it must be remembered that he used that term in a general sense, for he wrote: "It will be observed that I have in this paper often employed the term asphyxia neonatorum nosologically, in its widest sense, embracing in it all the conditions of suspended animation in the newborn infant, which have for their result to prevent the immediate establishment of proper respiration and circulation, whether or no the color of the infant be pale or dark." He described the pathological appearances, which at that time had been observed in cases of still birth after premature or difficult labor, such as capillary apoplexies and hemorrhages of other kinds, and to these attributed the symptoms. We know now that cicatricial lesions, the result of embolism or thrombosis or hemorrhage, may be found in the cord, along with secondary sclerotic changes, and that the lesion in the brain is often an enlargement of the lateral ventricles at the expense of the cerebral substance, a so-called porencephalus. Osler found in ninety brains some vascular lesion in sixteen, *i.e.* embolism in nine and hemorrhage in seven. The most certain pathological fact is the frequent existence of a lesion in, or of arrested development of, the pyramidal tracts, or of the parts of the encephalon directly connected with them. Despite all the researches that have so far been made, it is impossible in the present state of our knowledge to predicate from the clinical features of a case what is the anatomical lesion causing it, and the converse also holds good; therefore at present the pathology of infantile spastic paralysis has only an academic interest for the practical surgeon, whether he has to deal with the congenital or the acquired varieties of the disease. As was pointed out by W. J. Little in 1843, spastic rigidity or paralysis is often acquired, and Jendrassik, Strumpell, Lorrain, Apert, and others have brought forward evidence of the occurrence of a family form of the noncongenital variety. These and other authors have demonstrated the hereditary nature of some congenital cases. When the lower limbs are affected—and it is seldom that one or both of them escapes—the well-known spastic gait and appearance are seen. The feet are usually in the position of talipes equinus or equinovarus, the knees are flexed, and the thighs slightly flexed and adducted and rotated inwards, the knee jerks are exaggerated, and anxle clonus is generally present, if the contraction of the calf muscles is not too great to allow it to be elicited. The patient may not be able to walk, or may only be able to make his way from chair to chair or holding on to the edge of a table. If he is able to walk the characteristic jerky, half-running, spastic gait appears, the knees knock together or cross one another, and at every step a fall seems imminent. Epileptic seizures occur in a certain number of cases. The condition of the intelligence varies. It may be very low in a case of slight muscular contraction, or it may be high in a case of severe deformity of the limbs, but generally speaking, the mental ability varies directly as the physical. Defects of vision and nystagmus, squint, and motor defects of speech are not infrequently to be observed. Constipation is very commonly noted. If the contraction has not existed long enough for the development of secondary fibrous contracture in the muscles and tendons, the deformity will be found to disappear during sound sleep or deep anesthesia, and it may be overcome by strong, steady, and continued pressure. In the case of the ankle it will often be found that the varus has given place to valgus, the soles of the feet being flattened by the pressure which has to be applied to the ball of the foot. When the upper extremity is af-

fected it may be held down by the preponderating action of the pectoral and teres muscles and latissimus dorsi; the elbow is generally flexed, the wrist partially flexed and pronated, and the fingers incapable of perfect voluntary direction. Athetosis is often present in a greater or less degree. If the patient attempts to use the hand the flexion and pronation of the wrist persist, but the fingers may be extended fully and thus the well-known Z-form of hand is produced. This is

The Z-shaped hand.

well shown in the accompanying illustration, which is figure 50 of Little's Lectures on the Deformities of the Human Frame. Generally, the condition may be well summed up in the words of W. J. Little as "Impairment of volition, with tonic rigidity and ultimately structural shortening in varying degrees of a few or many of the muscles of the body." The bulk of the limbs is not obviously less than normal, marked atrophy not often occurring, but Hadden has described a class of cases in which with paraplegia of the lower limbs without atrophy, one upper limb is also affected with spasm and is much wasted. He attributed these cases to a lesion primarily unilateral in the brain, and thought that the paraplegic distribution of rigidity was due to an unusual decussation of the pyramidal tract fibers. Cases are classed as hemiplegic, paraplegic, or diplegic, according to the distribution of the spasm. The first named is the commonest. In some cases little change in the symptoms can be detected in the course of years. Many cases, on the other hand, improve spontaneously up to a certain point, the spasm diminishing or even disappearing and the power of coordination improving greatly. Other cases, unfortunately, get worse despite treatment of any kind. In making a prognosis it must be borne in mind that there is probably an irremediable defect in the brain or cord, and that improvement and not cure is the most that can be looked for. The effects of spasm may be reduced or removed by the excision of tendons, but the result cannot be the production of a normally balanced and coordinated musculature, but only a comparative cure. Although only one muscle or group of muscles may exhibit evident spasm, it must be remembered that the whole muscular system is probably abnormal in these cases, and in a condition of hypertonicity, which extends probably to involuntary muscular fiber. On this supposition the absence of serious bleeding in operations on the muscles can be explained.

It is most remarkable that after free division of vascular tissues, such as the adductor muscles, very little oozing occurs, and it is quite the exception for any vessel to need ligature. R. Jones and V. P. Gibney have noted the trivial amount of bleeding in such operations. We may suppose that the muscular coats of the blood vessels share in the general muscular hypertonicity and irritability.

Treatment.—Although during the sensational times of the promulgation of subcutaneous tenotomy a French orthopedic surgeon divided sixty or more muscles at one sitting, the result was not encouraging, and in 1843 and for many years afterwards the surgical treatment of this distressing disorder was limited to that described by W. J. Little in his lectures, namely, manipulations, instruments, and tenotomy as a *dernier ressort*. Under this treatment some striking results were recorded, chiefly in cases in which the contraction had existed many years and in which structural shortening of the muscles and tendons had supervened and the muscular fibrillæ had become more or less disorganized, so that while structural shortening had rendered tenotomy more necessary, the disorganization of fiber rendered reconstraction less probable. This continued to be the general rule of treatment among orthopedic surgeons until Listerism had made open operations on muscles and tendons as successful as only subcutaneous ones had been formerly, and Robert Jones of Liverpool and Lorenz of Vienna began to divide and excise portions of muscles and tendons which were not structurally shortened. Lorenz divided or excised ten tendons at one sitting in a patient of seventeen, and reported a good result. Many other surgeons have since reported good results from tenotomy, tenectomy, tenoplasty, etc. Lorenz has excised part of the anterior branch of the obturator nerve, with a view to paralyzing the adductor muscles.

Physicians, and especially neurologists, have generally discountenanced operation, Gowers' only reference to it being the following: "The tendo Achillis is sometimes divided for the contracture of the calf muscles, but the operation is useless and ought not to be performed." It is probable, and it is much to be regretted, that the opposition of such an authority as Sir William Gowers has hindered progress in the treatment of spastic palsy (in England, at least) considerably.

Among orthopedic surgeons there is a consensus of opinion, which is growing with increase of experience, that great benefits can be obtained by surgical measures. It is an established clinical fact that if a spastic muscle be prevented from active contraction for a time, either by keeping it stretched by apparatus, or abolishing one of its attachments by operation, the tendency to spasm is generally diminished, and it is a further well-attested fact that this sedative effect may extend to other muscles that are not directly interfered with. Orthopedic surgeons, however, are not all agreed as to the extent of the surgical interference justifiable or advisable. In this paper it is proposed to set forth some of the opinions held and to present briefly the writer's personal experience.

J. la Bonnardière, in the *Revue D'Orthopédie* (Paris) of November, 1896, after quoting Lorenz's case of multiple tenotomies, etc., and others which had been as much improved by less heroic measures, said that most authors limited tenotomies to cases in which fibrous retractions persisted under chloroform. Bocker in 1899 recommended tenotomies, massage, gymnastics, and redressement forcé. In the same year B. E. McKenzie of Toronto advocated the free practice of tenotomy and myotomy. As a result he claimed a great "lessening of reflex action, which is of exceeding benefit thereafter." In an interesting discussion which followed, Shaffer said that he had given up operating in such cases; he had often seen talipes calcaneus occur as a result of section of the tendo Achillis, and the operation was often unnecessary, as the spasm disappeared

spontaneously in many cases. Kidlon said that after dividing one tendon the spasm disappeared in other muscles. Therefore he would only divide the tendo Achillis at one sitting and wait two months before operating on the hamstrings and other tendons. He advocated early operation, repeated in case of relapse. In hemiplegia he had noted improvement in the upper extremity following on section of the tendon of Achilles. Bradford approved of tenotomy. Weigel referred to two cases of section of the hamstrings, the result of which still remained good, despite the mental defect. An improvement in the mental condition occurred after operation, and was marked before the patient left the hospital.

In 1899 Tubby, who had formerly found multiple tenotomies useless in the upper extremity, divided the flexor tendons of the wrist and fingers in a case of infantile hemiplegia and transplanted the tendon of the pronator radii teres from the front to the back of the radius, and reported a good result. He has since frequently performed this operation. In 1900 Codivilla published a paper on Transplantation of Tendons in Infantile Spastic Paralysis. He admits that in most cases the condition of the brain leaves no hope of the adaptation of the nervous system to the new action of the transplanted muscles, except in Little's disease, which term he limits to cases due simply to incomplete function of the pyramidal tracts. Despite this drawback he thinks transplantation beneficial to all sorts of cases. In Little's disease the new muscle fulfils a new rôle, and in patients with the extensive and profound lesions of spastic palsy, in whom we can only expect a passive result, it is nevertheless efficacious because the spastic force distributed (by the operation) uniformly around the joint can no longer oppose itself to voluntary muscular contraction. Then a slight muscular action is enough to produce the willed effect. The transplantation has further a good influence on the spasm besides improving the position and movements; this sedative effect has been before noted by Sonnenberg, Vulpius, and Hoffa. Codivilla notes a tendency to spontaneous improvement in Little's disease. He says that early operation before the muscles are damaged by long spasm has a good effect on the central nervous system, prevents the bad effects there of constant spasm, and favors the development of the antagonist muscles, which would otherwise waste from disuse. In 1903 Robert Jones of Liverpool, who has been a pioneer in the active surgical treatment of spastic palsy, in a paper in the *Medical Press and Circular*, based on a large experience, takes a very hopeful view of the subject, and deprecates pessimism. In mild cases he says that long continued fixation by apparatus will often effect a cure of the spasm. In the hand and arm tenotomy alone had proved somewhat disappointing, and should be confined to the flexors of the carpus. Tendon transplantation was more trustworthy than tendon lengthening. In the lower limbs excision of portions of the superficial adductors and, if necessary, division even of the adductor magnus and pectineus and subcutaneous tenotomy of the tendo Achillis and open-section of the hamstrings are recommended. He writes: "No opportunity should be lost of performing a tenotomy. Even in mild cases, where a spastic tendon is to be felt, let us ruthlessly divide it." Jones insists, however, on the necessity of after-treatment and training, lasting at least a year, and often much longer. Writing in 1903 Redard deprecates all surgical and orthopedic treatment as long as the myospasmodic element persists, but advocates it in permanent contractions. He recommends tendon transplantation and lengthening, massage, mobilizations and passive movements, and retentive apparatus between whiles. Lange in 1905 advised tenotomy and tendon transplantation. Hoffa in 1906 laid stress on the importance of schooling, massage, and exercises, especially in Little's disease; failing these, tenotomy and tenectomy. The adductors, the hamstrings, and the tendo Achillis should all be operated at one sitting and the limbs fixed in overcorrection by means of gypsum. Tendon lengthening and transplantation are of the greatest importance in the treatment. In the upper extremity he recommends Fraenkel-Leyden exercises and tendon transplantation.

In 1904 Bartow reported a case treated by transportation of hamstrings, also a case of elongation of hamstrings. Both were cases of diplegia, and the results were good.

Bradford in the same year advocated fasciotomy in the upper extremity, and after describing three cases of transfer of the pronator radii teres said: "The writer has not found as much benefit from tendon transplantation as has been mentioned by some writers. It must, however, be clearly understood that these operations are simply a basis for careful muscular development and muscular training by use and exercises carefully suited to the patient. If these are not attended to, the benefit from the operation will be slight." V. P. Gibney in 1904 reported a case in which after twice dividing the tendons of Achilles and once the adductors, he excised the whole of the tensor vaginæ femoris muscle, for the correction of internal rotation. In 1905 Glaessner gave some interesting statistics of infantile diplegia. He recommended subcutaneous section of the adductors, open section of the hamstrings and section, lengthening or transplantation of the tendo Achillis. Muscular reeducation was necessary, and much patience was required. In his opinion the school of Hoffa is too optimistic.

Young of Philadelphia in 1906 says: "Tenotomy and tenoplasty offer the greatest hope in these cases."

Royal Whitman in 1907 says that the treatment of paraplegia is more difficult than that of hemiplegia. He advises multiple tenotomies. He writes: "The advantage of tenotomy, aside from the simple correction of deformity, is that by elongation of the tendon the response to the exaggerated motor impulses is lessened, and an opportunity for more effective control is afforded." This beneficial effect is very marked in older patients. Referring to Lange's transfer of the hamstrings to the quadriceps, he says: "The good effect of the operation is to be ascribed in all probability in far greater degree to the removal of the deforming force than to the extending action of the flexor muscles."

At the Congress of Pediatry in Algiers in July, 1907, Froelich reported fifteen cases of Little's disease. He insisted on the importance of reeducation. He used tenotomy, forcible rupture of muscles, and immobilization. He operated as soon as a gleam of intelligence appeared. In the discussion Kirmisson said that German writers had made too much of tendon transplantation. He would not operate until the seventh year. He had never had occasion to divide the hamstrings

in Little's disease. At the same congress Soulié reported a case of spastic paralysis in which he had treated the talipes by arthrodesis of the ankle joint.

The authors quoted above, while they are by no means all those who have written on the subject during the last ten years, are sufficiently representative to give a fair idea of recent surgical opinion on it. They appear to be fairly unanimous in favor of surgical interference in most cases, excluding the idiotic, the microcephalic, the passionate, and those subject to frequent fits or general rigidity.

In the writer's opinion treatment should be begun early, but should at first take the form of fixation in the corrected position by means of splints, gypsum bandages, or instruments. These should be persisted in for six months or a year, during which in a few cases the spasm may disappear, or diminish to such an extent as to render operation unnecessary, as in the following case.

Case I.—Edith I., aged six years; spastic paraplegia. Was brought to the hospital in September, 1897. No history was obtainable. The mental condition was not markedly abnormal. She had talipes equinovalgus of both feet and walked with a spastic gait. The spasm could be overcome and the feet dorsiflexed by firm pressure. Right angled splints were ordered for night wear and boots with steel uprights extending to the calves, and springs to dorsiflex the ankle for use in the daytime. Sixteen months later the entry runs: Walks better, falls less, but the gait is still jerky and slightly tottering. The left tendo Achillis is contracted. No operation was performed and in October, 1899, the note was, "She can dorsiflex both ankles voluntarily, the right the best." The progress in this case was satisfactory and enough to contraindicate operation.

In one idiotic patient who was very fat and whose mental condition seemed to prohibit operation a marked improvement followed the administration of thyroid extract and was maintained for nearly a year and as long as the patient attended the hospital.

The following is typical of a class of case in which much benefit may be expected to follow operation:

Case II.—I. W. H., aged four years; spastic paraplegia. First seen in September, 1906. History, labor at term normal. Walked at one year, talked at two years. On first walking said to have turned the left foot in; afterwards walked on the toe. The mental condition is not much, if at all below normal. The knee jerks are lively. The lower limbs are equal in length and well nourished. The right leg is very slightly affected. The left foot is in a position of equinus; it can be forcibly dorsiflexed to about a right angle. The upper extremities are normal.

In May, 1907, the left tendo Achillis was lengthened by Anderson's method about one inch, and the leg and foot put up in gypsum in the corrected position. A month later, on removing the gypsum, there was no spasm. Two months after operation he walked well without spasm, but with a rather jerky gait. In this case tendon lengthening was preferred to simple tenotomy in order to avoid all risk of talipes calcaneus.

The next case, a not very satisfactory one, is cited as an instance of the varying condition of the spasm. It was observed for seven years.

Case III.—Edward C., aged four years; spastic paraplegia; first attended in October, 1898. He was born asphyxiated after delivery by forceps. The head was much squeezed. He talks, but is backward in intelligence. There is some spasm of the adductors of the thighs. The limbs are equal in length. There is talipes equinus. He cannot walk. Right ankled splints were ordered for the feet and ankles. A year later, in 1899, he could walk with a stamping gait, putting his heels well on the floor and extending the knees well. A year later still (1900) there was no spasm, except of the adductors of the feet (tibials, etc.). Four months later, however, talipes equinus in one foot was so marked as to necessitate division of the tendo Achillis. In 1903 one and a half inches of the adductors were removed in each thigh and the hamstrings were divided. He left the hospital wearing instruments, but in 1905, although the right limb was in fair condition, the left was rotated inwards, the knee bent and the foot in the position of equinus again, so that operations on the hamstrings and tendo Achillis were recommended again.

The following case illustrates the greater difficulty of restoring function in the upper extremity as compared with the lower, although correction of deformity may be fairly easily procurable.

Case IV.—Doris D., aged five years; spastic hemiplegia with atrophy of the lower limb. First seen in September, 1904. A very bright and lively child. She was well till she was fourteen months old; she walked before that time. She then had a "fit," followed by unconsciousness and left hemiplegia. The left elbow is flexed and the hand flexed and pronated. She cannot voluntarily extend the elbow or supinate or extend the wrist. There is spasm of the calf muscles and talipes equinus and the great toe is held in extension. The limb is half an inch shorter than its fellow. She walks well, however, with the heel on the ground.

The pronator radii teres was exposed and one inch of its tendinous end was excised and the tendon of the flexor carpi radialis was divided at the wrist. The forearm and hand were then fixed in the corrected position. Six months later, in May, 1905, the left wrist, fingers and thumb were still contracted and accordingly the tendons of the palmaris longus, flexor carpi radialis, and the flexor sublimis digitorum were divided by open operation at the wrist and the tendon of the flexor carpi ulnaris was lengthened. In April, 1906, there was no grasp with the left hand, but very little deformity.

The following case exemplifies the good effect of excision of tendon as compared with lengthening:

Case V.—Rose L., aged twenty; spastic hemiplegia. First seen in March, 1900. The condition was first noticed after pertussis, when the patient was five years old. "The left hand is pronated and it cannot be supinated either voluntarily or passively. The left foot is in equinovarus." The tendo Achillis was divided subcutaneously and a right angled splint applied.

In February, 1902, strong spasm of the left peroneus longus and contraction of the left knee were noted. In August, 1902, tendon transplantation. The tendon of the peroneus longus was divided and its end attached to that of the entire tibialis posticus. In September considerable power of adduction of the foot was observed. The tendon of the flexor carpi radialis, which was apparently the main obstacle to supination of the wrist, was exposed and lengthened enough to allow of complete supination and the tendon of the palmaris longus was divided. Three weeks later the tendon of the

biceps cruris was transferred to the front of knee, where it was sutured to the tendon of the quadriceps extensor.

Six weeks later the knee was straight and there was slight power of extension of the leg. Flexion, extension, pronation, and supination of the wrist could be well performed voluntarily, but the tendon of the flexor carpi radialis still felt rather tight.

A year later (in 1903) the wrist was again contracted and accordingly a portion one and a half inches long of the tendon of the flexor carpi radialis was excised, including the site of the previous lengthening, which was scarcely recognizable. The tendon of the palmaris longus was again divided. The result was excellent and seemed permanent four years after this operation.

In May, 1907, adductor spasm was giving trouble and portions of these muscles were excised and the limb abducted with satisfactory results. She can now extend the left wrist and fingers well and supinate the hand almost normally. The grasp of the hand is strong and she walks fairly well.

The following case is one which is published more as a warning than as an example to be followed. The general condition was too severe for much to be hoped for from operation, but after some years of observation the writer yielded to the wishes of the friends that something more should be done. As far as regards the mechanical condition of the feet, the operation of arthrodesis was quite successful, but the disability higher up was a bar to progress.

Case VI.—Lewis H. C., aged four and three-quarters; spastic paraplegia. First seen in September, 1894. "The condition is said to be congenital. There is talipes equinus of both feet, which is easily overcome, but the muscles all over the body become rigid upon a slight stimulus. There are signs of past rickets." He was ordered walking apparatus extending from the feet to the pelvis. In 1894 he did not walk properly in the instruments. In 1902 he could get about with the help of a chair, but there was strong spasm of the hamstrings and calf muscles and the adductors of the thighs. The feet were flat on forcible dorsiflexion. He walked with a typical spastic gait without assistance. Over one inch of each tendo Achillis was removed and arthrodesis of the tibio tarsal joints performed. Two months later portions one and a half inches long of the tendons of the biceps cruris, semitendinosus, and semimembranosus were removed and a little later portions of the spastic adductors of the thighs were excised and the limbs fixed in full adduction by means of gypsum bandages. Two months later, in February, 1903, when the plaster was removed, the limbs were found to be stiff in the abducted position. Under an anesthetic they were moved forcibly. There was about 10° of movement at the ankles. In April, 1903, adduction of the thighs having recurred, some bands were divided subcutaneously. When the patient left the hospital in May, 1903, after a seven months' stay, his powers of locomotion were but little improved, and there was still a tendency to recontraction at the hips and knees, despite the free removal of muscles and tendons.

In considering and estimating the value of the results which may be obtained, it should be borne in mind that, as already stated, a complete cure in the sense of restoration to the normal, cannot be hoped for. Nevertheless, any improvement, however small it may seem to onlookers, is to the patient and his or her friends worth having, especially when it can be got without serious risk to life or limb and with little danger of making the condition worse, instead of better. While, therefore, in the writer's opinion, some surgeons, notably in Germany take much too favorable a view of the prognosis after operation, the gloomy views of a few surgeons, and particularly of the neurologists, are still less justifiable.

In the lower extremity the functions to be performed are comparatively simple and do not involve an extremely delicate balance of muscular action, and there, therefore, we find, as we might expect, that the results of operative interference are better than in the forearm and hand. Beevor has shown how complex a seemingly simple movement of the hand may really be and how very seldom, if ever, a single muscle may be said to act alone and unaided by its neighbors. In the upper extremity we may succeed by division, excision, or transfer of tendons in abolishing the deformity, but if this was originally a complex one, in which many muscles were affected, it is not very likely that function will be restored to any great extent. Cases IV. and V. are illustrative of negative and good results, but even in the former the patient's hand was not less useful after the operation than before. Tenotomy, either subcutaneous or by the open method, is often enough in slight cases, and there is hardly any bad result which is liable to follow. In a few cases talipes calcaneus has been observed as a sequel, but if this is found to cause serious disability arthrodesis of the ankle joint can be performed and will give a firm and useful foot. Should recontraction follow on tenotomy, a portion of the offending tendon can be excised as in Case V.

Certain Continental surgeons have vaunted the merits of tendon transplantation as almost a panacea in the treatment of deformities of all kinds, but in the writer's experience the results of this procedure hardly justify the roseate tints with which they are often painted, for while there is no doubt that the transplanted muscle may be shown to contract and produce some feeble movements in its new position, the good effect is a negative one; that is to say it is due to the removal of the deforming muscle and its consequent inaction in its old position, more than to any positive action in its new position. In spastic paralysis the nonspastic muscle is not inactive; for instance, the quadriceps in the case of the knee, and were the hamstrings in their new rôle of extensors to act with anything like their former force the extensor action would be excessive. Their abolition as flexors is all that is necessary, and the writer has therefore of late abandoned tendon transplantation for spastic paralysis and prefers in cases in which simple tenotomy is not enough to excise a portion of tendon or muscle. This proceeding, which has given such excellent results in the case of the adductors of the thigh is simpler, takes less time, and involves less disturbance of the parts than transplantation.

In some of the foregoing cases will be found examples of its usefulness in various parts of the body. If little has here been said of the physical reeducation of the spastic child it is not because the writer does not consider it important, but because in hospital practice it is very difficult to carry it out. It involves the expenditure of much time, great perseverance, and special aptitude on the part of the teachers, and it is difficult even in an orthopedic hospital to secure these desiderata. After months of sojourn in the wards where some systematic training can be attempted, the patient is seldom so fortunate as to have it continued by the friends, who either are not able to go on with it or else think that with discharge from hospital

treatment should cease. Even with these imperfect arrangements, however, it is possible to do a good deal to lighten the burden of these distressing cases to the patients and their parents, but it is much to be desired that they should be systematically and perseveringly treated in institutions where they might remain for years instead of months.

TEST OF THE STRING-CUTTING METHOD FOR IMPERMEABLE ESOPHAGEAL STRICTURES.*

By ROBERT ABBE, M.D.,

NEW YORK.

SURGEON TO ST. LUKE'S HOSPITAL.

After a test of fifteen years I desire to offer a second report on a method which, with recent slight modifications, I demonstrated then for the first time as a novel and safe substitute for the surgical treatment of a previously hopeless condition—the impermeable esophageal stricture. It has been my privilege to watch, until now, the perfect health of the patient then reported.

In brief, the case was that of a young lady who had by mistake swallowed caustic, and produced a destructive inflammation of the esophagus, which was followed in less than a year by a tight stricture, which during three years allowed only fluids to pass. Her feebleness and rapid loss of weight brought her to despair, as she saw the amount of fluid she could swallow growing daily less. It was impossible to pass through the stricture even the very smallest filiform bougie.

In a similar case I recalled that Prof. Henry B. Sands, whose assistant I had been, had, with great trepidation, tried a small, cutting instrument within the esophagus. It was devised like a urethrotome. His great dread of any cutting instrument so near the aorta restrained his hand, so that he gained but little on the stricture, and that little at the expense of considerable hemorrhage. To relieve my patient I had therefore to choose between two methods—either *cutting* by such an instrument (in case I could insinuate a guide for it under ether) or *dilating* from below through an opening in the stomach.

It had already been demonstrated by Albert, Billroth, v. Bergman, Maydl, and others that an esophageal stricture which permits no bougie to enter from above will almost invariably permit it from below, because by reason of the long-persisting pressure of food in the esophagus trying to pass down, the canal becomes basin-shaped, while on the distant side the esophagus is funnel-shaped—and thus a small bougie is naturally guided upwards through the stricture.

Once having passed a fine bougie upward, the safe dilatation by Billroth's method is often accomplished. This consists in drawing a strong thread from the stomach to the mouth by the preceding guide, to which it has been tied. Then, to the lower end, are fastened in succession conical bougies whose tips are capped by a metal point into which the string is tied. From the smallest to larger and larger ones, these are thus safely drawn up, with no danger of perforating the very tender wall of the esophagus. This danger is by no means small—if no guiding string is used—and results in disastrous mediastinal abscess.

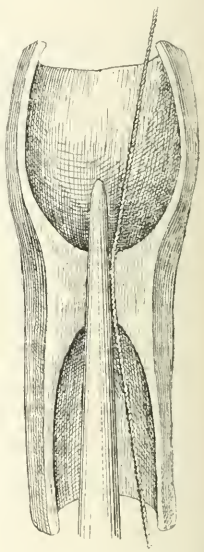

Fig. 1.—String-cutting method; usual shape of the esophagus above and below the stricture; dilating bougie and string in place.

A few such strictures can be cured by dilatation alone—persisted in for life—but a majority are so dense and tight that, like urethral strictures, they are best cured by first cutting and then maintaining the opening.

It happened, in the case narrated, that I was confronted by the worst type of case, and prepared myself with every kind of bougie. Under ether I opened the stomach and stitched it to the abdominal wall, so that I could slip two fingers into it without soiling the peritoneal cavity. On pressing my fingers against the upper wall of the stomach from within, I was impressed, as I have been on many other occasions, with my inability to immediately locate the esophageal opening. This has been extremely interesting to me from a physiological point of view. We ordinarily think of the stomach as pictured in anatomy, showing a funnel-shaped expansion of the esophagus where it joins the stomach wall. It has never been my experience to find this condition in the living stomach. As the finger passes back and forth over its upper interior aspect, one feels an even surface more like the interior of any dome-shaped cavity. This surface is maintained by the circular sphincteric muscle layers, and it is not until a moment's pressure of the finger at the right place causes them to yield that it slips upward into the esophagus. I have never seen this point stated in

*Read before the Practitioners' Society, October 11, 1907.

surgical work, and it has interested me as representing an always present physiological condition which prevents food regurgitation.

Once having yielded, the opening remains for the finger to find easily during the rest of the operation. Guided by the index finger, a long filiform whalebone bougie was passed from the stomach to the mouth, though impassable from above downward. To the end of this a string was tied and pulled up through the esophagus. To its lower end a Billroth dilating bougie was tied, which was drawn up until it engaged in the stricture. As it would not pass through, it was withdrawn temporarily, an extra string drawn up, and again the bougie pulled tightly into the stricture.

By pulling the second string back and forth, while the wedge-like end of the bougie was tightly crowded into the stricture, I was delighted to feel the bougie rapidly pass up. Larger ones were

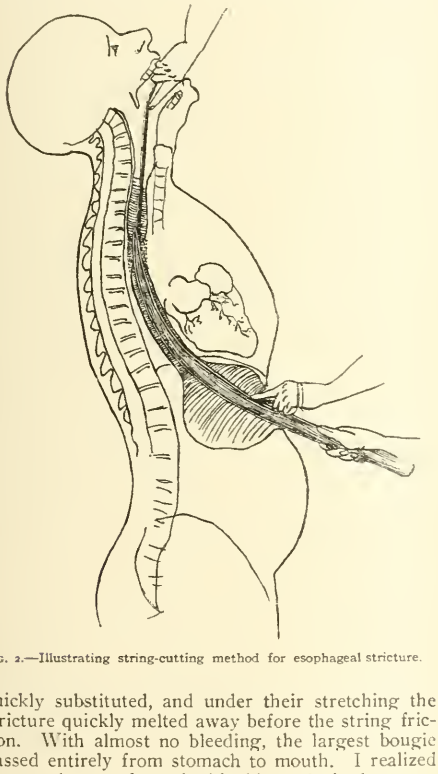

Fig. 2.—Illustrating string-cutting method for esophageal stricture.

quickly substituted, and under their stretching the stricture quickly melted away before the string friction. With almost no bleeding, the largest bougie passed entirely from stomach to mouth. I realized at once that a safe method had been devised to remedy this incorrigible condition, and that the principle of action was logical.

A few days after operation the patient was permitted oysters and semi-solid food. Two weeks later the gastric fistula was easily closed, from which moment the patient rapidly gained weight. The largest bougie was passed down every few days, then once a week, and monthly during the latter half year. Since then, once a year, I have tested the esophagus, and there has never been the least recurrence of stricture. Thus we have ample demonstration of permanency of the cure.

Since the publication of this so-called string-cutting method, it has been widely adopted by surgeons. Dr. Mixter of Boston has had a specially large experience with it, and recently wrote me in highest praise of it.

Some interesting modifications of technique have been made by Bryant Dunham and others, but the essential principle stands proved that the wearing away of the cicatrix by string, while it is made tense, is the safest and most enduring method of cure. One or two writers, however, in describing it have failed to emphasize the foundation principle, that the dilator must be pressed tightly into the channel in order that the string moving to and fro may eat its way through the stricture. No tissue will be affected by the string, except where it is on the stretch.

Let me now record a second admirable illustration of this method. In June, 1904, a child of three years, visiting in St. Louis, swallowed lye, producing immediate inflammation of the esophagus. Three months of anxious treatment followed, and she was brought to Philadelphia in an emaciated condition, only small quantities of fluid trickling into the stomach through the esophagus. Her physician, Dr. Ludwig Loeb, consulted Dr. Keen and Dr. Deaver. Two attempts under ether failed in passing even the smallest filiform into the stomach. One of the surgeons advised a permanent gastrostomy; the other advised her to be brought to me to try the string cutting. It is needless to say the feebleness of this puny child gave me much concern, and a very quick operation was planned. Under ether anesthesia, the stomach was opened and a whalebone probe passed up through the esophagus to the stricture. Only the finest filiform, however, could be passed up through it. A string was pulled up; then a small, conical, Billroth bougie; but it stuck tightly. The string-sawing with a second string, however, immediately relieved the obstruction, and in five minutes the largest bougie permitted by the normal child's esophagus passed stricture after stricture and appeared at the mouth. In this case more than half the length of the esophagus was densely cicatrized.

The operation was completed by inverting the stomach opening and tightly suturing it about a feeding catheter by three purse-string stitches, one over the other.

The child sucked ice by mouth and was fed hot nutritive fluid through the gastric tube until it was strong. Then the gastric fistula was easily closed and rapid convalescence followed.

Dilatation as usual was continued. In the course of months, however, omission to continue this faithfully led to partial closure, although swallowing of soft food continued.

We now faced a new problem. Knowing the denseness and length of the cicatrices, which would not now yield to the bougies, and not caring to reopen the stomach and repeat the string sawing, I devised a dilating metal guide which carried a string down to the face of the stricture and back again, so that working entirely from the patient's mouth the stricture could be worn through on the same principle.

Dr. Bryant has formerly devised a bougie à boule carrying such a string, but my modification after many changes following its use in this case at last was brought to a freedom in working that enabled me to say it had reached a practical working form. Its action is exceedingly quick. As soon as etherization is well established, an assistant holds the head back and the instrument is pushed gently down the straight esophagus—until the probe ending guide engages in the stricture, and the metal shoulder bears hard on it. While the operator forces the instrument onward, a third as-

sistant pulls the string back and forth in the tube, and wears away the cicatrix where the string presses against it. It is thus impossible for the instrument to go astray from the canal—which widens as it advances—and harmful perforation cannot occur. With better attention to frequent dilatation during the ensuing year no more trouble followed.

The child remains in robust health to-day and eats everything. Her physician writes this week that no one could be in better health, three and a half years after the accident.

These two cases are so typical of the utility of this safe and simple method, and so demonstrative of the permanence of the good results in this grave condition, as has been shown also in many other patients, that I am satisfied they can be repeated in all proper cases, and the test of time may now go on record.

Finally, I would note (1) that most of the obstructive cicatricial esophageal strictures can be dilated from above and should be so treated; (2) that those which are only permeable by a fine bougie offer great chance of serious perforation of the wall of the tube during dilatation where much force is needed to push it through; (3) that such as admit a probe of some size can be safely cut from above by the string-cutting esophagotome; (4) that very tight or impermeable ones can always be safely, quickly, and permanently cured by gastrostomy, followed by the string cutting.

It almost goes without saying that this method should never be applied to esophageal strictures resulting from other causes, such as are made by pressure of mediastinal tumors, aortic aneurysm, spasmodic strictures, or malignant stenosis.

For these no better relief can be found than a permanent gastric fistula, which can now be made free from leakage by any one of several methods.

With this late report, I feel that a small but definite contribution has been made to surgical technique.

13 West Fiftieth Street.

OPEN-AIR TREATMENT OF PNEUMONIA; MY TWENTY-NINE YEARS' EXPERIENCE.*

By STEPHEN HARNSBERGER, M.D.,

CATLETT, VIRGINIA

Pardon a bit of personal history: While yet a youth my one desire was to be a doctor. I was ever on the alert for knowledge that would be of practical help to me in after life. One thing that I then learned has been of constant use to me—the value of open air. It was often mentioned in my hearing that the consumptive men who went into the army during the Civil War, and who survived its hardships, came out with health restored. It was hard to understand why this was so, but after much thought over the matter I came to the conclusion that it was due to the open air and its toning effect on the vital phenomena. Imbued with this idea, I began to direct tuberculous persons before I undertook the study of medicine. The diagnosis was not mine, to be sure, but that of reputable physicians. That was in 1871 and later. These persons were advised to live and sleep in the open air, to take exercise short of undue fatigue, and to eat plain, substantial diet, including a per cent. of hog fat up to the individual digestive capacity of each. I recall three persons, one with hemorrhages and hectic—these recovered and at least two are living to-day. I graduated in medicine in 1877 and began the active practice of my profession the same year. From that day on I have treated the tuberculous and those predisposed to tuberculosis on this same general plan and I have had no reason to regret it. We need open air in health. We must have open air to keep health. If open air is so important in health with good and ample chest space and movements, surely it is much more important when chest space is lessened and chest movements restricted. Viewing the matter in this way, I have invariably advised open air in every case of pneumonia coming under my observation. So much open air have I demanded for my pneumonia patients that my professional life for twenty-nine and more years has been a fight and a struggle against the protests and officiousness of friends and members of the family of the patient under treatment.

In the winter of 1881, I saw Miss L. B. of Fishersville, Va., age about eighteen years. Mother, father, and other members of her family tuberculous. She had not recovered from an attack of pneumonia the previous year. In her present attack she was attended by another physician, who had left the case on Saturday because "nothing more could be done." On Sunday another physician was called and he confirmed the previous opinion. On Monday, Dr. D. W. Hanger, an excellent retired physician and neighbor, was sent for. He came for me in person, as he had no medicines. I was then a young man and of course did not care to assume the responsibility of so grave a case, for Dr. Hanger agreed with her former physicians, and I could expect nothing short of a death on my hands. He finally prevailed on me to see her and upon purely humanitarian grounds. My first visit was at 10 o'clock at night. She could not retain even water and had not been able to do so for several days. Both lungs were involved. It seemed to me that she was as weak as a person could be and yet be alive. Every symptom pointed to a quick demise. I had a blister applied, administered morphine and atropine hypodermically and when this began well to affect her, I ordered a small quantity of liquid food. But I had her given plenty of open air—she needed air. The next day I saw her about 10 A.M., and again that night. The treatment of the first visit was continued. As I could not see her so often, I got Dr. Harris, a dentist, who lived in the village, to give her the night hypodermics. The nausea and vomiting continued, except when under the influence of the morphine compound, for about ten days. After the vomiting ceased, the nausea kept up for some time. Finally she could retain suitable food and some medicine. In six months I pronounced her well. It has been eight years perhaps since I heard from her. She was then well and weighed one hundred and sixty pounds. I can't help but think it was the open air that did most to cure her.

The importance of maturing observations and verifying them by the test of experience, before laying them before the public, is why I have not written on this subject before.

Why is pneumonia more fatal to-day than one hundred and more years ago? I see this claim made in the journals and I see it made in an article in the 1906 transactions of this society. It is denied by some and is a question in the minds of many. Of course we should consider the more exacting diagnosis of the present day, excluding bronchitis and other affections simulating croupous pneumonia. This would naturally cut down the number of cases of pneumonia and would apparently in-

*Read before the Tri State Medical Association of North Carolina South Carolina, and Virginia, at the meeting held in Norfolk, Va., June 3 and 4, 1907.

crease the death-rate. Personally I feel that the death-rate has increased. If it has not increased, the mortality in former years, under universal bloodletting must have been fearfully large. The text-books tell us that the mortality lessened with the shelving of the lancet. It is a well observed fact that much morbidity or much mortality calls forth much discussion in contemporaneous print. To-day we find paper after paper on the subject of pneumonia. This every one will concede. To get a better insight into this matter, I took the trouble to examine carefuly volume after volume of the *Medical Recorder,* the leading medical publication of ninety and more years ago, and there is scarcely a line—in fact, I may positively assert that there is not a line by domestic writers on the subject of either broncho or croupous pneumonia. This of itself, it seems to me, should merge argument into belief. Then if true, why was it?

The disease must have been frequent in those days, because the causes which our text-books lay down for us—exposure, deprivation, hardships, intemperance, etc., acted then in ten-fold strength. If we except blood-letting, the treatment of pneumonia at the present day varies but little in principle from the treatment eighty and one hundred years ago. Now, if it is a fact that the death-rate from pneumonia is greater to-day than it was one hundred years ago, why is it greater under a more conservative treatment, with better nursing and a more sustaining diet? It should be less. It is not because there is a greater per cent. of cases of pneumonia, for reasoning from the teaching of our text-books, exposure was greater one hundred years ago than it is to-day. Now, if we accept the dearth of literature on the subject as support of our claim, then we recognize the fact that when the death-rate was at a minimum exposure was at a maximum. Nor should we omit in making this estimate, the nutritional disturbances and consequent loss of resistance —the natural concomitant of one, two, and perhaps repeated venesections. So, then, it seems that a better etiology has not helped us; a later pathology has not helped us; a more exacting diagnosis has not helped us. With a dimmer knowledge and the overexposure of the past, a less death-rate. It's paradoxical, but it seems to be true.

When we read the mortuary reports, we are summarily forced to the conclusion that pneumonia is at the present day an alarmingly fatal disease. In fact, the profession in general, if we reason from the printed remarks on the subject, is of the opinion that deaths from tuberculosis are steadily decreasing while deaths from pneumonia are as steadily increasing and have done so gradually for the past one hundred and more years. The question naturally arises, why is this increase of death-rate from pneumonia? It can't be that the seed is stronger and the soil richer. The soil for tuberculosis is more favorable for the growth of the disease than it was one hundred years ago, and yet the disease is diminishing. The soil fit for tuberculosis should likewise be a soil fit for pneumonia, and pneumonia we are having, but why is the death-rate from pneumonia increasing while that from tuberculosis is decreasing? I speak now of tuberculosis of the lungs. Some say it is because of the enervating life we lead—the great mental and physical strain, without diversion that rests and gives time for mental and physical repair. But it is not worth while here to enumerate all the views on this subject. Perhaps each of us who studies the subject holds his own view as to the reason. You have yours, I have mine, and it is mine that I am here to give on this occasion. The reason, in my mind, for so great a death-rate from pneumonia as we have to-day is told in a few words—*lack of open air.* One hundred and more years ago, when pneumonia was an almost benign disease, our forefathers lived in rudely constructed habitations, the air came up through holes in the floor, down through openings in the roof, and poured in through cracks in the sides. They lived in the air during the day and slept in the air during the night. Pneumonia patients in those days were practically out-of-doors—they had fresh air pouring in from the outside through openings that were a part of the crude existence of early pioneer life. Pneumonia patients got well then simply because they had what pneumonia patients needed—open air. The exigence of early pioneer life furnished them what an enlightened civilization deprives them—open air. One hundred and more years ago the pneumonia patient got well, or the death of one was so infrequent that it did not even count as an item of professional interest. In the succeeding decades, as wealth and civilization advanced, we find somewhat better houses were built and with the better houses came an increase of death-rate from pneumonia, and so on with each succeeding decade up to the present time, when houses are almost hermetically sealed to exclude air, we find a corresponding increase in the death-rate from pneumonia. No more is it a fact that tuberculosis is a house disease, than that death from pneumonia is a house death. It is the lack of open air in both cases. Who would be so foolish as to turn on the gas to improve the breathing and yet we find pneumonia patients in rooms with the windows down, the doors shut, fires ablaze, and numerous friends and visitors sitting around the patient's bed, and this, too, in the open knowledge of the attending physician. Everything done that could be done is the verdict when the pneumonia patient passes to the great beyond, and yet the one thing that should be done is not done—letting in the open air. It is virtually asphyxia, and asphyxia kills whether it is from too much gas turned on or too much air kept out—it is the deprivation of oxygen in either case. All rational effort in the treatment of pneumonia is to prevent asphyxia, and of all the measures that conspire to kill the pneumonia patient no one thing so surely contributes to that end as artificially heated air. Give the open air, pure from the outside. It lowers the fever, calms the brain, slows the pulse, quiets the respiration, gives a livelier tinge to the blood. Under an abundance of open air the temperature is never a cause of alarm and delirium is scarcely ever observed.

Illustrative Cases.—Case II.—Was called to see Annie P., aged sixteen, in 1898, and as I thought in consultation, perhaps for serious heart trouble, as it was generally understood that her death was expected at any time from some such malady. When I got to her home, however, I found she had double pneumonia. The cyanosis, dyspnea, etc., at first glance showed her condition as being serious. My consultant (her former physician) gave a grave prognosis. I had her in a shed room, with large holes all around the roof where the air came in freely—the holes were large enough to run one's hand through. There was no need of begging for air here, as it was cold, blustery weather. The neighbors pleaded for fire and predicted her death, because I would have none. She got well.

Case III.—Miss S. H., centenarian. Her extreme age would at once proclaim her condition critical. Though the ice was nine inches in thickness, I would permit no fire. To keep warm, the

nurses wore extra wraps, and when the cold became unbearable they thawed out by the fire in a room across the hall. This patient, though so old and feeble, recovered.

Case IV.—J. S., aged eighteen years. A lingering case, unresolved pneumonia. Had had night-sweats every night for forty nights, when I was called to see him in a rather protracted absence of his family physician. He was terribly emaciated, weak, and pale. No appetite. Both lungs involved. One window was directly by the head of his bed and another opposite. I ordered the fire extinguished, heat to his feet, and the windows opened for one hour. He missed the usual night-sweat the first night and never had a return. The length of time of the "airing" was increased each day. He gained in weight, is full of energy, and is able to stand constant hard work.

Now, these were all bad cases, and it is with just such cases that open air is needed. In mild cases the patient will get well any way. I will not attempt to say what percentage of my pneumonia patients get well, but I will say that I look upon open air in the treatment of pneumonia with the same unbounded confidence that the surgeon looks upon the knife in the treatment of appendicitis—*it is the only hope for the bad cases and will certainly save ninety-eight in one hundred if used early and properly in all cases.*

Guided by a distinct perception of the needs of each patient, with open air and good nursing, one need not worry over the contingency of death from pneumonia. The air can't be too fresh, nor its temperature too low. There's no danger of "taking cold" while the fever is on. The younger the patient, the older the patient, and the more hopeless the case seems, just so much the more important it is to enforce open air and exclude artificial heat. Keep the patient's feet warm, but don't heat the air he breathes—don't.

In the house and hospital treatment of pneumonia, as formerly altogether and latterly mostly carried out, the walls are usually air-proof, the windows and doors are kept closed, and to this is added a heating system which admits of scarcely any ventilation. They call it ventilation with a window down an inch or two at the top, and occasionally some are even bold enough to have another window (if there's more than one to the room) up an inch or two. Allowing 2,000 cubic feet of air to the person in such a room, it is impossible to get in 2,000 cubic feet of fresh air to the person per hour and still more impossible to remove the vitiated air, so that as a natural consequence the vitiated air is gradually increasing and the pure air is all the while decreasing and with it the bad pneumonia patient grows worse and worse.

For want of time I shall pass over the etiology, pathology, and diagnosis of pneumonia, nor shall I consider to any great extent the symptoms. These can be better obtained from the text-books. But in order to bring out more clearly the value of open air in the treatment of pneumonia, I shall indicate as accurately as possible some of the factors that go to make its prognosis unfavorable.

The symptoms which usually demand attention are pain, cough, and dyspnea—the cyanosis will generally take care of itself. The pain and cough will also, as a rule, yield to rational therapeusis. The dyspnea may be substantive or vicarious. Substantive dyspnea has reference solely to the lung disturbance and is due in part to the pain and in part to the amount of lung tissue involved, and as these causes can be readily met, in most instances, by open air, topical applications, etc., the prognosis is, for this reason, altogether favorable. If called to a patient who affirms that the shortness of breath is of earlier date than the accompanying pneumonia, we may infer, with a certain degree of confidence, that a part of the dyspnea, at least, depends upon a pre-existing functional or degenerative weakness elsewhere in the system. Hence vicarious dyspnea, which antedates the lung trouble, is seen usually about the age of puberty and is perhaps an expression of a neurotic irritability. In adults, and notably in the old, vicarious dyspnea is associated with cardiac, renal, hepatic, etc., diseases, or to stasis caused by mechanical pressure of tumors, etc. It is well to take this contributing influence of difficult breathing into account, as it modifies both the prognosis and the treatment. Substantive added to vicarious dyspnea should excite our earnest solicitude.

For our immediate purpose, I may properly divide the respiratory process into mechanical and chemical, both being essential for the normal process of respiration. The mechanical disturbances may be varied and frequent and yet not seriously modify or threaten life, but once the chemical process is materially lowered, impeded, or yet rendered entirely passive, the ending is so ghastly certain that it needs no further comment. This normal chemical process primarily and essentially depends on fresh air—fresh air going in laden with the element upon which life hangs and coming out burdened with the elements inimical to life.

Cell integrity is not life. What life is we know not. But for all practical purposes, cell integrity—that is, cell functioning—is synonymous with life. Cell exaltation or cell inertia leads to cell alteration and, if prolonged, to cell exhaustion, disintegration, and death. Cell integrity depends on cell metabolism—the balance of waste and repair within physiological limits. The existence, development, and function of all other cells rests primarily in the blood cells or corpuscles. Weaken the blood cells and you weaken the tenure on life—destroy the blood cells and you destroy life. No single injurious factor is so potent for evil to the blood cells as is the exclusion of fresh air. Pneumonia limits the ingress and egress of the air in the lungs, and to some extent in proportion to the amount of lung tissue involved in this process of respiration affected. Lung involvement associated with complications makes the picture still more alarming. In my opinion, it is not the pneumonia that kills so much as the lack of oxygen and the pent-up waste products hastening asphyxia. Forced elimination and open air are essential in this disease—especially in the hopeless cases. Nothing can replace the oxygen of the atmosphere. Artificial oxygen may do at times and it is perhaps better than no oxygen, but it is expensive, fatiguing to the patient, and lacks many of the concurrent benefactions which are an inseparable part of fresh atmospheric air. It is a well understood physiological fact that an abnormally large proportion of artificial oxygen in the blood leads to diminished breathing movements, and if the proportion be large enough, to their temporary cessation. Now, in the generally lowered condition of vitality of all the tissues and organs of the body, as found in most of the bad cases of pneumonia, is it not at least possible that the pushing of artificial oxygen to the extent of saturation of the blood with the gas, might be the cause of death in not a few instances? Is its use always devoid of danger under an eager, anxious administration? The over-charging of the patient, the additional exhaustion consequent upon the fa-

tigue produced, is it not possible that these things may do irreparable harm? But it is not alone the constant and plentiful supply of fresh air taken into the lungs that does the good by the open air treatment—of greater importance is the constant and plentiful removal of that which is vitiated. This of itself is eminently a gain in favor of atmospheric over artificial oxygen. Then in addition to this, we have the soothing, quieting, bracing, and widely sanitive effect of atmospheric air, which cannot form a part of the good done by artificial oxygen.

Shade important. The good done by open air is not due to the cold alone, for the open air of summer, particularly in the shade, not only conserves but augments the vital phenomena. I find that my pneumonia patients do just as well in summer as in winter. This fact was seen but not recognized many years ago. The *Medical Recorder*, Vol. XV, 1827, gives the following report from La Charité Hospital, foreign. Total number of cases (of all kinds), 281; deaths, 39. "To show how uncertain is the ratio of mortality in the same disease at different periods, we may remark, that out of eighteen cases occurring in the spring quarter of the above period, six died, while in an equal number of cases occurring in the summer, there was not a single death." Had the profession recognized then that the open air made the lessened death-rate, there would be no need of paper after paper on the subject of pneumonia at the present time.

We tell the patient with bad headache to lie down in a quiet, cool, dark room. Why? Simply to give the disordered nervous system an opportunity to gather itself together and thus return to the equilibrium of normal function. Critical clinical observation has made it plain to my mind that heat and light, whether natural or artificial, if intense or continued, induces nervous instability, mental irritability, with restlessness, muttering, and insomnia—and so does the stimulation of drugs when carried beyond the individual requirement. Therefore, let in the open air and draw the blinds. The darkened room and the cooler atmosphere soothes the nerves and quiets the mind. Edge the building with the sunlight if you will, but keep down the glare and ward off the heat of its direct rays. These things are easy in winter, but not so in summer. In the summer months, put your patient in a large airy room, but amply protected by wide porches, or if this cannot be had, put up large awnings, the under surface of which is of some dark color. If you can't have porch or awning, improvise a canopy of brush. Any contrivance that will shade and yet will not obstruct the air, is better than no protection. This is not alone important in pneumonia; for twenty-eight years open air, elimination, a shaded room, and exclusion of milk has been my almost constant rule in typhoid and other fevers and my professional colleagues know with what success. Nor could I treat the puerperium without open air and the darkened room. With these and the collateral aids of individual prophylaxis, ergot, strychnine, and posture, I have had neither mortality nor morbidity.

This open air and shade treatment is nothing marvelous, nor is it new—it is as old as time. It is only a return to nature and nature's way. Death in pneumonia is for the most part due to a form of toxemia, the presence in the blood of an abnormal amount of the products of faulty metabolism—the want of open air, the most efficient factor, functional or structural disturbances of the liver, kidneys, etc., contributing coefficients. Whether the hepatic, renal, cardiac, vascular, etc., conditions are directly attributable to alcohol, the degeneration of old fibroids, uric acid, or other metabolic products, clinical experience warrants me in emphasizing the importance of elimination, first, by the lungs; second, by the liver; third, by the kidneys; fourth, by the skin. So that while open air is good for all cases of pneumonia and essential in the bad cases, it may not be out of place for me to mention some of its trustworthy aids.

We now come to what is styled the "expectant treatment." There's a weak girder in the bridge; we drive on it, the structure goes down. That's the expectant treatment. Far better to have forestalled the danger and avoided it, than to have waited and come face to face with it. While I hesitate to differ with the text-books, why should we remain idly expectant? The condition is nothing more nor less than a toxemia. The approved treatment of toxemia is by elimination. In pneumonia it begins and should end with the influx of open air, supplemented by every other means that can add a whit to the comfort or well-being of the patient.

When at all indicated, I prescribe ammonium chloride, which probably has no less a selective action in pneumonia than has quinine in malaria. It exalts excretion from the skin and kidneys and increases secretion from all the mucous surfaces. Increasing the secretion of the bronchi, it eases the cough and facilitates expectoration. This allows a freer ingress of air and lessens the tendency to dyspnea. Rarely have I observed gastric discomfort—occasionally some diarrhea, which is always beneficial, and even so is the slight nausea or vomiting it very infrequently seems to produce. It also increases buccal, faucial, and nasal secretion. If for no other reason, this is a gain in comfort to the patient; but it does more: by reason of this increased secretion, it limits the entrance of pathogenic organisms into the lungs, and as it is found unchanged in the secretions of the nose and adjacent cavities, it may not only weaken, but destroy the aggressive pneumococcus. If it prevents the entrance of, weakens, or destroys the pneumococcus, it cuts short the further extension of the disease.

It is of more or less value in removing the functional hepatic derangement almost invariably associated with pneumonia. Its diaphoretic and diuretic actions are influential in relieving the portal circulation and allaying pain. It is frequently a reliable remedy in intercostal neuralgia and should help in mitigating the pleuritic pains of pneumonia. Its great value in relieving hepatic congestion, would point to it as a rational help in the pneumonia of drunkards—in fact, its whole range of action on the economy makes it one of the accessory therapeutic aids we should welcome in our bad pneumonia cases. Besides, it seems to be a mild stimulant to both the circulatory and nervous systems. If not a stimulant, its action upon the system is so benign that it soothes the circulatory and nervous systems into a better repose. Used in conjunction with an abundance of open air, you can have nothing more dependable in the majority of bad cases. Should you stumble on an idiosyncrasy, or later on in the case, and when there is pronounced dyspnea, feeble circulation and great depression, especially in children and the very old, ammonium carbonate seems specially indicated. It is esteemed more certainly bracing than ammonium chloride. Once in a while it may be better practice to use ammonium carbonate from the beginning; again it seems preferable to administer the chloride preparation through to complete resolution. However, we must bear in mind that each case requires its own additions and subtractions.

Often before, but usually with the subsidence of

the morning temperature, I put my patients on petroleum. It lessens and loosens the cough, facilitates expectoration, assists digestion, retards intestinal fermentation, and, as its action is entirely local, must assist somewhat the intestinal function. Patients gain weight and strength more rapidly under its administration. The alkaline salts, especially when in combination with potassium bicarbonate, are often of the highest service in freeing the blood of pneumonia patients of the excess of waste, particularly of the urea compounds. Lastly, water, as simple as the air we breathe, and, in its way, no less important. Water should be used liberally. The lithia waters give the best results.

I must not omit a word on local applications. In the bad cases, with torturing pain, great dyspnea, etc., I am an advocate of turpentine plentifully applied. I have it rubbed over the affected area and well beyond, until it burns and burns briskly. The danger is in too little and not too much burning. When it becomes too annoying to the patient, a touch of cream will quickly soothe the irritation. Then, if necessary, I have the cotton jacket wrung out of boiling water, to which turpentine has been added, and I have this put on, and when it can be had, oiled silk for an outer covering.

About 10 P.M., January, 1879, I was called to see a boy, aged about fourteen years. Pleuritic pain severe, dyspnea distressing, cyanosis profound. Temperature, 106½° F., respirations panting, and pulse apparently gone. I ordered heat to his feet and legs and then opened the windows and door to let in the outside air. I hurriedly made a cotton jacket, wrung it out in boiling water, poured hot turpentine over it, and put it on the boy. It began to burn him in a very few minutes, and in less than a half hour the burning was so intense that he lost sight of the pleuritic pain. I took the jacket off simply because I could not stand to see him tortured longer. I ordered the jacket to be kept hot, using no turpentine, and kept on until my return. I then gave calomel and Dover's powder. Saw him the next morning about 11 o'clock. The cyanosis had disappeared, the dyspnea was almost gone, temperature 102°, and respiration and pulse down in like ratio. The treatment was perhaps severe, but the condition was grave—the result was satisfactory. If the turpentine and open air didn't save this boy, what did? After a considerable experience with the various external means recommended from time to time, I must say that there is nothing like the cotton jacket, boiling water, and turpentine—applied to the maximum of irritation; then gently lessened. Turpentine stimulates capillary and lymphatic circulation better than any other local application. The kaolin preparations do very well under the moist heat of the cotton jacket in infants, but, used alternately with turpentine, adults will learn to call for the latter. While the turpentine is not so agreeable in the beginning, it yields greatly more comfort, and comfort in all cases of pneumonia represents substantial benefit. To get the best results, kaolin should carry at least 60 per cent. of glycerin.

Hygiene of the nose, mouth, and throat has a distinctly beneficial action in all cases of pneumonia—especially in the very young and very old. The parts should be sprayed frequently with pleasant antiseptic solutions; the nose with an oily solution, in order to get a more prolonged contact. Spraying soothes the mucous membranes and protects them from infective material.

Next to diet in disease, stimulation is one of the most interesting subjects that comes up to us in medicine. Because on nutrition hinges life, and stimulation, while infrequently needed, is, when needed, more often abused than properly used. If it is alcohol you mean, then I can tell it in few words: Alcohol is good for the well to get sick on, but bad for the sick to get well on. The pneumonia patient, if seen early, directed along the lines succinctly marked out above, and nursed with care, will rarely, if ever, have need for alcohol. There may be, and occasionally will be, some depression, but no marked crisis, and with no positive crisis there's no need for alcohol. Its psychic effect on the patient and moral effect on his friends sometimes calls for its administration. Then, and always, its giving should be guided and guarded by the same safe rule that should guide and guard the administration of other stimulants—fractional doses at fractional intervals. I fear the depression of the reaction from large doses of alcohol vastly more than I do the depression of the crisis. Under an abundance of open air, and the further depuration by rational elimination, ample and easily digested food, there is rarely ever forced upon us a crisis for alcohol.

It has been said that "drunkards are more sensitive to alcohol, and therefore at times require larger doses than the same apparent condition calls for in the temperate." I wish to say, however, that rarely ever in the case of drunkards do I allow alcohol, surely not in the doses we are taught to give it. If the failing heart, in drunkards or others, is due to loss of functional power in either muscle or nerve, it seems to me that with alcohol, digitalis, and similar stimulants, given in free doses, there is imminent danger that the contributory stimulation may prove more than the heart can bear, and cause it to cease to beat from sheer exhaustion. I think I have seen such unfortunate endings. Then, again, the loss of functional power of the heart may be due to the direct action of the poison of a nondepurated blood—whether from want of adequate oxygenation, retention of urea compounds, or other products of waste, and if so on what reasonable grounds should stimulants be plied here to the maximum? Would it not be better to "away with" the offending causes of the depressed heart? Stimulants forced may postpone the patient's sufferings until death, but they will not prolong his life.

In alcoholics, when the action of the heart becomes weak or the mental activities disturbed, I have found tincture of capsicum determine efficient control. Capsicum promotes mouth and stomach secretion—thus aiding digestion, and it exalts the peristaltic action of the intestines. It is also a mild cardiac stimulant and assists the action of diaphoretics. It quiets the nervous phenomena better than any other one drug; combined with a fluid preparation of quassia, etc., its action is markedly enhanced. High enemeta of normal saline solution, if enough is used, and half to a pint is left in the colon, sustain the heart, tone the nervous system, increase the flow of urine, favor diaphoresis, and, of course, assist in the elimination of waste and the subsidence of fever. Their administration, I feel sure, is frequently indicated. Patients feel better after the irrigations—they are both physically and mentally refreshed.

If the dyspnea and cyanosis deepen to the point of apparent dissolution, and do not yield to other therapeutic measures, depletory infusion promises benefit. A few ounces of blood drawn, while a half pint or more of normal saline solution, to which adrenalin chloride solution is added, is injected into the cellular tissues, may not only lessen the tendency to increase of fibrin in the blood, but it may also further the excretion of toxins—it will cer-

tainly lessen the bronchorrhea present in many bad cases.

For the cardiac enfeeblement during the period of great obstruction, whether from a large involvement of lung tissue or otherwise, we want a remedy, the physiological action of which is a cardiac stimulant without simultaneous deviation in capillary and arteriole tension. In this respect we have a remedy that bids for a more extended trial. It acts more rapidly than digitalis, and its effects in moderate doses lasts from four to six hours. When prompt action is desired in pneumonia, especially when the patient gives evidence of antecedent disease of the myocardium or of the valves of the heart, sparteïn sulphate should give results. The indication for the drug is not frequent. If used, I would say, keep down to minimum doses.

Foster says "digitalis is eminently the medicine for a dilated rather than for a weak heart." It should never be used when there are changes in the cardiac muscle or atheroma of the blood-vessels. It has no place in the pneumonias of the elderly.

While strophanthus is less dangerous than digitalis, it is no better than the latter when the heart muscle is impaired. But the drug is so quickly toxic in its action, even when administered with caution, that the best safety lies in its non-use. Personally, I have no use for digitalis, strophanthus, and nitroglycerin in the treatment of pneumonia. To emphasize my position: J. W. W., aged about fifty years; family history tuberculous; patient tuberculous; had been under the treatment of one of our best physicians for about two years. I was called March 8, 1905. Diagnosis, croupous pneumonia. Condition serious from start. Consultation was refused. A week later, however, he was extremely ill from discharging abscess, right lung. The patient's son, who was just up from Washington, called a consultation. I could not be with the consultant. However, I met him on his way home. He pronounced the case hopeless, and it did look that way. During our talk he took a vial from his pocket and asked me if I was well supplied with stimulants. I said, "Doctor, don't pull those things on me, for don't you remember what I have so often told you about digitalis, strophanthus, and nitroglycerine?" He exclaimed, "What?" I replied that every time I had yielded to use them the patient had died. He replied, "Well, you know this man is going to die." I said, "Not if I can help it." I did not use the compound and very little, if any, whiskey, but I had a good nurse and open air. He got well and is well to-day. When stimulants do not kill at once, they may as surely lead to a fatal ending by slower action. Mrs. L., aged about seventy years; native of England; seven brothers and sisters had died of "heart disease;" patient was feeble from a like affection. Saw her in the afternoon. Diagnosis pneumonia. Next morning had consultation. Opinion, no possible hope—she was too feeble and heart condition too impaired. She was put on a digitalis, strophanthus, etc., compound, and all up to maximum doses. I did not see her for two days and nights, as I was with obstetrical cases. When I did see her she was restless, unable to sleep, skin dry, and tendons jerking. The end seemed at hand. I sat down by her bed and studied the situation. Finally, I made up my mind that she was getting too much stimulation; so I cut the stimulants down one-half and gave her acetanilid and waited. In about an hour she seemed less restless and skin less dry. In two hours she was quiet and the skin was moist. In three hours, by midnight, she was asleep. Every two hours she was aroused for nourishment. The next morning I found her in a more favorable condition. She got well. Acetanilid has other indications in the disease—properly used it is a valuable drug.

Nux vomica, or its alkaloid, meets more demands as a stimulant than any other single therapeutic agent. In small doses it stimulates the motor nerve cells of the spinal cord, the cardiac motor ganglia, the respiratory and vasomotor centers of the medulla. Its benign action reaching out to and including all the functional processes of the economy, virtually confirms nux vomica as a nutrient rather than a stimulant. In times of great prostration, with cold extremities, almost imperceptible pulse, and life apparently at its last ebb, the tincture administered in drop doses every few minutes demonstrates a sustaining and insistent power that carries the patient gratefully to eventual recovery. Nux vomica also seems to counteract the vasomotor paralysis, to which most of the injurious effects of alcohol are due, so that whatever may be the etiological beginning of the cardiac feebleness, or the character of the contributory complications, nux vomica or strychnine stands preeminently above all other stimulants. It is a good stomachic tonic. By promoting the gastric, pancreatic, and biliary secretions, it aids digestion, a most important aid in the treatment of pneumonia, especially the pneumonia of drunkards. It does more—by exalting peristalsis it assists intestinal elimination, and, as it is excreted chiefly in the urine, it helps to maintain the urinary output. Rationally administered, it sustains the broken compensation until repair harmonizes the disturbed forces.

Diet.—Lean meat juices, blood, bone marrow, and egg albumen, with pure grape juice, until convalescence is well under way. We need these to keep down blood attenuation and to keep up nerve tone. In guiding and guarding the pneumonia patient, we need the easiest and fullest functional activity of both heart and lungs—then don't confide in milk—it ferments, it disturbs, it makes the heart labor, and embarrasses the respiratory movements. Milk is hazardous in pneumonia and kills in typhoid fever. Only recently I attended a man of eighty-nine years with pneumonia. He did well—the temperature became lower, the pulse went down, the respirations quieted, and the mind cleared. About 8 P.M. he called for a glass of milk, which the nurse gave. He gulped it down. Gas formed; his heart began to labor, and about 7 o'clock the next morning the end came. Don't give milk. To get a better conception of the present-day treatment of pneumonia, I enclosed five questions to a few eminent clinicians, and, without further delay, I wish to acknowledge their prompt and courteous responses. The small amount of time allotted to this paper precludes analytic reference to the valuable information embodied in their replies, which I present in tabulated form for easy comparison. Comparison of views is the only basis of broadened knowledge. To know what others think preserves the equipoise of one's own thoughts, and shapes the way to fewer errors of judgment. Though my paper was written before I received the answers to my questions, the little time I have had to give to them has already awakened valuable suggestions.

As a part of the above table, it affords me pleasure to be able to make the following excerpts from letters of Dr. Joseph H. Pratt of Boston: "The treatment of pneumonia in our hospital is chiefly expectant. Few drugs are used. Personally I look with favor upon the hydrotherapeutic procedures recommended and used by Dr. Baruch. My friend, Dr. Millet, of Brockton, has obtained excellent results by the fresh air treatment which he has em-

TREATMENT OF PNEUMONIA.

	Internal	External	Most Important Factor	Mortality Per Cent.	Why is Pneumonia More Fatal To-day Than 100 and More Years Ago?	Remarks
Dr. E. Fletcher Ingals, Chicago.	Symptomatic, but opiates to be avoided excepting in extreme conditions Laxatives to be used very guardedly.	Oil silk jacket useful in many cases—much better than poltices. Leiter's coil over painful area when temp. is high. Strychnia when heart is weak.	Quiet, fresh air, sufficient nourishment.	Varies according to age—from 20 to 35 the best period. After 50 about 75 per cent. die In hospitals all kinds of cases—from 30 to 45 per cent. die	Probably this depends largely on the diagnosis being more accurately made now—cases of bronchitis are not now claimed as pneumonia.	
Dr. Thomas McCrae, The Johns Hopkins Hospital, Baltimore.	Liquid diet, large amounts of water, bowels kept open, alcohol or whiskey, if toxemia Strychnine hypodermically and digitaline hypodermically if necessary for the heart condition. Codeine and heroin for cough, morphine hypodermically for pain, dyspnea, or, if necessary, for sleep.	Rest in bed, cold sponges, ice-bag to affected side, room cool, 65° fresh air.	Diet, large am'ts of water, and stimulation used with judgment, along with as much sleep as possible.	About 25 per cent. in large series. This includes all cases. In any statistics it is impossible to note whether the terminal lobar pneum. cases are included. They are nearly always fatal and compose about 10 per cent. of our mortality.	Is it? Personally, I doubt this very much. So far as we know, pneum. mortality has varied but little. Remember that in yrs. with certain other diseases, *e g*, influenza, prevalent, the number of cases of *broncho-pneumonia* increases greatly, but this is not *lobar* pneumonia The distinction is important.	Bleeding sometimes at onset if severe distress in full-blooded subjects, during course of m'ked cyanosis and right heart be overloaded.
Dr. E. G. Wood, Nashville.	Place patient in best possible condition to resist the disease by maintaining his nutrition, supplying abundance of fresh air, a good nurse, and absolute rest in bed with treatment of symptoms as indicated No routine medication Drugs resorted to only when symptoms severe and cannot be relieved by other measures, such as opiates, the first day or two, if the pleuritic pain prevents sleep; stimulants for heart failure, etc.	I prefer the ice-bag, some use mustard, but never blister.	Fresh air and rest, with good nursing.	10 1-3.	.....	As stated above, I believe fresh air is the most important single factor in the management of a case of pneum. After that careful nursing with careful nutrition and the relief of symptoms which either interfere with the patient's rest or in other ways lower his vitality.
Dr James Tyson, Philadelphia.	Supporting and stimulating. Of late am prescribing creosote in addition, without having been able to discover any direct results from its use or to trace to it any especial effect.	Generally local applications of ice to inflamed lung.	Am not certain what is intended by this question, but if it refers to tr'tm't would say that m'st important factor is the internal supp'rt'g and stimulat'g effect.	Average mortality at the Pennsylvania Hospital for 5 yrs., 17.4 per cent.	I do not know why, i am not certain that it actually is.	
Dr. Jno. B. Calwell, Assistant Warden, Cook County Hospital, Chicago.	Treatment is almost wholly that of symptoms Patient put at absolute rest and on liquid diet No routine treatment No specifics Heart stimulation, whiskey strychnine, digitalis, etc Expectorants, KI, etc. Catharsis, diuresis, etc.	Local applications, ice-bag, hot water bag Occasionally venesection.	Care of heart....	Has been almost 50 per cent. for several years. Out of 738 cases treated the past year, 347 died.	I believe the disease more fatal than formerly because of changes in the individual due to different modes of life. Intemperance, luxury, and reckless exposure without gradual seasoning, make susceptity greater.	
Dr. B. Merrill Ricketts (Harry Silver, Assistant), Cincinnati.	Lobar: Ammonium carb., 5 to 7 gr. t.i.d. Whiskey ½ to 1 oz. t.i.d. Strychnine 1-40 to 1-30 t.i.d. For cough: Codeine, ½ to ¼ gr 0.6 hr Morph if necess'y For fever: Plenty of fresh air, and —phenacetin, 7 gr., acetanilid, 2 gr., caffeine, 1 gr.—repeat when necessary	Pneumonia jacket of flannel	Stimulation.....	Uncomp'l'ted cases Cincinnati City Hosp. rpts about 1891, 31%; '92, 38%; '93, 28%; '94, 24%; '95, 34%; '96, 38%; '97, 25%; '98, 28%; '99, 14%; 1900, 28%; '01, 23%; '02, 20%; '03, 28%; '04, 28%; '05, 32%.	You will see that the rate here is higher during the last 5 yrs. I think that low mortality of 100 yrs ago was due to more fresh air as result of open houses. The tr'tm't now is practically "*Open house.*" I think that oxyg. is the most import of all unless it is op'n air	
D. Wm. A. Jenkins, Kentucky School of Medicine, Louisville	Alkaloidal: In full blooded patients, 1 granule aconitine gr. 1-124, viratrine, 1-124, digitalin 1-67 at 20 min until pulse softens. Clean out prima viæ calomel gr. 1-6, podophyl, gr. 1-6, followed by saline Codeine for cough if necessary If there is intes disturb, give purified sulphocarb'tes of lime, soda, and zinc until st'ls are deodorized To sup. heart strych and whiskey For conval use triple arsenates with nuclein.	I always use a cotton batten jack't and I very frequently use hygroscopic substances such as antiphlogistine	Early *elimination* and *defervescence*. In most cases intestinal antiseptics and heart support.	Mortality is extremely variable, higher in hosp. practice than in private prac. Varies with the epidemic some years extremely high again on other occasions relatively low I know of no rational explanation of this feature	*It is not; see my answer to No. 4.*	
Dr. Carpenter, Barnes University, St. Louis.	I regret very much that the valuable contribution by Dr. Carpenter has been mislaid or lost. I hurriedly ran over his answers and remember that he specially emphasizes the value of Norwood's Tincture, veratrum viride. For 27 years success was the rule. Then he abandoned its use for a while and to his sorrow. He had no failures in 50 years' use of it. He does not consider it toxic when circumspectly administered. He cited an unusually interesting case in illustration.					

ployed for a number of years, and which, as far as I know, he was the first to advocate in this section of the country, if not in the United States.

"During 1905, one hundred and fifty-one patients with croupous pneumonia were treated at the Massachusetts General Hospital. Of these twenty-eight died and six were in the hospital on January 1, 1906. There were during the same period forty cases of bronchopneumonia; three of these patients died.

"How do you know pneumonia is more frequent now than a century ago? Remember that Laennec's epoch-making work on the physical signs of pneumonia did not appear until 1819. Accurate diagnosis before that date was impossible.

"I think Dr. Northrup of New York has done more than any other man to arouse interest among the profession in the open-air treatment of pneumonia. He read a short paper on this subject before the American Medical Association at its last meeting. You will find it with the discussion in the last volume of the *Journal of the American Medical Association*, XLVII., p. 1182. I think that another paper by him was presented at the meeting of the Association of American Physicians last year, but of this I am not sure. Apparently the honor of first introducing this form of treatment belongs to Dr. Northrup, as he states that he used it first fifteen years ago."

In conclusion, modern conditions cannot be altered at one stride, but a hint from the past is not amiss, and, while sharing the apparent comforts of air-secure houses under a high artificial heat, an effort should be made to return as much as possible to the common sense security that is waiting in the mixture of open air and a little more roughing it.

GASTRIC EXFOLIATION AS A FEATURE IN THE PRODUCTION OF ACUTE GASTRIC ULCER.

By ANTHONY BASSLER, M.D.,

NEW YORK.

VISITING PHYSICIAN TO ST. MARK'S HOSPITAL CLINIC

THE etiological factors that enter into the production of gastric ulcer may be divided into two main groups, those that assail the gastric mucosa from the interior of the stomach and those that unfavorably affect the integrity of the glandular layer from the systemic side. The important ones that affect it from the interior are superacid gastric juice, bacteria, trauma, thermic, and chemical agents. While those from the other group are the blood dyscrasias, thrombi and emboli, disease of the arteries, lesions of the vagus, inflammatory changes in the gastric nerves, pressure effects, and possibly bacterial infections derived from the system. Naturally any two or more of these factors may combine or work successively in the production of ulcer. The interior factors are varied, but all of them are of the nature of an effect upon the membranes by an agent, while those of the second group (excepting the factors of bacteria and emboli, of which both may be said to be questionable) have to do with the circulation in the way of quality or quantity of nutrifying blood supplying the organ.

Based on clinical observations, all authorities agree that high acidity (HCl) of the gastric juice and a low status of nutrition to the stomach walls are the commonest factors or concomitants found in cases of acute gastric ulcer. While cases of ulcer are seen with low acidity or antacidity, most of the acute cases seen show a hyperchlorhydria. Accepting all of the outside factors as means that lower the resisting vitality of the glandular layer of the stomach to the irritation of an excessive acidity from within, I have made repeated examinations of wash waters taken mornings from the fasting stomach in patients who after an Ewald test meal showed a total HCl count of over 100 and compared the findings with thirteen other gastric cases that showed a normal or less than 60° secretion of hydrochloric acid with the result that the hyperchlorid stomach shows a greater degree of cellular exfoliation and a smaller amount of mucus than is found in any of the other stomach affections.

In all eighty-one specimens were examined, twenty-nine of which were from the seven cases of hyperchlorhydria. Eleven were from cases of gastritis acida which, like the other cases of gastritis that had a lowered acidity, showed an exfoliation but not to the extent that the hyperchlorhydria did.

Columnar cells from the stomach were found in every case of hyperchlorhydria, sometimes in considerable numbers, attached side by side, at other times in groups of two or more and often single ones. In five of the cases I found groups of cuboidal or irregularly rounded cells attached together, cells which were most probably from the gastric tubules. In one of the specimens, which showed a free HCl 56° combined HCl 80° and a total acidity of 151°, I saw plainly a single sided section through an infundibulum of a tubule which showed on one end columnar cells, in the middle shorter and wider ones and at the other end cells from the interior of the gland.

It can be stated that practically the lining epithelium and glandular elements from a normal stomach are not shed. In stomachs that secrete mucus in increased quantities (gastritis chronica) the glandular cells are often to be found with an occasional columnar and goblet cell usually incorporated in the mucus. I agree with Adolph Schmidt (*Virchow's Archiv*, Bd. CXLIII, S. 498) that in the inflammatory conditions of the stomach the epithelium of the surface of the stomach is preserved better, in the way of exfoliation, than the gland cells. But not with Siegel, that the gastric juice cannot affect unfavorably the delicate layers of epithelium during life and that a hyperacidity affects only the course of the ulcers healing, and that alone. The latter may be true in hyperacidities when there is mucus enough to protect the cells, but in these cases of high hyperchlorhydria the quantity of mucus is generally remarkably low and the investigations proved that not only were the gastric cells shed but that they were shed in larger numbers in these cases than in any of the other stomach disorders.

Technique of procedure: 240 c.c. of distilled water containing sodium chloride, 21 grains; sodium sulphate, sodium carbonate, and sodium phosphate, of each 1 grain; and potassium chloride, 1¼ grains, was given mornings on an empty stomach. The object of adding the salines was to prevent as much as possible the hydrolytic action of the water on the cellular elements and the changing of their shape by swelling. Although I think that if the entire specimen is centifuged and examined at once (requiring a large centrifuge like those used to separate cream from milk) the cells would be separated better out of the plain water than they would from the higher specific gravity saline solution.

The patient was made to run up and down stairs several times and the fluid further agitated in the organ (just before removal) by a series of deep, quick pressure movements over the stomach. Five minutes after the drinking of the fluid it was siphoned out with a long stomach tube, the patient

encouraged not to strain any. After standing in a cylindrical test glass for from two to eight hours 10 c.c. quantities were drawn from the middle zone and bottom, centrifuged for two or more minutes, and the sediment examined microscopically in the fresh state without staining. If the return contained incorporated mucus (all floating and top mucus was removed) the specimen was rendered alkaline to litmus by the addition of a normal lye solution, shaken vigorously in a heavy glass bottle containing washed bird shot, and examined as above stated.

With a low power all of the cells are discernible. In the preponderance of the squamous cells seen (they line all of the structures from the lips to the cardia) the columnar and cuboidal stand out in contrast. Care must be taken that the columnar cells observed are the free edged cells from the stomach and not the swallowed ciliated ones from the upper half of the pharynx, post nares and respiratory tract. With a high power they can be differentiated by observing their cilia, or a zone between the cell protoplasm proper and the free edge. they are also more pyramidal in shape (usually pointed at one end), are generally found incorporated with mucus, are seldom seen and usually found only singly. Also, unless the cuboidal cells from the tubules are in groups one often has difficulty in telling whether they are gastric, half digested, squamous, or other innocent cellular elements such as freed mucous cells, leucocytes, etc.

A common picture in a specimen from a case of high acidity is the great number of free nuclei seen. They are from cells (mucous probably) the protoplasm of which had been digested down to the more resisting nuclear membrane. To observe them best the specimen should be stained (fixing with methyl alcohol, and Biondi's polychrome methylene aquous stain used) and examined in the dry state.

In chronic gastritis, when much mucus is present, the mucous corpuscles share in preponderance with the squamous cells with an occasional cuboidal and goblet cell but rarely a gastric columnar in addition.

The work was tedious and especially discouraging when quantities of incorporated mucus were present. Some of the specimens took several hours to examine. A case of hyperacidity would often show definite desquamation of stomach cells at one time, and when next examined for it the same conclusion was difficult or impossible, particularly when the mineral alkalies had been used in the case. But the examination proved that, compared to other stomach conditions, there was distinctly more gastric exfoliation in the cases of superacidity, especially when the high acid secretion had existed for some time, and particularly when there was present a gastrochylorrhea in the case. Enough gleanings, however, could be deducted from the examinations to at least theoretically conclude that on these places of denuded basal membrane in the submucosa with a lowered resistance and repair power from poor nutrition (from whatever the cause) an acute gastric ulcer could easily make its beginning, assisted most probably by the bacteria ordinarily found and reported associated with the cases of peptic ulcer.

It is also suggestive to observe that, according to Brinton, gastric ulcer occurs in the stomach 43 per cent. in the posterior wall, 27 per cent. in the lesser curvature, and 16 per cent. in the pyloric end, the very locations in the stomach in which the membrane would be compelled to stand the greatest brunt from an increased acidity.

While gastric ulcer has been reported in cases of anacidity, that is no argument against the above conclusions, since the hyperchlorhydria and blood changes (the two common conditions found in most of our acute ulcer cases) is so numerously an argument against it. And it may be further stated that what is a normal amount of hydrochloric acid secretion in one stomach may be a hyperchlorhydria, or even a subacidity, in another.

It seemed to be proved also that, depending upon the quantity of mucus in the hyperchlorhydrias, the glandular layer was protected against the exfoliating work of the acid, and I observed that when the secretion of acid was decreased and the mucus had increased to a more normal quantity, the exfoliating of the cells subsided.

In this connection I wish to report the history of a case that I had observed, which is particularly significant.

E. M., September 20, 1906, age 24 years; married, no children; occupation, housewife. History—Family: Father killed at 47; mother died at 54, cause unknown. Personal: Dysmenorrhea since puberty; pneumonia five years ago; drinks four or more cups of tea and coffee a day; habits otherwise good, excepting is confined in house too much; had stomach trouble more or less for four years. More distressed during the past three months; habitually constipated. Present, troubled much with eructation of gas and distention after meals, particularly after dinner; has pyrosis and regurgitates acid fluid after meals. Physical examination shows fairly well-nourished woman; mucous membranes good color; tongue thinly coated, with red edges and tip; patient nervous and apprehensive; epigastric distress on pressure; abdomen moderately distended with gas; fecal mass in sigmoid. Analysis, September 21, 1906. Ewald test meal, expression easy, return 110 c.c., looks poorly digested, very little odor, no incorporated mucus; total HCl, 121°; total acidity, 133°. Urine amphoteric and heavy in phosphates. Diagnosis, hyperchlorhydria.

On the morning of the next day (September 22, 1906), when fasting, drank 240 c.c. of saline solution, which was left in stomach five minutes; 75 c.c. of return was examined and showed as follows: fluid distinctly acid (HCl) and bile stained, no incorporated mucus apparent, no visible food particles. After standing for three hours specimens from the middle zone were examined in lots of 10 c.c., which were centrifuged for two minutes or more with the following microscopical findings—large numbers of squamous cells, numerous free nuclei, considerable columnar cells and a few cuboidal ones from the gastric glands, one group of columnar cells (seven or more in number) were seen; the cuboidal cells were found in several groups attached together, a few sarcinæ, some shreds of mucus, free mucous corpuscles, and particles of detritus. Specimens from the bottom of the stand glass showed the same cellular findings as above stated, excepting that there were more of them with the addition of numerous small rolls of yellow stained mucus, a few vegetable and partially digested starch cells, and more detritus.

On October 7, 1906, I saw the patient, who, under the prescribed high proteid diet and a compound powder of mineral alkalies, claimed she was quite well again.

Ten months afterward (July 9, 1907) I visited her at her home, where I learned that nineteen days before (June 20, 1907) she had been delivered of a seven months' viable fetus, after the third uterine hemorrhage in five weeks. On June 19, 1907, the patient, while asleep, had an exsanguinating hemorrhage, followed by syncope and continued semi-consciousness for nearly two hours. The attendant diagnosed a placenta previa, quickly tapped the

membranes, packed the vagina with cotton, and the next afternoon she miscarried. The post-partum course was normal, excepting that the woman remained obstinately pale and peaked looking. Six days after her delivery she began to complain of pain and distress in the epigastrium after eating. The pains continued more or less, depending upon the character of nourishment she took, until the day before my visit, when, her stomach feeling somewhat better, she partook rather heavily of raw fruits, after which she was seized with severe gastric pain and vomited. The pain grew worse during the night and the next morning, after a glass of ice cold milk, she vomited considerable blood. The history and physical examination showed that it was plainly a case of gastric ulcer, probably in the posterior wall.

My deductions from the case were that the hyperchlorhydria, from which she suffered more or less for years, caused an exfoliation of the cellular elements of the gastric mucosa. This exfoliating continued, and, like small traumas from food or stomach tubes, was not serious as long as the nutrition of the stomach was sufficient to repair the slight abrasion. But when, as a result of a severe hemorrhage, the system was impoverished and devitalized, the resistance of the basal membrane and submucosa was lowered and the acidity continuing an ulcer ensued on some exfoliated area.

228 East Nineteenth Street.

THE DIAGNOSIS OF KIDNEY DISEASES WITH SPECIAL REFERENCE TO THE SIGNIFICANCE OF SLIGHT ALBUMINURIA.*

By EDGAR BALLENGER, M.D.,

ATLANTA, GA.

LECTURER ON GENITOURINARY DISEASES, ATLANTA SCHOOL OF MEDICINE.

The scope of this paper is limited to a consideration of certain phases of albuminuria and its bearing upon the diagnosis in the obscure, rather than the clearly defined cases. There is little doubt in advanced conditions where there are casts, albumin, edema, high arterial tension, etc., but we often feel uncertain as to the diagnosis and prognosis if there are only slight evidences of kidney disease, such as a trace of albumin or orthostatic albuminuria and a few casts.

When Richard Bright first called attention to the significance of albumin in the urine the crude methods then used in testing it prevented the detection of small amounts of proteid that we now find so frequently and have so much difficulty in correctly interpreting. Hasting and Hoobler have made a large number of careful examinations, and have found that the cases of well-defined Bright's disease, in which the symptoms and physical signs pointed to a renal lesion, include only 12.59 per cent. of the patients with albuminuria. Nucleoalbumin was frequently found, and should always be differentiated from serum albumin.

Albumin in urine may be renal or extrarenal in origin. By renal we mean that it passes through the kidneys with the urine, and may be due either to a local lesion in the kidney or to a systemic condition which, by general changes throughout the body, or by toxins circulating in the blood, injure to some extent the renal structure, and allow the escape of albumin. Extrarenal albumin may come from any part of the genitourinary tract below the kidneys, and is a contamination of the urine with proteid substances, for which we should be alert constantly, so as to avoid the error of mistaking it for renal albumin.

The commoner proteid substances that are found in the urine are serum albumin, serum globulin, nucleoalbumin and albumose. Serum albumin is the most important of these as a positive finding, and suitable tests should be made to eliminate the other proteids. Cohnheim's method of "salting" the urine with a saturated solution of sodium chloride, over acidulation with 3 to 5 drops of 50 per cent. acetic acid and boiling, will throw down the proteids commonly found in the urine. Nucleoalbumin is not precipitated by heat and acetic acid, though in highly salted urine; consequentiy a cloudiness with this test usually means serum albumin (Hasting).

Albumose frequently has its origin in an inflamed prostate gland or seminal vesicle. The proteid substances that are secreted in the prostatic discharge are digested by a ferment called leucoprotease, which is liberated from the disintegrating pus cells, and only acts in a faintly alkaline medium (Opie & Barker). This albumose is not precipitated by boiling, nor does it give the cloudiness at about 60° C., as does Bence-Jones albumose. When precipitated with cold citric and picric acid a sediment is formed, but will disappear when heated, and again return when allowed to cool. If serum albumin or nucleoalbumin be present it only partially clears when heated, and, if the test tube is placed in a boiling water bath, these albumins will settle to the bottom, and when it is allowed to cool the albumose is deposited in another layer upon it, a distinct line of demarcation between them being perceptible.

Bence-Jones albumose gives a cloudiness below the boiling point, but when further heated clears. If stratified upon hydrochloric acid it will also cause the appearance of a white ring at the zone of contact. The other proteids do not react to this test (Bradshaw).

The acid secretion in the vagina prevents the digestive action of the leucoprotease which is liberated from the pus cells, and the proteid discharge is not changed into albumose, but is converted into an acid albuminate which cannot be detected by the ordinary heat test, and when precipitated will not clear up again, as albumose does, when reheated.

A prostatic abscess draining into the urethra will give large quantities of serum albumin and globulin at first and later albumose. The presence of pus and albumin in such amounts at once suggest an abscess of the kidney In a previous paper I reported the history of a patient with an insidious prostatic abscess with urine exactly simulating a renal abscess.

Having found that we are dealing with albumin from the kidney, an even more difficult task is to determine its significance. It may be orthostatic in variety, as described years ago by our ex-president, Dr. A. W. Stirling, under the name postural albuminuria, as it only appears when the patient assumes an upright position. This form of albuminuria may, or may not be attended with tube casts, and may or may not be followed by serious kidney disease. As a rule, however, it is the least harmful, and a rather common form of albuminuria It is known that more urea is eliminated when a patient is in the upright position, and that the urine has a higher specific gravity, and is more highly colored than when reclining. Why this should be the case we are unable to say. It has been assumed that the escape of albumin from the kidneys, when the patient is standing, is due to certain changes in the blood pressure or to a paresis of the vasomotor system of the kidney.

*Read before the Fulton County Medical Society, October 3, 1907.

The experiments of Lemoissier have shown that standing lowers the secretion of water by the kidneys in all individuals, but this diminution of water was found to be greater in those in whom the kidneys were diseased, and the difference was sufficiently marked and constant to indicate that excessive orthostatic oliguria is a very delicate sign of defective renal secretion. Concerning an increase in the albumin in the urine when patients with an undoubted nephritis assume an upright position, very little has been written, but from a consideration of the facts pertaining to orthostatic albuminuria I feel confident that such a condition exists.

Fox, following the work of Wright, thought the trouble was due to a lessened coagulability of the blood, and gave patients calcium lactate, and again made tests when the coagulability had been increased, and claimed that when the albumin was purely functional it would disappear after the calcium lactate had been given, while if there be an organic renal lesion the albumin will not be affected. I have tried this test on a number of patients, but have had no very conclusive results. One patient with only a few hyaline casts and an orthostatic albuminuria, before taking the calcium lactate, had an enormous increase in the casts on the day following, and as many as forty were counted in one field with the low-power lens in a specimen from urine which had not been centrifugated, but had only been standing in a glass for about thirty minutes. With this increase in casts there was a diminution in the quantity of the albumin.

Simidar has made a number of experiments on animals, and found that physiological (?) albuminuria occurs in them as well as in man.

Collier, among whose duties is the examination of students at Oxford University, has been in the habit of advising all students who have albuminuria after exercise to give up competitions involving great muscular strain. In 1906, however, he made systematic examinations of all the men training for boat racing and found that, without exception, every man who rowed the full course passed albumin in his urine, and at least half passed it in considerable quantity. The same was true of running men, and has been observed by a number of previous investigators. Collier no longer holds that such men should give up hard athletic competitions.

Heubner has recently reported the post-mortem findings of a child in whom orthostatic albuminuria had been observed for a year and a half previous to death which was caused by a brain tumor. The kidneys were found practically normal, the very slight changes being too trivial to be considered, and were thought to be due to the long death agony. A small tuberculous area was found at the apex of one lung, which tends to confirm the view held by some observers that postural albuminuria is a "pretuberculous" phenomenon.

Examples of orthostatic albuminuria have been found to precede certain well-recognized forms of nephritis, and albuminuria in convalescents from scarlet fever has finally changed to the orthostatic form.

Bruns has reported the history of a patient with intermittent orthostatic albuminuria during attacks of malaria. This observer was unable to say that malaria was the cause of the albuminuria, but asserts that it was undoubtedly a factor in producing it. In this connection I desire to report the history of a patient of my own with syphilis, in whom orthostatic albuminuria was strikingly demonstrated. There were a few mucous patches in his mouth, and he suffered with severe nocturnal headache. Syphilis had been contracted ten months previously and had received very little treatment. How long the albuminuria had existed I am unable to say. There were a few hyaline and granular casts. Under antisyphilitic treatment with iodide of potash and intramuscular injections of salicylate of mercury the headache ceased immediately, the mucous patches were well in a week, and the urine became practically normal within a month, but the albumin showed a tendency to recur at intervals during the next two months. The casts disappeared entirely. No etiological factor other than syphilis could be assigned as the cause of this patient's orthostatic albuminuria, and this view seems confirmed by the fact that under treatment for this disease it cleared up along with the obvious syphilitic symptoms, and again returned after the patient had discontinued treatment for four months while out of the city. It is my opinion that if left untreated this condition will develop into a true syphilitic nephritis.

Tunis wrote letters to a number of the leading men of this country for their opinion regarding the significance of small quantities of albumin in the urine, and from their replies, and from his own experience, he has reached the conclusion that the mortality must necessarily be higher in these individuals than in those who do not show this abnormality.

Casts have about the same significance as has renal albumin. There are many drugs that cause their appearance, especially the hyaline variety. Severe muscular exertions and overindulgence in certain forms of food and alcoholics also produce them where there is no nephritis. Merely their presence in a single specimen of urine which has been allowed to stand and the upper portion decanted off and the lower part carefully centrifugated, cannot be taken in itself as evidence of Bright's disease—even if a few granular casts are found. When irritated the nonnephritic kidney seems capable of producing them in larger numbers than can the diseased kidney—especially the interstitial nephritis in patients of advanced age (Emerson).

Conclusions.—In doubtful cases no positive opinion should be expressed until many specimens of urine have been examined, for it is the persistence of renal albumin and casts that is of more serious import than is their occasional presence in considerably larger quantities. The 24-hour specimen should be measured and a comparison made between the amount ordinarily passed, and when an excess of water is being taken. The specific gravity is of much importance if the amount of fluids ingested is considered. In addition, the condition of the heart, blood-vessels, arterial tension, diet, intestinal canal, habits, and past history should receive due attention.

Many patients with orthostatic albuminuria of renal origin will go for years without any evidence of nephritis, but our prognosis must not be made from the urine alone, but from the entire picture. Prudence demands that we be conservative, and yet not be too pessimistic and give patients unnecessary alarm about conditions which may not be dangerous. Success in discriminating between the insignificant forms of albuminuria, and those indicating renal disease, depends more upon eliminating nucleoalbumin and extrarenal albumin and albumose than in any further refinement in our chemical examinations.

I realize that this paper has not cleared up the subject very much, but I will feel that it has served its purpose if it has assisted any of those present in looking upon albuminuria in a more judicial man-

ner. It is important that we discard dogmatic statements and preconceived ideas that albuminuria necessarily means Bright's disease, and at the same time it is of as much consequence that we be not too positive in our assertions that orthostatic or the so-called physiological albuminuria is always harmless.

A CASE OF UNILATERAL THIRD NERVE PARALYSIS.*

BY J. JAY KAISER, M.D.,

NEW YORK.

ASSISTANT TO THE NEW YORK EYE AND EAR INFIRMARY, THE BROOKLYN EYE AND EAR HOSPITAL, AND THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

CASES of third nerve paralysis, of the classical type that was exhibited in the present instance, are so striking that the general practitioner should find no difficulty in recognizing them. It is to call attention to these interesting and easily recognizable cases, and to point out the value of appropriate treatment, that the following case is reported.

One interesting feature of third nerve paralysis is that the patient offers a complete clinical picture, in correspondence with a definite set of lesions, the most striking and pathognomonic objective symptoms being: (1) Complete ptosis or drooping of upper lid which is due to paralysis or deficient development of the levator palpebræ. (2) On opening the lid with the fingers we find the globe turned toward the temporal side and slightly down; this is brought about by the action of the external rectus and superior oblique muscles, which are not supplied by the third nerve. (3) The pupil is dilated, which is due to paralysis of the sphincter pupillæ, which contain the contracting fibers of the iris and supplied by the third nerve.

In the study of these lesions several features are of considerable theoretical as well as practical interest, the first being the origin of the affection, a question which plays such a prominent rôle in the selection of treatment, most of the standard authors insisting upon the syphilitic origin of the affection, and in many of the reported cases the syphilitic antecedents of the patients are clearly shown; but the present instance, after a careful inquiry and thorough examination failed to reveal the existence of any syphilitic taint, either acquired or hereditary. In spite of this, however, active mercurial treatment followed by potassium iodid produced results, the promptness and completeness of which left nothing to be desired. The causes of third nerve paralysis are rheumatism, diphtheria, traumatism, syphilis, aneurysm, tumor, and meningitis.

Mrs. D., age 51, family history negative. Previous personal history, the usual diseases of childhood. Symptoms simulating rheumatism for past three years. No head or face injuries. No history of syphilis could be obtained.

About six weeks prior to consulting me, the patient felt pains in back of the left ear, which radiated over the left brow. One week later the upper lid of left eye was noticeably drooped. Appearance of patient on first visit as follows: Head inclined toward left shoulder; facial expressions normal; upper lid of left eye closed, the patient having absolutely no control over its functions; slight ciliary tenderness; exophthalmos slight; pupil dilated; marked divergent strabismus. Upon elevating the lid the patient complained of dizziness and nausea. Movement in, down, and upward very much limited. Crossed diplopia for near and distant vision. False image higher and its upper end inclined toward paralyzed side. Pupil reacted neither to light, accommodation, or convergence. Ophthalmoscope presented a few small hemorrhagic spots visible toward nasal side of fundus.

Vision: O. D. 18/200 with + 3.50 sphere = 18/30 — O. S. 10/200 w + 5.00 = 18/30. Could not test for near on account of marked crossed diplopia. The field of vision was normal in right eye. Left eye there was concentric contraction as follows: Temporal 75°; nasal 45°; above 30°; below 45°.

Field for colors was practically normal. Atropine reaction was negative. The urine contained a faint trace of albumin with a few hyaline casts.

Having diagnosed the case as complete paralysis of the motoroculi, the oleate of mercury was prescribed, in form of inunctions, daily for 100 applications, selecting alternately the right thigh, left axilla, left thigh and right axilla. The faradic current was applied three times weekly, one pole at occipital region, the other over the supraorbital, infraorbital, and temporal regions. A saturated solution of potassium iodide was given in dose of ten drops in a wine glass of cold water, one-half hour before each meal, increasing one drop daily until twenty-five drops were taken, three times daily.

After three months of constant treatment the ptosis diminished considerably, the patient being able to control the movement of the lid. The strabismus was greatly improved and the pupil reacted to light, but movement of the globe upward and downward was very limited. The double vision still persisted at five feet, but the patient enjoyed good single vision at twenty feet with the proper lenses. The electricity was discontinued, also the mercurial inunctions. The biniodide of mercury, gr. 1/20 three times daily after meals, was substituted, together with a nutritive diet and attention to hygiene and digestion.

Six months after the first treatment the patient was entirely free from the ptosis and enjoyed good single vision, both for near and far, with the following lenses:

O. D. w + 3.50 sphere = 18/30 w + 5.50 sphere = Jäger number 2 at 13 inches.
O. S. w + 4.00 sphere = 18/30 w + 6.00 sphere = Jäger number 3 at 13 inches.

In third nerve paralysis, as in other paralyses, the lesion may be central or peripheral, according to its location, either between the cortex, and the apparent origin of the nerves, at the base of the brain or from the base of the brain to their peripheral terminations. It is often difficult to differentiate between central and peripheral lesions.

In closing, it may be of interest to mention my patient has had no return of the paralytic symptoms. It is now about eighteen months after first treatment. Epiphora of the left eye has yielded to dilatation and probing; this condition is in no way attributed to the third nerve paralysis.

New York, November 30, 1907.

THE PROPHYLAXIS OF SYPHILIS.

IT needs no argument to show that in general the greatest sufferers from venereal diseases and their consequences are not those who have acquired them through illicit sexual intercourse, but the innocent to whom those diseases have been transmitted in the marriage bed or through the medium of contaminated objects, such as towels, table utensils, surgical instruments, and the like. It is not the young man who has sown his wild oats and harvested a gonorrhea that suffers the most, but his innocent bride who has taken him for better or for worse. It is not the man who knows he has contracted syphilis and seeks treatment betimes that is ruined for life, but the comrade who shares his pipe or his spoon, or the fiancée who receives his polluted kiss, and who carries the disease untreated for months or years until irreparable damage has been done. In Russia, Tarnovsky says, over 70 per cent. of the syphilitic morbidity is due to extragenital infection, the disease being unrecognized and untreated for years, and so transmitted to the unborn children, implanting in them the seeds of early death, of degeneracy, and of parasyphilitic affections. Bulkley, in his important work on "Syphilis Insontium," has strikingly portrayed the deplorable evil to the community which may be wrought by the syphilitic who bears no external evidence of the plague which he is disseminating. The results of gonorrhea insontium are less widespread; they bear less upon the community at large, except as the disease fills the blind asylums, and so imposes a preventable burden upon society; but in the case of the individual they are often even more disastrous than those of syphilis.

All these facts are well known to the medical profession, but they are known only imperfectly to the laity. The subject of venereal disease is tabooed in polite society, and perhaps rightly so. It is a question how far a common knowledge of such things would go in shielding the innocent from the consequences of others' sins, and even the most fanatic of reformers could but wish for some other way of preventing the spread of such diseases than by instructing a pure young girl in their mode of dissemination. Associations such as the Society for Moral Prophylaxis are undoubtedly doing a good work, and the distribution to young men of tracts dealing with the evils of illicit sexual intercourse is commendable, but the suppression of venereal diseases and the evils resulting from them will never be accomplished by such means. Ignorance is not the only cause of syphilis and gonorrhea, for, as is often said, we all know that in spite of having been adequately warned, young doctors and students of medicine furnish a not inconsiderable number of victims. When the millenium comes, venereal disease will be abolished by abstention—but not until then. Moral suasion will save a few, but for the great majority the only hope of prevention is in medical measures instituted after the act. What is needed most is a Society for Prophylaxis, with "moral" in parentheses. Prophylaxis is the necessity—moral if may be and certainly by preference, but in any case phophylaxis. The objection, based on high grounds of morality, to post-factum prophylaxis would perhaps be tenable if the consequences of the act were confined to the individual, but when we know that the neglect of such prophylaxis may ruin another and perhaps many innocent lives, the refusal to sanction or advocate such prophylaxis seems almost, if not actually, criminal. In the case of smallpox the one suffering from the disease is forcibly isolated and the one who has been exposed to contagion is compelled to submit to protective vaccination. Society is not yet sufficiently evoluted to demand for itself the same measures of protection in the case of grand pox, but until it is it should not protest, on the ground of "morality," against individual measures of prophylaxis. Men will consort with unclean women, or women who are presumptively unclean, in spite of the teachings of religion and the warnings of medicine—they have done so from the dawn of history, and there is nothing in the present state of society to lead us to hope that they will not continue to do so. Moral suasion has been tried for centuries and has failed lamentably, and it is time now for the medical profession to safeguard society by instructing the malefactor how to protect, not himself alone or chiefly, but the innocent, from the consequences of his evil deeds. Moralists do not forbid the treatment of venereal disease, yet, so curious are the workings of the human mind, they protest vociferously against measures taken immediately after an impure sexual intercourse to prevent the development of disease. If one is permissible and even necessary, why should the other be wrong? If it be allowable to cure a gonorrhea rapidly by irrigations or other therapeutic measures, why should it be forbidden to take similar measures to prevent the occurrence of the disease? If it is allowable to give mercury for the cure of syphilis once it has declared itself, why should it be wrong to apply a mercurial ointment or to give arsenical injections immediately after sexual intercourse, to prevent the disease? Is it necessary to let the sinner suffer for a few days or a few months from the consequences of his act by way of punishment, even if by so doing we give him the opportunity to involve innocent beings in his punishment? It may be that the sins of the fathers must be visited upon the children, and those of the husbands upon the wives, but he is a stern moralist indeed who would willingly take an active or even a passive part in executing this sentence.

These thoughts are suggested by a report made by Metchnikoff to the recent International Congress of Hygiene in Berlin upon the prophylaxis of syphilis. The writer's first endeavors were in the direction of an antisyphilitic serum or a vaccine, and he

presented a paper on the subject at the meeting of the Congress in Brussels in 1903. The first experiments seemed to give promise of good results, but the promise was not fulfilled, and work in that direction was abandoned. Then a bichloride wash was tried, and finally resort was had, with apparent success, to an ointment of calomel 33, vaselin 10, and lanolin 67. Metchnikoff, working in collaboration with Roux and Salmon, made numerous experiments with this ointment, and after a large number of favorable results obtained in inoculations of monkeys, a physician, Dr. Maisonneuve, lent himself for a final and more conclusive test of the remedy. He was inoculated with a large dose of syphilitic virus and one hour later the calomel ointment was freely applied at the site of the inoculation; he remained free from any symptoms of the disease.

A condition of success in the employment of this calomel ointment is, of course, that it shall be applied within a short time after suspicious contact, and when several hours have elapsed it is not to be expected that a local application will destroy the virus already in part absorbed. In such cases it is evident the remedy must be given internally. The favorable action of the arsenic-acid anilide (atoxyl) in certain spirillum infections led to experiments with this remedy. It was found that its hypodermic employment as late as two weeks after the inoculation, in doses of 33 mg. per kilo of the animal's weight, sufficed to prevent the appearance of syphilis in the monkeys experimented upon. The objection to the routine employment of this drug in man is its highly poisonous properties, and a desideratum is a less toxic arsenical preparation having an equally destructive action upon spirochetes. When this is discovered, Metchnikoff says, we shall be in possession of an absolute prophylactic of syphilis up to as late as two weeks after the impure contact, this being rendered possible by the fact that the reproduction of the specific microorganisms does not occur for a comparatively long time after their introduction into the body.

REPORT OF THE BRITISH TUBERCULOSIS COMMISSION.

The British Royal Commission on Tuberculosis has published recently a second volume of the appendix to the second interim report. This volume deals with Dr. Louis Cobbett's evidence on the pathogenic effects of human viruses. Dr. Cobbett's experiments were made with the object of classifying the various strains of tubercle bacilli according to their virulence for different kinds of animals. The animals used for the investigation were the goat, ox, pig, dog, monkey, rabbit, guinea-pig, and rat. A few experiments were made also on the cat, mouse, and fowl, three on the chimpanzee, and two on the baboon. The majority of the experiments were made by inoculation and with viruses classed as virulent and slightly virulent.

The results from these experiments on bovines and rabbits were quite important, as Dr. Cobbett demonstrated the fact that "the viruses obtained from man were, with the exception of one from a case of lupus, found to be broadly separable into two groups—namely, those which caused fatal tuberculosis and those which did not." The investigator states that injected subcutaneously into the calf in suitable doses, such as 50 mg. of culture, they either produced rapidly fatal general tuberculosis, or they caused no more than a transient disturbance of health and localized or minimal lesions, which soon became retrogressive. The viruses which were highly virulent for the ox species were also highly virulent for the rabbit, while those which had a low degree of virulence for the calf had also a low degree of virulence for the rabbit, and very rarely caused progressive or fatal tuberculosis.

In the light of Dr. Cobbett's experiments, the proceedings of the International Conference on Tuberculosis, which took place in Vienna from September 19 to 21, were of much interest. Prof. Flügge of Breslau, the chief advocate of the inhalation theory of tuberculosis infection, put forward as a strong point in favor of his views that it was very difficult to infect animals with food mixed with tuberculous material. Cobbett infected bovines by feeding, although not so severely as by injection, and found that when tested on the chimpanzee both types of bacilli were capable, in small doses, either by feeding or by subcutaneous injection, of causing acute general tuberculosis. Of course this does not wholly disprove Prof. Flügge's theory, but it seems to go a very long way in this direction. Perhaps there may be two kinds of tuberculosis, one of which is rapid and fatal, and the other kind comparatively innocuous. As to the mode of infection, Prof. Orth of Berlin expressed himself at the Vienna conference in a manner which will probably meet the views of a very large number of physicians in all parts of the world. He said that the bacilli of Koch could establish themselves in the lungs and produce tuberculosis either after having gained access by means of the inhalation of air charged with them, or after having first invaded the glands and thence found their way to the lung either by the circulating lymph or blood, or by direct access owing to the breaking down of glands. They would also enter the body from the intestinal canal, which might itself, however, remain completely unaffected. A special predisposition was necessary to produce tuberculous lesions of the lungs. Such a predisposition might be acquired by repeated attacks of bronchitis or similar diseases. Even small quantities of bacilli gave a positive reaction in the lung, but large quantities were often inactive in the intestinal canal. From the point of view of prophylaxis, the question of the channels of infection was of only secondary interest, for the object to be aimed at was the destruction of all sources from which infection might take place. Such sources were the milk and butter from diseased cows and the sputum of tuberculous individuals. Bovine tuberculosis was undoubtedly infectious for human beings.

The British Commission on Tuberculosis has done valuable work, and has definitely shown that bovine tuberculosis is transmissible to man, at least as clearly as this can be demonstrated. The results already known as to the danger of bovine tuberculosis to man should act as a spur, if such were needed, to health authorities to insist upon a pure milk supply and the pasteurization of all milk the purity of which cannot be absolutely guaranteed.

A Discovery of Hygienic Value in Telephony.

Much has been written of the danger of infection from public telephones, and that this danger is very real has been amply demonstrated by the bacterioscopic examination of scrapings from telephonic transmitters. To obviate this danger a vast amount of ingenuity has been expended in devising membranous diaphragms to cover the transmitter, a new diaphragm being used by each user of the telephone, and various forms of apparatus for spraying a disinfectant into the transmitter. None of these has proved itself to be generally practicable. The diaphragm muffles the voice and the disinfecting apparatuses are more or less clumsy, and, moreover, when a telephone is in constant use there is no time for the disinfectant to work. A discovery that promises to be of real practical value is announced in the *New York Times* of November 25. This is that the voice is transmitted as clearly if the transmitter is pressed firmly against the chest while talking as it is when one speaks into the tube. The *Times* despatch states that the discovery was made by two young women in St. Louis, but it is now stated that it is not new and that a transmitter for body telephony was invented several years ago in Europe. It is nevertheless new to most telephone users. Apart from the danger of infection, the use of a public telephone, reeking as the transmitter sometimes is with the odor of tobacco and alcohol, is disgusting and only tolerated because of its necessity. It is a fact that the voice carries as well and as clearly, with a somewhat lower tone, when the transmitter is applied firmly to the lower end of the sternum, as it does when one speaks directly into the transmitter, and the intervention of the clothing seems to make no difference. A desk telephone is necessary, as one cannot conveniently stand on a stool to press his chest against a wall transmitter, but the hygienic utility of the chest method of telephony is so obvious that the telephone companies, most (or we might better say some) of which are progressive, will doubtless devise a new form of transmitter which can be used in this way. In the meantime we would strongly recommend to all users of the telephone, whose apparatus lends itself to it, to employ the chest method. It is a real advance—it is easy, it is efficient, and it is hygienic.

The Codification of Medical Practice.

We have often envied the old-time homeopathic practitioner, who had a little book in which every symptom was noted, with its therapeutic indication plainly stated. It must have been conducive to much peace of mind when a patient said she had a desire to curse and swear to be able to turn to that symptom and find that anacardium would restore the moral balance; or, when one disliked going down in a sky-scraper elevator, to be able to raise his spirits, even as his body was lowered, by borax, 30. Hitherto regular practitioners, both internists and surgeons, have had no such aids, and have been compelled to rely upon their own judgment, faulty as it might be, in the treatment of disease. The dawn of a better day has come, however, and if the lawmakers of the country will only act upon the suggestion of the president of a national society which recently held its annual meeting in Chicago, the practice of the healing art will be wonderfully simplified, and those engaged in it will be relieved of much sleep-chasing and life-shortening responsibility. A Chicago despatch to the *Evening Post* of October 18 quotes this reformer of medical practice as saying: "I think the time for legal recognition of and punishment for delay in diagnosis and operation for appendicitis is due, and unless the profession awakens to its shortcomings an enactment will soon be placed on our statute books." We are not in general disposed to accept too literally the reports in the lay press of the sayings and doings of medical men, and it may be that in this and the further quotation, that "the practice of procrastination in all acute infections should no longer be tolerated by the profession and will not be by the public," less than justice has been done the speaker. We hope, however, he has been correctly quoted, for the idea is one full of fascinating possibilities. Nothing could be easier and more remunerative to the surgeon than to be compelled by the courts to diagnose appendicitis and operate at once if his patient with a stomach ache could be made to squeal when McBurney's point was prodded. What confusion, too, would overtake the disciples of Osler if the law drove them to treat pneumonia by specifics, or the active principles, instead of leaving the patient to work out his own salvation according to the self-limited disease theory! The pernicious research laboratories would be closed, the investigators therein could go to work to earn an honest living, and the rabbits and guinea-pigs could be canned to feed the starving millions, for of course the law would not recognize anything so uncertain as the results of laboratory investigation. The Council on Pharmacy and Chemistry could rest from its labors, for the law would naturally prescribe only pharmacopœial remedies; this would save the *Regulator* ems upon ems of costly composition and reduce its issues to readable size. The more one thinks of this plan of the legal codification of medical practice the more attractive it appears. The practice of medicine and surgery would indeed be simple if its professors had only to treat their patients according to a legal code, as formerly the younger men among them had to regulate their own conduct according to the quaint provisions of an ethical code. We fear, however, this is only a dream. Even Congress would shrink from the task of codifying the whole of medical practice. There is only one man in the country who would feel himself competent to undertake the job, and he is busy now.

The Cause of Sudden Death in Swimmers.

A question that has given rise to a great deal of discussion without apparently any very fruitful result is the cause of the sudden death that sometimes overwhelms even skilful and experienced swimmers under circumstances that do not seem in any way abnormal. In addition to the popular and more than vague diagnosis of "cramps" numerous explanations of accidents of this sort have been put forward, heart failure being a favorite but not very satisfactory one. Syncope, nausea and vomiting, rupture of an ear drum, and the effect of entering the water shortly after a meal are other alleged causes of sudden death under these conditions, but they are all more or less indefinite and leave a great deal to the imagination. Revenstorf (*Münchener medizinische Wochenschrift*, November 5, 1907) points out that Du Bois Reymond has already shown that the effect of simple immersion in deep water is to increase the energy output necessary for respiration by about ten per cent., while the very active muscular exercise attending the act of swimming

greatly augments the tax on the respiratory muscles which are then called up to do at least fifty per cent. more work than when the body is at rest on land. Müller has found that the pulmonary intake during swimming is 51 liters per minute as opposed to 42 liters during mountain climbing. This increased tax in the respiratory capacity together with the very active muscular exertion in which good swimmers are apt to indulge, when combined with a third factor, that of gastric distention, is considered by Revenstorf sufficient to explain many instances of apparently inexplicable drowning. If the stomach is distended with food, fluid, or gas the effect of the increased pressure on the surface of the body in impeding the movements of the diaphragm is greatly augmented and respiratory failure can occur without the victim's having received any warning of the impending collapse. Revenstorf describes several cases in which no abnormality could be found to explain the sudden death, but the stomach was more or less distended with food, and while all the swimmers who die suddenly while in the water undoubtedly do not do so as the consequence of bathing too soon after eating, the author's argument is a cogent reason for adhering to the old rule not to enter the water until an hour or two after the last meal.

Cutaneous Sensibility in Gynecological Conditions.

The significance of the highly ingenious researches of Head by means of which he was enabled to map out on the surface of the body areas or zones corresponding to the spinal segments in connection with the different organs, has not been altogether appreciated, or even admitted. While most authors who have concerned themselves with the matter have with some minor modifications corroborated the conclusions reached by the English investigator, the practical application of his results has found fewer exponents. In a recent communication in the *Deutsche medizinische Wochenschrift* of November 7, 1907, Alsberg gives some sketches showing the location of areas of cutaneous hyperesthesia found in patients suffering from gynecological conditions and expresses the opinion that they should be sought for in all cases. Owing, however, to the fact that they occurred in only about 8.5 per cent. of the patients examined by him and did not appear to exhibit a very definite relationship to special organs or affections he considers that in gynecological conditions their diagnostic value is at present rather slight, and consists chiefly in that, if found present, they indicate the necessity for a careful examination of the nervous system.

News of the Week.

Harvey Society Lecture.—The third lecture in the Harvey Society course will be delivered by Prof. David Edsall of the University of Pennsylvania at the New York Academy of Medicine, on Saturday, November 30, at 8:30 P.M. Subject: "The Bearing of Metabolism Studies on Clinical Medicine." All interested are cordially invited to be present.

The Nobel Prize in Chemistry.—The next award of this prize is to be made to Sir William Crookes of London, who has lately discovered a process for extracting nitrogen from the atmosphere and rendering it available for human use.

Large Output of Radium.—The Imperial Academy of Science of Vienna is reported as having succeeded in greatly cheapening the cost of production of radium. About three grams of the finished product were obtained at a cost of $10,000 from ten tons of uranium and pitchblende given to the Academy by the Government from its mines in Bohemia.

Radiographic Test of Death.—Dr. Vaillant of the Lariboisière Hospital in Paris last week, in a paper read before the Academy of Sciences, stated that the differences between radiographs of the trunk made before and after death were sufficiently great to enable this method to be used as a means of determining whether or not life was extinct.

Automobiles for Viennese Physicians.—The medical men of Vienna have organized an association to aid its members in acquiring automobiles. It is proposed first to persuade manufacturers to build a car specially adapted for medical work, and the members will be enabled to buy the machines from the club on the installment plan. The monthly payments will be less than the present cost of hiring a carriage by the month, as most doctors do. The club will have its own central garage, and branch garages will be opened in various districts of the city as the demand increases. The promoters of the association hope to increase the number of motoring doctors from the present twenty or so to at least two hundred.

"American Journal of Orthopedic Surgery."—This excellently edited and very readable journal is to be enlarged by the addition to each number of one or more monographs of not less than twenty pages and fifteen pages of abstracts of orthopedic literature. This is the only journal in the English language devoted exclusively to orthopedic surgery, and the proposed improvements will easily place it at the head of journals of this specialty in the world.

Loss of Life in Switzerland.—The official statistics relative to the tourist season in the Italian, Swiss, and Austrian Alps show that the number of lives lost by mountain climbers was seventy-five, and 350 cases of grave but not fatal injury are recorded. Most of the accidents are ascribed to the foolhardiness of inexperienced climbers in attempting difficult ascents without guides.

Street Car Accidents.—The reports of the Public Service Commission show that during the month of October forty-seven persons were killed in street car accidents in this city. The total number of accidents recorded for the month was 4,866, as against 5,202 for September, and 5,500 for the last twenty-six days of August. The total number of serious injuries inflicted, including the fatal cases, is given as 191 for the month, as against 216 for September and 189 for August. The decrease is ascribed to the fact that closed cars were substituted for the open ones in use during the summer months, the operation of the latter being more likely to cause accidents.

Football Casualties.—With the football season practically over the *Chicago Tribune* states that this year's record shows eleven deaths and ninety-eight cases of serious injury. Last year the same number of deaths and one hundred and three cases of injury were reported.

Plague.—Surgeon Blue of the Marine Hospital Service, who is in charge of the plague situation in San Francisco, has reported to Surgeon-General

Wyman that the disease seems to be on the decrease. Up to November 16 there had been ninety-six cases of plague reported in San Francisco, from which sixty deaths have resulted. A bounty of ten cents has been offered for rats, and during the first week of this month 13,000 rats were poisoned or trapped. The last case in Seattle was reported on October 30. In India the situation is increasing in gravity, especially in the Punjab. From April 18 to September 14 of this year in that district there were 339,557 cases, with 306,905 deaths.

Red Cross Society.—The New York State Branch of the American National Red Cross Society at its annual meeting in this city last week passed resolutions to make in times of peace a special fight against tuberculosis and to study the subject of preventable accidents. A special effort is also to be made to increase the membership of the organization.

Smallpox of a mild type is occurring in Jefferson, Lewis, and Oneida counties of this State, and about a hundred cases have been reported.

Cholera.—Cholera is reported as having broken out in Constantinople.

Yellow Fever in Barbadoes.—An outbreak of yellow fever is reported from Barbadoes where four cases with two deaths have occurred among the seamen of the British cruiser *Indefatigable*.

The Temperance Movement in Germany.—The Prussian Minister of Justice is leading a movement among the alumni of the universities to check drinking on the part of students, especially by abolishing compulsory drinking on the part of members of the Student Corps. The Government also has been petitioned to set apart cars on the Prussian railways Saturday and Sunday nights for intoxicated persons, or if that be deemed inexpedient to reserve cars for abstainers, with train hands at the doors, when the trains stop, to exclude intoxicated people and thus afford abstainers quiet traveling.

Slow Payments in Germany.—The Medical Association of Eastern Prussia is about to compile and distribute among its members a black list containing the names and addresses of persons in good circumstances who are slow in paying their doctors' bills. The list is to be revised every six months.

Rockefeller Institute for Medical Research.—The directors of the Rockefeller Institute for Medical Research have received from Mr. John D. Rockefeller a further sum of $2,600,000 to serve as an endowment fund for the maintenance of the institute. Mr. Rockefeller's previous gifts had amounted to $1,200,000.

Bequests to Philadelphia Hospital.—By the will of the late Hanson L. Withers the sum of $5,000 is devised to the Hospital of the University of Pennsylvania for the endowment of a free bed to be used for patients suffering from diseases of the lungs, the beneficiaries to be named by the testator's daughter and Dr. Edward Martin. The residue of the estate also is devised to the University Hospital on the death of the daughter without issue and on the death of a son during whose life it is to be held in trust. This fund is to be devoted to the erection of a ward to be known as the Alice M. Withers Ward, and the purposes to which it is to be put are to be designated by Dr. Edward Martin.

Public Hospital for Springfield (Illinois).—An additional public hospital for this city is provided for in the will of the late Col. Stephen Logan Littler. The testament creates a trust of the bulk of Col. Littler's estate, which is said to amount to nearly $1,000,000. Provision is made for the payment of the net income to relatives and other beneficiaries until the death of the longest lived of the beneficiaries, when the entire trust estate is to become immediately available for founding and maintaining a new hospital. Twenty-five per cent. of the value of the property may be used in purchasing grounds, erecting buildings, and equipping the institution, and the annual income of the remainder of the estate is to be used in maintaining the hospital.

Nurses at the Cook County (Illinois) Hospital.—The hospital committee of the county board recently submitted to the board a report of recommendations for the improvement of the county hospital service. The report advises an increase in the number of nurses to 200, and the establishment of a training school for nurses. It also says the city of Chicago should assume care of all contagious and alcoholic cases.

California Northern District Medical Society.—At the seventeenth annual meeting of this organization, held in Marysville on November 12, the following officers were elected for the ensuing year: *President*, Dr. John Jones of Nevada City; *Vice-Presidents*, Dr. H. S. Tickwell of Nevada City, Dr. F. R. Fairchild of Woodland, and Dr. J. H. Barr of Marysville; *Secretary*, Dr. J. W. James of Sacramento; *Treasurer*, Dr. O. Stansbury of Chico.

Hardin County (Ky.) Medical Society.—Officers as follows were elected at the meeting of this society held in Elizabethtown on November 16: *President*, Dr. C. W. Rogers; *Vice-President*, Dr. John Glasscock; *Secretary*, Dr. J. M. English.

Southern Illinois Medical Society.—At the thirty-third annual meeting of this organization held in McLeansboro on November 8 the election of officers resulted as follows: *President*, Dr. J. W. Hamilton of Mt. Vernon; *Vice-Presidents*, Dr. G. R. Rainey of Salem and Dr. O. B. Ormsbee of Murphysboro; *Secretary*, Dr. E. E. Tyke of Centralia; *Assistant Secretary*, Dr. T. M. Adderhold of Zeigler; *Treasurer*, Dr. A. T. Telford of Olney.

Rockingham County (N. H.) Medical Society.—The following were elected as officers at the meeting of this society held in Portsmouth on November 14: *President*, Dr. John J. Berry of Portsmouth; *Vice-President*, Dr. A. M. Mitchel of Epping; *Secretary*, Dr. Walter Tuttle of Exeter; *Treasurer*, Dr. Alice M. Chesley of Exeter.

Black Hills (S. D.) Medical Association.—Officers as follows were elected at the annual meeting of this society held in Deadwood on November 12: *President*, Dr. W. G. Smith of Sturgis; *Vice-President*, Dr. A. G. Allen of Deadwood; *Secretary*, Dr. Felix Ashcroft of Deadwood; *Treasurer*, Dr. F. S. Howe of Deadwood.

In Memory of the Late Dr. Francis H. Markoe.—At the meeting of the Medical Association of the Greater City of New York the following report was adopted relative to the death of the late Dr. Francis H. Markoe: To the enumeration of the many honors and distinctions so freely given to, and so richly deserved by Doctor Markoe, one would wish to add a more personal note; to speak of the charm of his personality, of the gentleness and kindliness of his nature, of his high ideals and standards. To his assistants and pupils he was ever an example of the enthusiastic and untiring worker, of the seeker after truth, of the kindly adviser. To his patients he gave, with his rare technical skill and wise coun-

sel, an unselfish devotion and a most helpful sympathy. Most impressive were the last weeks of Doctor Markoe's life. From many men we may learn how to live, but few teach us how to die. This preeminently Doctor Markoe did. In his example of patience and fortitude in suffering, and of the separableness of the spirit from the body, of the soul half from the mortal half, he rendered to each and to all of us the highest service. (Signed.)

FRANCIS P. KINNICUTT,
CHARLES T. POORE,
FRANK HARTLEY,
Committee.

In Memory of the Late Dr. Richard H. Derby.—The following resolution was adopted at a meeting of the Medical Association of the Greater City of New York held on November 18, 1907: *Whereas*, Death has removed an honored member from our midst; be it *Resolved*, That the heartfelt sympathy of the Fellows of this Association be extended to the bereaved family, and that a copy of this minute be sent to them; also *Resolved*, That a copy of these resolutions be sent to the MEDICAL RECORD and the *New York Medical Journal*. (Signed.)

C. COLE BRADLEY,
R. O. BORN,
W. B. MARPLE,
Committee.

Obituary Notes.—Dr. WILLIAM NATHAN BELCHER of Brooklyn died suddenly of pneumonia on November 20, in his forty-fourth year. He was a graduate of the Long Island College Hospital and had practised in Brooklyn for about twenty years. He was connected with the Seney and Long Island College Hospitals.

Dr. HUGH T. MURRAY of Washington, D. C., died suddenly on November 21, at the age of sixty years. He was a native of Culpepper county, Va., and was educated in Georgetown University, Manhattan College, and the Baltimore College of Medicine. For eighteen years he had been house physician of the Arlington Hotel.

Dr. D. D. STEVENS of this city died suddenly of heart disease on November 19. He was visiting physician to the Hahnemann and Metropolitan Hospitals.

Dr. SAMUEL HOUSTON of Washington, D. C., died on November 17, at the age of sixty-five years. He was a native of Lancaster, Pa., and for twenty-five years had been connected with the medical bureau of the Pension Office, of which for many years he was chief medical referee.

Dr. CHARLES N. THAYER, formerly of Cape Cod, Mass., died on November 16, at the home of his son, in Fairhaven, at the age of seventy-nine years. He was born in Attleboro and had practised in Cape Cod for over thirty years. He retired from active practice about ten years ago and since then had resided in Fairhaven.

Dr. D. W. HARRIS of Dallas, Tex., died on November 12 at the age of seventy-eight years. Dr. Harris was a native of Indiana but had practised in Texas for over thirty years. Some years ago advancing age compelled him to retire from active work.

Dr. J. F. GRAHAM of Hot Springs, Ark., died on November 17 of heart disease, at the age of fifty-six years. He was a native of Alabama and had practised for a time in Arkadelphia before coming to Hot Springs about nine years ago.

Dr. W. W. ESSICK of St. Louis, Mo., was instantly killed in a railway accident in Murphysboro on November 15. He was a member of the faculty of the St. Louis College of Physicians and Surgeons and was surgeon for the Mobile and Ohio railroads.

Dr. S. G. GLOVER, formerly of Arlington, Neb., died in San Diego, Cal., on November 14, of heart disease, at the age of seventy-two years. He had been a resident of Arlington since 1869.

Dr. GEORGE F. WOODWARD of Morrisville, Vt., died on November 11, of pneumonia, at the age of fifty-four years. Dr. Woodward was born in Danville and began practice in Morrisville over thirty years ago.

Dr. GEORGE E. ALSOP of Newport News, Va., died on November 10 at the age of sixty-eight years, after a lingering illness. Dr. Alsop was born in Spottsylvania county and lived in Fredericksburg until twenty-four years ago, when he removed to Newport News. He had retired from practice several years ago.

Dr. WILLIAM F. HELD of East Pepperell, Mass., died on November 13 at the age of sixty-four years, after a long illness. Dr. Held was born in Boston and was graduated in medicine from Dartmouth College. After practising for a time at Newport, Me., he removed to Pepperell in 1888.

Dr. HARRY P. JACKSON, formerly of Detroit, died on November 11, in Simcoe, Ont., at the age of forty-five years, after a long illness. He was a graduate of the University of Toronto and the University of Edinburgh, and practised in Detroit for several years before ill health compelled his retirement.

Dr. J. C. GATCHELL died at Lampeter, Pa., on November 17 at the age of sixty-eight years. He was graduated from Jefferson Medical College in the class of 1860.

Dr. ALFRED WHELEN of Philadelphia died at Naples, Italy, on November 18, at the age of fifty-four years. He was graduated from the medical department of the University of Pennsylvania in the class of 1874.

Dr. JABEZ PERKINS of Owosso, Mich., died on November 6, at the age of eighty-seven years. Dr. Perkins was born in Defiance, O., and was graduated from Wesleyan and Western Reserve Universities. He began practice in Springville, Mich., and was elected to the State Legislature from that place. In 1860 he removed to Owosso, and from 1863 to 1865 served as cavalry surgeon in the Civil War.

Dr. J. H. HARRIS of Rome Ga., died on November 3, at the age of sixty-nine years. Dr. Harris had been a resident of Rome for about eight years.

Dr. J. W. WHITE of Lancaster, S. C., died in Spencer, N. C., on November 6, after a lingering illness. For many years he was a resident of Lancaster, but about a year ago failing health compelled him to give up active work and retire to Spencer.

Dr. W. L. DOWNING of Iowa City, Ia., died in Chicago on November 2, at the age of forty-five years. Dr. Downing was a native of Daytonville, and was graduated from Rush Medical College in 1885. He had practised in Nebraska and also in Minneapolis. For some years he had been retired from active practice.

Dr. J. W. WINN of Plattsburg, Mo., died on November 5 at St. Joseph's Hospital in Kansas City, at the age of forty-eight years.

Dr. JOHN T. BELL of Independence, Cal., died on November 4 of pneumonia at the age of twenty-eight years. Dr. Bell was a native of Nebraska, and was graduated from the University of Southern California Medical School in the class of 1905.

Correspondence.

BACK TO AN OLD IDEA.

LAWSON TAIT AND HIS WORK.

To the Editor of the Medical Record:

Sir:—Probably in the minds of many who read the scholarly and suggestive address of Dr. Morris at the last meeting of the Association of Obstetricians and Gynecologists there will not be lodged a full appreciation of the real virtue of the operative work of Mr. Lawson Tait—the famous "surgical juggler" of the last century.

No surgeon ever lived who condemned more the presence and retention in the peritoneal cavity of pus and other filth, including blood clot, than did Mr. Tait, nor made more determined and persistent effort for their removal. Undoubtedly he believed that by sponging and copious irrigation this end could be attained, to be followed by drainage to provide for the escape of future accumulations. In relation to him the word "persistent" should be taken in a somewhat paradoxical sense. It was a skillful but *rapid* persistence during which there was not a moment's intermission from start to finish. Like a bullet from the rifle in the hands of an expert marksman, there was no wavering in design or execution, no curve, eccentric, nor *ricochet*—the bull's eye was reached by a "royal line," inspired in the cerebration of the man of genius behind the gun, but all the details were thorough and complete.

I repeatedly saw him remove bad pus tubes, cleanse the peritoneal cavity, drain, and close the incision within ten minutes, and on one occasion do a Porro operation, removing a living child, in the same time. His manipulations were "lightning-like," but not always the gentlest. In the latter respect he is surpassed by Joseph Price and perhaps Dr. Morris, but my impression is that they are a trifle slower in operating.

Mr. Tait anticipated the depressing effects of trauma and anesthetics, his rapid dexterity minimized these effects almost to the vanishing point. The theory of phagocytosis had just then been announced. He laughed at it, but kept on with his rapid, clean, and drainage operations, which brought splendid results without reference to any subtle and, as yet, unproved explanation. Were he alive to-day I fancy that his practice and thoughts would be the same, notwithstanding Bier, Wright, and Metchnikoff.

Mr. Tait was good in anatomy, but he "puttered" not over its exquisite detail and refinement. He humorously but enthusiastically endorsed a remark he had heard was made by Warren Stone of New Orleans, who declared that "a good surgeon pays little attention to layers when operating for hernia, but knows gut when he sees it, and therefore cuts for gut until he finds it, for thus can the operation be made short and no less safe." Likewise in his abdominal operations, time was saved by employing the simplest and fewest details in technique, but that these were sufficient, his brilliant results fully demonstrated. Long lines of complicated suturing appealed not to him, but, as Dr. Morris has well said, the patient's vitality appealed more, and the suturing provided a nice adjustment for the latter to the success of the operation. Interrupted sutures were placed quickly at reasonable intervals, and interfered little with the nutrition of the wound edges. "Surgical foolishness," with its time loss and perhaps disaster, was rigidly eschewed.

Mr. Tait was a good naturalist. He closely studied the habits, temperaments, and endurance of the lower animals, for which he had a great affection, and, although bitterly opposed to vivisection, he was often known to compare their characteristics with those of the human being. These comparisons were useful in surgical work, and to the fullest extent possible he realized their import in this relation. Moreover, he was a fine mechanic; could shoe a horse with nicety and dispatch, and splice a rope, or tie and untie a complicated knot as well as an average sailor. Machinery had an especial charm for him, and he never lost an opportunity to investigate any useful mechanical device which came in his way; hence his adoption of the Staffordshire knot which, instead of "strangling two thieves," was made in his hands to constrict the two divisions of an ovarian pedicle with celerity and security.

Mr. Tait almost defied unexpected complications during an operation, for they yielded quickly to his resourceful genius. Said Mr. Marsh—a fine surgeon on the staff of Queen's College Hospital at Birmingham—"the difference is that Tait, when faced by complications, finds a ready and safe escape without apparent deliberation while we must stop and consider." Mr. Tait himself said, "deliberate during your work, but do this quickly," for in such circumstances oftentimes "he who hesitates is lost." Here, also, the word "deliberate" discovers an abstruse meaning which represents a rapid-fire discharge of thought-cell metabolism only to be found in the magazine of a great intellectual genius. In operating on a large abdominal tumor with assured complications, which had been blinked at by several noted surgeons in London and Edinburgh, Mr. Tait immediately dug through to its pedicle, secured this, and enucleated the enormous mass out of dense and widespread adhesions from below upwards with amazing rapidity, and saved the patient. He always paid great respect to the omentum, which in this case was mutilated, and bled copiously. It was sandwiched between two broad metal plates, the upper one being heated by the thermocautery; this promptly arrested the hemorrhage without ligatures.

Multiplied arrangements for the operation, entailing time loss and confusion before, during, and after its performance were avoided habitually. The patient was operated upon in her room and lifted from a warm bed to a table equally warm which stood near; consequently, there was no risk of chilling, and but one transference. The table was a large ironing board, supported on trusses. A small stand on which could rest two little pans containing the ligatures, needles, and instruments, of which there were not more than half a dozen for the most radical operation, was placed to the right of the operator. Curved needles, needle-holders, and retractors were conspicuous by their absence. Two straight needles, large and small, threaded with silk, did all the sewing. Briareus stood abashed, a juggler could work with a single pair! Mr. Tait and one assistant donned plain white aprons. Having cleaned their nails, they rinsed their hands with turpentine spirit, washed this off with soap and water followed by plain tap water. Not a word was spoken during the operation, save an exceptional reprimand to a nurse for stupidity or inattention. Instruction was given after the patient was returned to bed, and not then unless leisure wisely afforded the opportunity. The stay in the room was very brief, but I often saw the patient awake with almost perfect intelligence—no hypodermics, no transfusion, no stimulating enemas. Everything was done within the abdominal cavity with the patient in a horizontal position, trauma was minimized, and the entire organism but slightly disturbed in its functions by the careful administration of the small amount of anesthetic used. I wonder what Mr. Tait would say if ushered into some of our modern operating rooms!

It will be conceded that it was the presence and harmonious cooperation of many essential qualities that evolved the perfect surgical species of the divine afflatus in the makeup of this remarkable man. He knew little of the asserted rôle of opsonins, phagocytes, *et hoc genus omne* as protective agencies of the economy against the destructive effects of bacteria, but that he would have placed any reliance in these to neutralize even the smallest amount of pus left either designedly or inadvertently during an operation cannot be claimed. He was the stentorian apostle of "free and unlimited" drainage, albeit his results, in part, may be explained now on other grounds; but surely these are insignificant and negligible factors when others are considered which about eliminate their importance, notwithstanding his drainage may have been imperfect and in some degree harmful. Only in his latter years would he have anything to do with gauze for any purpose whatever, but I understand he finally employed iodoform gauze somewhat after the method of Mikulicz, where much oozing was probable from torn adhesions; but rubber and glass tubes were his articles of faith, and he never discarded them. Were it possible, he never would have closed an abdomen with any pus inside, which he must nevertheless have suspected happened in some cases that speedily and completely recovered. But he vouchsafed no explanation—his faith in drainage was never impaired, much less abandoned.

I may be permitted to add that Lawson Tait was a kind-hearted and generous man. He was plain and blunt, without toleration of snobbery and morbid sentimentalism; he had no time for these. His friendships were strong and lasting, but when aroused he was a vicious opponent who never asked or cried for quarter. He lived for the benefit of humanity and a profession which I apprehend has done him scant justice and has lent too ready an ear to the discredited tale of two women, one of whom was discharged from his service for gross insubordination, and chose a method of revenge that may recoil upon any surgeon who enforces his authority in similar circumstances.

Let us "back to an old idea" and make bright the record of as deserving a hero as ever stood in the forefront of our profession. The watchman said: "The morning cometh * * * turn ye. Come."

Dallas, Texas. Henry K. Leake, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL SOCIETY OF MEDICINE; THE SECTIONS AT WORK—SLEEPING SICKNESS—A NEW DIPLOMA—MEDICAL INSPECTION OF SCHOOL CHILDREN.

LONDON, November 8, 1907.

THE Medical Section of the Royal Society of Medicine began its work with a discussion on the complications of pneumonia, opened by Dr. Hector Mackenzie on the 22d ult. and continued on November 5. Regarding pneumonia as a defensive process against acute bacteriemia, he remarked that where antibacterial substances abounded, as in the young and adolescent, recovery was usual, but where they were deficient, as in infancy and after middle age, death was common. The pneumococcus was almost constant in the blood through which it reached distant organs and there set up inflammatory changes. Toxemia was the cause of the graver constitutional symptoms and so far we had not produced an antitoxic serum. Animals could be immunized, but their serum, though antibacterial, was not antitoxic—so the serum treatment of pneumonia and its complications had hitherto been proved unsatisfactory. Of the complications, pleurisy was most common, empyema the most important. In gout, of ten cases of empyema the cause was the pneumococcus. When the onset was acute the effusion was almost certainly pneumococcic and purulent; when gradual it was most likely serous and tuberculous. Gangrene of the lung was rare, but almost always a fatal complication. Abscess also was rare and seldom recognized during life. Pericarditis was, next to pleurisy, the most frequent complication. Endocarditis was not so common, although one out of every four cases of the ulcerative form was due to the pneumococcus. Peritonitis was rare after pneumonia; when it occurred the microbe probably reached the serous membrane through the stomach or intestines. Herpes, otitis media, meningitis, cerebral abscess, neuritis, transitory hemiplegia, arthritis, pseudomembranous inflammation of mucous membranes, croupous colitis, thrombosis, tonsillitis, subcutaneous abscesses, cellulitis, conjunctivitis, corneal ulcer, hypopyon, nephritis, all these were mentioned by Dr. Hector Mackenzie as among the rarer complications of pneumonia, and on most of them he commented from a diagnostic or clinical point of view. Often, he observed, several complications coexisted, greatly aggravating the danger, as pointing to a pneumococcal bacteriemia, which in a severe form was invariably fatal. As to the effects of treatment by serums and vaccines, it was necessary to bear in mind the varying mortality at different ages, especially the fact that most young subjects recovered under ordinary treatment, while the old and infants generally died.

Mr. A. G. Foulerton said that in discussing the vaccine treatment it was necessary to distinguish between the early and late stages, for it was only in the late stage that a vaccine was indicated. He had found 75 per cent. of empyema cases in adults were streptococcal and only 25 per cent. pneumococcal, but in children over 80 per cent. pneumococcal. In some cases of pneumonia in old subjects and with slow resolution, he thought an antistreptococcal serum worth a trial. In acute cases the question was between a vaccine and an antiserum. During the first three or four days, *i.e.* in the negative phase, a vaccine was dangerous. He agreed that hitherto serum treatment had failed; of seven test cases at the Middlesex Hospital only two succeeded. The cause of the failure seemed to be that the antibodies disappeared very rapidly from horse's serum. Dr. Herringham produced a series of statistics from St. Bartholomew's Hospital and commented upon them. Similar figures from the Middlesex were presented by Dr. Pasteur, who related two cases of pneumonia complicated by dilatation of the stomach and two of gangrene of the lung with recovery.

At the adjourned meeting on Tuesday last other statistics were brought forward from the London, King's, East London Children's, St. George's, St. Mary's, and Guy's Hospitals. An analysis of all these would be rather a full dose to inflict on general readers, and the figures will be easily obtainable a little later by all who may be especially interested. Dr. Hadley found that in nearly half the complicated cases certain conditions of a fatal kind had preceded, such as alcoholism, nephritis, and cardiovascular changes. In pericarditis there was little chance, unless the diagnosis was frank and the sac opened or aspirated. Chronic cases were most suitable for inoculation, but any protection conferred must be short, as one attack seemed to predispose to another.

Dr. Gossage found pneumonia as common under ten as over and the diagnosis more difficult under that age. Complications were more common in childhood and the mortality higher. Under one the rate was largely due to toxemia.

Dr. A. Latham found the knee-jerk sluggish or absent in only 30 out of 125 cases. One case treated with antipneumococcic serum was observed and rapidly recovered. In some treated with antidiphtheritic serum the temperature fell at once.

Dr. Caley said that in empyema the sooner operation was done the better the outlook both for recovery and for the duration of illness. Pericarditis was often associated with endocarditis. Only two cases of infective endocarditis were among 437. There was evidence of myocardial change in about a third of the cases. His figures also included a recovery with antipneumococcic serum.

Dr. S. West remarked that the pulse-respiration ratio was often more marked in convalescence than in the attack. Knee-jerks disappeared about the seventh or eighth day. The coccus which gave rise to lesions in different parts might not be identical with the one producing the pneumonia.

Dr. Tirard thought the fatality of complications less than sometimes thought, and he considered hemoptysis in pneumonia rather favorable.

Dr. Fawcett said of 15 cases with serous effusion at Guy's, only three required tapping.

Dr. B. Harris described two cases of slow pneumonia treated with a vaccine obtained from cultures of their own pneumococcus and a case of staphylococcus pneumonia with erysipelas with serum from the *Staph. alb.* from the patient, and said the organism should always be from the patient himself.

In the Section of Obstetrics and Gynecology, Drs. W. E. Dixon and F. E. Taylor gave an epidiascopic demonstration on the effect of placental extracts on the circulation. It resembled the effect of adrenalin, but caused a less rapid rise of blood pressure but a more prolonged rise and a less marked cardiac effect. In the pregnant uterus there was increased tonus of musculature and of rhythmic contractility, and so they suggested that the placenta produced a substance the liberation of which by contracting the uterus and the vessels might bring on normal labor.

Dr. A. Routh mentioned a case of his in which labor occurred during paraplegia, and induced Dr. Mott to suggest that at any rate in part the onset of labor might be due to metabolism of the pregnant uterus. Dr. Griffith objected to the view that labor was brought on by a placental substance because it increased uterine contraction, for there were many substances which increased contraction but were quite useless for the induction of labor. Dr. Longridge referred to a suggestion that had been made as to the effect of calcium in the blood, but as that was insoluble in alcohol it could not be present in the placental extracts employed in the experiments submitted to the Section.

The Neurological Section opened with an exhibition of most interesting cases, which scarcely lend themselves to brief description.

The Therapeutical Section began with the president's address—an account of the rather short life of the Society it supersedes. After this, Dr. Robert Hutchison discussed the scientific treatment of dyspepsia—perhaps I should say the dyspepsias, for he was emphatic on the necessity of accurate classification. His treatment is of the old-established kind and he did not trust much to ferments or electrotherapy.

The Surgical Section had so important an opening meeting that I must postpone my notice of it to my next, as space and time alike fail me.

Dr. Albert R. Cook, on the 18th ult., gave an address on sleeping sickness at the Society of Tropical Medicine and Hygiene. He said Greig's method of diagnosis was best—viz., puncture of the swollen cervical glands, so frequently met with. The gland juice usually showed the trypanosomes under a one-eighth objective, even in early stages. But occasionally they could not be found. In Uganda segregation was tried as far as possible, but the natives clung to their homes and did not believe that the kivn (tsetse fly) conveyed the disease. Clearing extensive areas around markets and landing places was a further plan of restricting the disease, and the circulation of instructions in the native languages and, most important of all perhaps was the enlisting of the active cooperation of the chiefs. Atoxyl was by far the most successful treatment that had been tried and its value was first shown by Dr. Thomas of Liverpool—a credit to English investigators, who were all along in the front rank of research in tropical medicine. Of late the frequency of injections of atoxyl had been increased. The effect in a bad case was at first magical. Even in a late case it powerfully influenced nutrition and the patient's death was more easy, for he died without the extreme emaciation and bed sores. The trypanosomes disappeared from the gland juice a few hours after injection, but there must be others—perhaps

immature or encysted—for sooner or later they reappeared. Thus the hope that a perfect treatment had been discovered is disappointed, but though atoxyl is not absolutely curative the relief it gives is of the greatest value. Experiments are being made as to whether some other arsenical compound may not prove effectual.

Professor Koch has permitted himself to be interviewed on board the ship in which he is returning from East Africa. Our newspapers are consequently giving us his opinions on sleeping sickness. I do not find in the reported interview anything new, but of course the interviewer took all his opinions as discoveries—and most of the statements are to be assigned to other observers. But the professor says he has found the blood of the crocodile is the chief food of the tsetse, which sucks it between the plates of the creature's hide. He will give a detailed account of this on his return. He could not destroy the crocodiles by poisoned meat, as the natives would be likely to eat it.

We are threatened with a new diploma. The two Royal Colleges have agreed to give certificates in tropical medicine to students of the London school. When the public health diploma was inaugurated I expected the example would be followed if it proved profitable. Why the certificate should be attainable only by students of the London School of Tropical Medicine is not quite clear. The Liverpool school is just as efficient. It is also to be confined to those who are qualified by one of the two colleges. Thus a graduate of any of the universities is not eligible for admission to the examination, although he has studied at the tropical school, unless he also holds a college diploma—which seems absurd. If any certificate were really desirable the tropical school itself should be ready to grant its own testimony that the person had gone through a course of study to the satisfaction of its staff.

It seems probable that the duty of inspecting school children may prove a more far-reaching one than has been supposed. If the children are to be carefully examined as to their physical and mental fitness for entering on school work, the examiners must be very numerous. It is, moreover, the intention of the Education Board to direct examinations on other occasions. It was thought at first that the medical officers of health might undertake this duty, but it would be scarcely possible for those in charge of a large district to do so, and it is suggested that the general practitioners residing near the schools are the proper persons for the work.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

JAPANESE RIVER FEVER AND SPOTTED FEVER OF MONTANA—MADURA FOOT IN THE PHILIPPINES—CHOLERA IN MANILA.

MANILA, P. I., October, 18, 1907.

THE regular monthly meeting of the Manila Medical Society took place October 14, at 8:30 P.M., at St. Paul's Hospital. Drs. Ashburn and Craig of the Army Board on Tropical Diseases read a paper entitled "A Comparative Study of Tsutsugamushi Disease and Spotted Fever of Montana." The authors were of the opinion that while the diseases presented many points of resemblance, yet the points of difference were so marked and clear-cut that there seemed to be but little question that the two were entirely separate and distinct. In the first place, Tsutsugamushi disease invariably starts from the bite of a mite, which produces a small papule, which later becomes a pustule, and the lymph glands of the area involved show marked signs of enlargement; whereas, with spotted fever, the point of entrance of infection is scarcely ever so clearly defined. While the distribution of the rash, on its appearance, is about the same as that of spotted fever, yet the latter was much more pronounced. However, this may have been more apparent than real, owing to the darker skin of the Japanese, making the rash appear less prominent. In Japan the disease only occurs in low-lying valleys which are subject to regular inundations, and is practically confined to those persons who gather mulberries in the region referred to, after the floods have subsided. Owing to the lack of microscopical apparatus, they were unable to make any satisfactory distinctions by microscopical work.

Dr. Musgrave exhibited another case of what he regarded as madura foot, but the laboratory report has not yet been completed. He also stated that the report of the first case observed in the Philippine Islands would shortly be published, the diagnosis having been positively confirmed by producing the disease in a monkey.

Another clinical case was also presented by Dr. Musgrave, as one which might be regarded as gangosa. After an examination by a number of those present, the consensus of opinion seemed to be that the case was probably an atypical form of syphilis. The case presented no particular symptoms, with the exception of the perforation of the hard palate with some involvement of the nasal septum.

The quarterly report of the Bureau of Health for the quarter ended September 30, which has just been issued, makes the following statement with regard to cholera: "The death rate in Manila has to some extent been augmented by Asiatic cholera, which has probably been present since the early part of the quarter, at which time a few cases of gastrointestinal disorders closely resembling cholera were reported, though the suspicions were not confirmed by laboratory examination. It was not until the last of July that the presence of cholera in Manila was actually confirmed by laboratory diagnosis. Since that time the disease has been more or less prevalent, and during the last week of the quarter averaged about three cases daily. The disease was not confined to any particular locality, as the cases were found widely separated, with no apparent relation between them. If there had been a central focus the matter of suppression would have been simplified. Painstaking efforts were made to trace every case and connect it with some other case, and while such efforts were not entirely successful, they led to the conclusion that the most probable source of the disease was the unhealthy and filthy practice of the market gardeners of fertilizing their products with human excreta. The Secret Service was asked to investigate the matter and it was not long before convictions were secured, thus substantiating the conclusions which had been reached by the Bureau."

Progress of Medical Science.

Boston Medical and Surgical Journal, November 14, 1907.

Hemorrhage Following Tonsillotomy.—The chief interest in the two cases reported by E. A. Crockett lies in the fact that the bleeding followed removal of the tonsils with the cold wire snare, a method commonly considered as free from this danger. Case 1 was that of a boy of eight years. The hemorrhage began three hours after operation in hospital, the boy being kept quiet in bed, and was checked by, first, digital, and later instrumental pressure, the clamp being kept on eight hours. Hypodermoclysis and rectal saline infusions were resorted to. The throat was quite septic for some time, and it was six weeks before the boy could resume attendance at school. Case 2 was that of a twelve-year-old girl. Bleeding came on in four hours, but stopped of its own accord. Recovery was complete in eight days. Crockett is not disposed to abandon the use of the snare with a No. 5 steel wire, but insists that all tonsillotomy cases should be within easy call of the operator for the first twenty-four hours after operation.

An Abdominal Lesion Simulating Cancer.—B. B. Cates reports the case of a man of fifty years of age attacked with sharp pain in the left lower quadrant of the abdomen. There was over this area some sense of resistance and great tenderness on deep pressure. Four inches from the anus there seemed to be a slight bulging of the bowel on the anterior surface. Pressure against it caused pain. Exploratory incision was made parallel to and above Poupart's ligament. The pelvic cavity was found full of small bowel, and so adherent to everything that the operator abandoned the first incision for the time being, and opened the abdomen in the middle line, in order that he might have a better field for operation. The small bowels filled the pelvis and hid the sigmoid and rectum from view. In sponging the adhesions apart, he broke into a pocket of half a pint of foul-smelling pus on the left side of the sigmoid and rectum. While the pus had a foul fecal odor, there were no fecal concretions, nor did he find any communication with the bowel. He then placed the patient in the reversed Trendelenburg position, placed gauze around the bowels, so as not to infect the general peritoneal cavity, introduced cigarette drains from both wounds down to the pocket of pus, and closed the wounds down to the drains. Recovery was without incident. The only cause for the lesion was suggested by a statement of the patient that he was induced by some friends to eat sand for constipation. The sand might have lodged in some of the folds or pockets of mucous membrane of the sigmoid or rectum and caused ulceration, secondarily setting up suppuration around the gut.

New York Medical Journal, November 16, 1907.

Relief of Nutritional Disorders by Developing the Abdominal Supports.—J. M. Taylor declares that many

forms of gastrointestinal disease, especially putrefactions, gouty phenomena, over- and undernutrition, are caused in part, if not wholly, by displacements of the abdominal organ. Defective elaboration is not seldom due to errors in hydraulics. The author aims to establish the efficacy of improving power and mobility in the supporting structures of the abdomen, thus enhancing their capacity to exert needed pressures on and supporting reactions in the viscera. This action, he says, is duplex upon (1) the caliber of the organs directly, and (2) upon the regulative functions of the blood-vessels. We should endeavor to arouse the vasomotor integrity, reflexly through the paravertebral tissues innervated by the posterior primary divisions of the cord; (2) by stretching the contracted structures, and (3) by motor education, that is, the education of the voluntary muscles concerned, in supporting and maintaining in their natural and necessary positions the large, hollow viscera. Surgical procedures for the replacement of prolapsed viscera do not give entire satisfactory or lasting results. First of all, we must endeavor to bring about a proper contour of the body. A well-proportioned trunk implies a fairly straight spine, showing only the normal curves. The pelvis, designed to contain and protect the lower hollow viscera, should be carried practically on a level. This permits greater freedom of the action of the thighs and encourages a better bodily poise. All this leads up to functional competency. The key to a normal posture resides in a correct attitude of the thorax. The entire body will assume natural attitudes in almost any position, standing or sitting, provided the ribs are maintained in their normal erectness, that is, at the top of their upward excursus. Then, also, a most important factor in normal abdominal support follows, viz., the lower ribs remain well above the pelvis. A slouching position, inducing a relaxation of the erector spinæ and other muscles, invites a sagging down of the viscera, which thus not only rest upon the pelvis unduly, but the impending weight of the upper structures bears hurtfully upon those within the pelvis and encourages disuse of the lower supports. This pressure long continued makes for a variety of derangements, among which are congestions, passive hyperemia, etc., etc. As illustration, note the fact that even rebellious constipation is often cured by remedying this one defect alone.

Amebic Dysentery (Chronic) a Surgical Disease.—J. M. Holt defines a chronic case in this connection as one in which the *Amœba coli* still persists in the stools after the patient has faithfully tried colon irrigations for the space of one year. If, under these conditions, the sigmoidoscope reveals no ulcers, we should advise an appendicostomy or colostomy. The author advises the plan advocated by Weir of flushing the colon from above through the appendix, and reports three cases. He advocates the gridiron opening, as the wound is not completely closed at the time of operation. The appendix is freed from its mesentery, its vessels carefully spared for future nourishment to the parts, is then brought up through the incision until its base and the adjacent cecal surface are flush with the parietal peritoneum, where two or more anchor sutures hold it *in situ*. Other anchor sutures are introduced at the skin level of the wound, and the entire wound closed about the appendix, the tip of which is left protruding through the sutured wound. After forty-eight hours, when adhesions have formed, the appendix tip is opened. By this time the peritoneal cavity is effectually sealed from possible infection. In one of the author's cases the appendix was so slender that, after forty-eight hours, when the extraabdominal appendicular tip was clipped off, the caliber of the appendix was so small that the finest silver probe could not be introduced, and it was only after the second or third dressing that introduction was finally accomplished. Gentle manipulation only was practised, as the abdominal wound was of so recent origin.

Microscopic Traumatic Gangrene.—According to J. W. Beveridge, this process explains some of the unexpected and mysterious cases of wound infection. In many tedious abdominal cases the layers of adipose tissue which have been separated by the incision lie exposed for two hours or more. The capillaries and the lymphatics are constantly being drained; fat cells and the connective tissue cells that lie in the immediate path of the knife break down and disintegrate; the small amount of circulation which is present in adipose tissue has been severely taxed. A condition is at once created so minute as to be microscopic in its character, but nevertheless present, wherein a continuation of breaking down of the fat cells and the connective tissue cells continues for a long period. Later on the usual pus appears, and this is due to the condition created by the surgeon in causing an incision trauma wherein the usual surfaces were either held by retractors for too long a period, or the drainage of the lymphatics and capillaries was permitted to cover a time that was inadequate to the recovery of the minute cellular circulation. The result is a continuous breakdown of the cells of the adipose tissue, *i.e.* traumatic microscopic gangrene, and, on their breakdown, a pathological formation of sterile pus ensues. Experiences from various hospitals and records of private cases have shown that in major operations lasting over two hours from the time of the primary incision till final wound closure pus is nearly always found under the line of incision. Apparently it takes about two hours or a little over for the adipose tissue to receive damage severe enough to cause a minute gangrene to set in. This pathological change does not take place in the muscular tissues, as the blood supply and nerve supply is much stronger. The cause of the slight rise in temperature is a toxin formed from the dead fat cells, connective tissue cells, and epithelial cells, an action the same as that of a toxin from dead bacilli.

A New Treatment of Diabetes.—S. G. Soules reports one case, that of a physician of sixty-two years of age, with 10 per cent. of sugar. The remedies named below were given for some two years without apparent effect, but in the third year results became evident. Capsicum annuum pulverized and given in doses of grs. xxx, t. i. d. (preferably in capsules) reduced the sugar about one half, and its effect in this regard lasted for several weeks. Grindelia robusta did nearly the same. Dose ʒi, t. i. d. fluid extract saw palmetto in doses ʒii, t. i. d., about the same. However, these agents seem to be of very little consequence compared to chimaphila, which in doses of ʒii fluid extract at each meal time taken in a glass of milk, well stirred immediately before its ingestion, proved a veritable nugget of the purest gold from the mines of therapeutics, and banished the sugar completely in twenty-three days exactly. It, however, returned in ten days, after eating a large quantity of starchy food and reducing the remedy to ʒi of the fluid extract. The author states that he has found less than ʒii of the fluid extract of chimaphila insufficient to eliminate all the sugar from the urine. Under this dose it disappeared in less than a month. As soon as the sugar disappears, arsenic in small doses should be added to the treatment and gradually increased to a medium dose. This should be continued for two months at least, and if the sugar does not appear in that time, starchy diet should be resumed very gradually. If the sugar should at any time appear, starchy diet should be dropped at once, and the antidiabetic diet resumed, together with a full dose of the medicine, which should be reduced one-half at the time of the commencement of a starchy diet. After a few weeks (two or three) starchy diet may be cautiously tried again, and so on, until the patient is cured.

Journal of the American Medical Association, November 23, 1907.

The Ferments of Milk.—R. G. Freeman gives a résumé of the facts known concerning the effects of temperature on the biological properties of milk and those in regard to the ferments it contains, summarizing especially the results of the studies of Spulverini, Hippæus, and others on the subject. He finds from the more recent observations that, in order to preserve the normal ferments of milk in pasteurization, a temperature not exceeding 140° F. should be used. Such a temperature will scarcely alter the chemical composition, will not destroy the ferments, and the most recent observations would seem to show that if kept up for from 30 to 40 minutes it will destroy tubercle bacilli in milk, unless they are enveloped in thick mucopurulent material, or are protected by a film formed on the surface of the milk. Such conditions are not likely to exist in sealed bottles of properly handled milk from healthy cows.

Flatfoot.—E. H. Ochsner says this is a much more common and disabling deformity than is commonly supposed. It is not so apt to be caused by weakness of special muscles or parts as by general muscular weakness; and a very important factor in the production of flatfoot, in Ochsner's opinion, is the lack of correlation between the strength of the muscles and tendons and the weight of the body that occurs about puberty. In fact, he considers that the symptoms in most cases appear about this time and are caused by the changes then taking place, and this is the time when treatment is most effective. Of course, there are other factors in special cases, such as trauma, ill-fitting shoes, and occupation demanding continuous standing, and he also thinks the habit of toeing out favors the production of flatfoot. The condition is very often incorrectly diagnosed as rheumatism or neuralgia. In the treatment of

the condition, besides the use of regulated exercises, correction of faulty footwear, attention to general hygienic measures, etc., he calls special attention to the method employed by him of using adhesive plaster strapping, which was briefly alluded to by him in a paper read before the Illinois Medical Society six years ago. The straps are so placed as to supinate and abduct the foot, support the arch, and relax the muscles, thus securing rest and relieving pain, as well as furnishing massage to the extremity with every step, thus favoring regeneration of the muscles and ligaments. The application of the straps is described and illustrated. He has used this method for nine years, and it has seldom failed.

The Abdominal Belt Treatment of Pertussis.—T. W. Kilmer reports the result from letters of inquiry in regard to the value of the abdominal belt in whooping-cough, sent out to pediatrists in various parts of the United States, to which forty-five replies, covering over 550 cases, were received. The results are given in tabulated form, and show 484 out of 556 patients improved (nearly 88 per cent.), and only 72 showing no improvement. Most of the replies were of interest on account of their testimony to the good effects of the belt in the prevention of vomiting. This was the chief benefit claimed by him, and he is pleased to have the support of these additional witnesses. A large number of cases with complications were reported in the answers, but he finds by further inquiry that in most cases these existed before the adoption of the belt treatment. Drugs were also used in many of the cases, but the effect of the belt on the vomiting was marked, independent of the medication.

Renal and Biliary Calculi.—A. M. Pond remarks that there is a striking similarity in the formation, symptoms and resulting pathological conditions in calculous disease of the kidneys and that of the biliary tract. This fact makes a diagnosis sometimes exceedingly difficult when the right kidney is at fault, owing to the relational anatomy being so intimate and the nerve supply of the viscera involved so complex and extensive. He reviews the conditions of calculous formation, showing that the same general laws apply in both cases, analyzes the symptoms and pathological conditions, and points out how confusion and diagnostic difficulties may arise. His findings are recapitulated as follows: (1) Kidney stone is found usually in the pelvis of the kidney and the frequency of the right kidney is 119 to 68 in the left. (2) Ureteral stone is found in 40.7 per cent. of the cases at the upper flexure of the psoas flexure. (3) More than half the gallstones found in the common duct are located in the ampulla of Vater. (4) Both of these regions are connected with the pneumogastric distribution through the renal plexus, and this explains the nausea and vomiting during the acute seizures. (5) The pelvis of the kidney, the usual site of kidney stone; the psoas flexure of the ureter, the location of 40.7 per cent. of all ureteral stone; the fundus of the gall-bladder, the site of gallstone in more than half of all cases; the descending common duct, the distal portion of the duct of Wirsung; the ampulla of Vater, which is the location of 57 per cent. of all common duct stone; and the descending portion of the duodenum are all contained in a space covered by a silver dollar, between the ninth rib and the umbilicus. (6) The pain of a kidney or ureteral stone does not always radiate to the groin or bladder, but is sometimes more evident about or above the umbilicus. It is clear, therefore, that disturbance of any of these structures may cause pathological conditions in the adjacent ones. The article is illustrated.

Pulmonary Gangrene in Early Life.—D. J. M. Miller describes the etiology, symptomatology, and physical signs of gangrene of the lung as it occurs in young children, and reports a case. The condition follows measles in children more often than any other acute condition, but more cases are due to aspiration than is generally supposed. Weakly marasmic infants may readily aspirate, unnoticed, small particles of food; septic materials from necrotic processes in the mouth or pharynx, and foreign bodies can also be taken into the lung. The association of otitis media with pulmonary gangrene in children was noticed by Guillemot in 1899; seven out of ten cases observed by him were of otitic origin. The diffuse form is most often observed in children, several centers of necrosis being usually present. The disease is generally unilateral, but both sides may be affected. The symptoms also differ from those commonly observed in the adult, children do not usually expectorate, and the characteristic fetor may be absent. Hemorrhages are common. The physical signs are not in themselves of special significance; it is the order of their evolution, taken in connection with the general symptoms, that is important. Localized signs of consolidation, gradually developing into those of a cavity, with marked fetor of breath and general hectic symptoms occurring in the course of pneumonia, particularly secondary pneumonia, warrant the diagnosis of gangrene. The condition, however, may be entirely latent, and this is more common in children than in adults. The diagnosis is often only a conjecture to be confirmed by autopsy. The prognosis is always grave, most cases ending fatally unless relieved by operation. Sometimes gradual improvement progressing to a cure occurs, but relapses are liable to happen. The treatment is the same in children as in adults, operation offering the only hope in most cases. In the case here reported, a child of two years, the symptoms were characteristic and the diagnosis hardly to be questioned, but the child made a good recovery. The exact seat of the gangrene, however, could not be determined, hence operation was deferred from time to time until the patient's condition had rendered it needless. The continuous open-air treatment employed in this case is worthy of note, and to it is largely attributed the final good result.

The Conservative Treatment of Middle-ear Disease.—S. Theobald deprecates too hasty resort to radical operative procedures without giving sufficient thought to other methods by which success can in many instances be attained. The points on which he lays special stress are: First, the patient should not be made wholly dependent on the surgeon for the carrying out of the treatment; he should be taught to treat himself to a reasonable extent. Second, in the treatment constitutional measures are almost, if not quite as important as local measures. Apart from the removal of nasal polypi, operative measures, he holds, are seldom called for in chronic middle-ear suppuration, unless there is evidence of mastoid involvement. Even curetting granulations and removal of tiny areas of carious bone are, he thinks, usually superfluous, as they tend to mend themselves when the discharge is brought under control. He advocates the use of antiseptic fluids instead of powders, and has found solutions of bichloride of mercury (1-8,000 to 1-4,000), and boracic acid in saturated solution, the most satisfactory. Syringing the ear with these as often as is necessary to control the suppuration, in chronic cases seldom more than once a day, in acute cases with abundant discharge somewhat oftener, is advised. Powders are only used by him in recent years in long-standing cases with extensive destruction of the drum, and then only after failure with the solutions. Any concurrent nasal disease or systemic condition on which the ear trouble may depend must, of course, be duly treated. That every patient can be cured by only these measures is not contended, but Theobald holds that many can, and that in others still the risk of serious complications can be reduced to a minimum. The cases he finds least amenable to the treatment are not those with extensive destruction of the drum head, but those in which the membrana vibrans is intact and the discharge escapes through a comparatively small perforation in the membrana flaccida. Even if the mastoid antrum is involved it does not necessarily follow that operation is inevitable. If drainage is free it not infrequently happens that the antral trouble disappears when the tympanic suppuration is controlled. In these cases he has found great benefit in the administration of liberal doses of sodium pyrophosphate, as previously recommended by him.

The Lancet, November 9, 1907.

A Contribution to the Analysis of the Mental Process in Criminal Acts.—After a general discussion of the subject, T. C. Shaw states his position in the matter in the following words: In criminal acts the mental process introduces no fresh element. If in the insane a criminal act occurs the only fresh element is the false motive, which, however, acts in the same way as does a normal one. The constituents of the voluntary process are the same in kind as in normal minds: motive, desire, feeling, end in view, action on presentation (otherwise impulse), action upon reflection—all may occur in the same way as in normal thought processes. The only difference is not in the mechanism of the elements, but in their nature; thus the motive may be a wrong one (*i.e.* against the accepted obligations of society) or the element of feeling may be an irregular one due to structural conditions, but we must remember that just as social systems are temporary—are themselves in a mutable condition—so are mental processes. We have not in the one the perfection of organization, though such as it is it acts in accordance with its construction; neither have we in the other any but a temporary adaptation, though such as it is it acts in the way we should expect it to do, and in this expectation we are rarely disappointed.

Cancer Infection and Cancer Recurrence; A Danger to Avoid in Cancer Operations.—This topic is discussed by C. Ryall, who in a freely illustrated paper summarizes the details of twenty-five cases. He believes that carcinoma is a highly infectious disease. Proof of its communicability from one person to another may be wanting, but when a person once becomes the subject of the malady there is not only the liability of its spreading by a well-defined infective process, but also in those cases in which the surgeon attempts to remove the disease there is a risk of reinfecting the patient from the growth, the removal of which is undertaken. Cancerous infection of wounds is of frequent occurrence, and its occurrence during operation is responsible for the occurrence of the malignant nodules in the site of the operation wound. Suture-hole infection is especially common. Cancer infection is also responsible for diffuse recurrent carcinoma taking place in operation wounds, and especially in those cases where a general flare-up occurs after interference with a cancer growth. In fact, Ryall regards cancer infection as the reason why chronic carcinomatous growths so frequently run a very acute course after attempted operations. In the parent growth the cells are, more or less, encapsuled in fibrous tissue, but some cells escape during operation and find a resting place in the wound, which is comparatively unprepared to meet and to resist the invasion. Cancer infection is also responsible for the unusual behavior of some abdominal wounds after operation, and is nearly always the cause of unexpected postoperative abdominal fistulæ, whether gastric or intestinal, developing after a cancerous growth has been explored or dealt with in some way.

Clinical Observations on the Origin of Fever.—A. Lorand declares that the maintenance of health depends on the integrity of the internal secretions of the ductless glands, especially the thyroid. Persons and animals deprived of it suffer from all sorts of infection. He then goes on to show that Graves' disease and fever have similar clinical manifestations, as rapid pulse, thirst, sensation of heat; after awhile abundant perspiration, etc. Vasodilatation and sweating can be produced by thyroid feeding. This latter symptom of fever is a device of nature for eliminating toxic materials. Its occurrence is generally followed by an improvement in the general condition. The diarrhea of some infectious diseases is a typical Graves' symptom. To complete the analogy, the author mentions also toxic decomposition of proteins, loss of weight, muscular weakness and fever, and increased urea elimination. In both Graves' disease there is increased oxidation, possible delirium, cutaneous eruption, etc. Fever symptoms, therefore, are due in a general way to increased activity. Consequently, it seems to the author that we are justified in believing that fever is a beneficent institution of our organism which is produced by an increased activity of the thyroid gland as a reaction against toxic products and poisons in general. The symptoms of fever are the expression of this increased activity, and they are directed towards the elimination of noxious elements. It would be unreasoanble to oppose this spontaneous healing tendency of nature by fighting these salutary symptoms, unless there be hyperpyrexia.

Berliner klinische Wochenschrift, November 4, 1907.

An Early Symptom of Ileus.—Ewald says that a symptom of intestinal obstruction that does not ordinarily receive the attention it deserves is the fact that the stomach becomes filled with intestinal contents very early in mechanical or paralytic intestinal occlusion. It is frequently possible on introducing the stomach tube to obtain material with a strongly fecal odor even at a time when no other symptoms such as fecal belching, or much less, vomiting, indicate the gravity of the illness, and there is hardly a suspicion that the case is one of intestinal obstruction. It is advisable to wash out the stomach at frequent intervals, even six to ten times a day, and enormous quantities of fluid may often be removed. The severity of the general condition as well as the prostration of the patients is greatly diminished by this procedure and if operation becomes necessary they are much better able to stand it.

The Differentiation of Transudates from Exudates.—Janowski refers to a test suggested some years ago by Rivalta, which is intended to aid in determining whether or not an effusion is of inflammatory nature or is simply a transudate. In order to perform it a drop of the fluid in question is allowed to fall into a solution of two drops of glacial acetic acid in 100 c.c. of water. Instead of glacial acetic acid 20 drops of ordinary vinegar may be used. If the fluid is an exudate the path of the drop toward the bottom of the vessel will be marked by a white or bluish white streak of precipitated albuminous material, while if it is a transudate the acetic acid solution remains clear. Effusions taken from cadavers always give a negative result, but this is unimportant, as the truth of the character of the process can usually be determined by inspection. Traces of blood do not interfere with the results and do not give any precipitate in the case of transudates. The test is negative with normal cerebrospinal fluid, the fluid from echinococcus cysts of the liver, hydronephrosis, and amniotic fluid. It is positive with fluid from incarcerated hernias, ovarian cysts, and hydrocele in children. In a large number of cases in which the method was tested by the author it gave uniformly reliable results and in some instances gave decisive information when the other data were inconclusive. Rivalta at first believed that the reaction was due to the presence of nucleoalbumin from the leucocytes occurring in inflammatory exudates, but in a later communication has expressed the view that it is caused by euglobulin and pseudoglobulin from the blood.

Deutsche medizinische Wochenschrift, November 7, 1907.

Acute Poisoning After Oil Enemas.—Buttersack reports a case of serious poisoning accompanied by methemoglobinemia occurring in a women of thirty-three years, who was given an enema of 250 c.c. of oil of sesame for an attack of gallstone colic. This remedy had been frequently used before for the same condition without any untoward consequences, but on the occasion in question the injection of the oil was promptly followed by symptoms of collapse which in a few hours became so severe as to make recovery seem doubtful. The blood was chocolate-colored and gave the characteristic methemoglobin spectrum, while the surface of the body was cyanotic and cold, especially the face, ears, fingers, and toes. Urine passed ten hours after the enema contained blood cells and traces of albumin, but no hemoglobin or methemoglobin. Twelve hours later hemoglobin was present in abundance. The treatment consisted in the administration of cardiac stimulants and in the inhalation of oxygen, which seemed to be particularly beneficial. The patient finally recovered completely. Examination of the oil revealed the fact that this was not oil of sesame, but a yellow paraffin oil. Several somewhat similar cases have been reported in which the oil of sesame used was the oleum sesami gallicum instead of the oleum sesami germanicum, and in these the symptoms strongly resemble those exhibited by the author's patient.

The Treatment of Perforated Gastric Ulcer.—Martens says that the less reluctance the public feels towards surgical operations, the more sensitive it becomes to abdominal pain, and the less castor oil, enemas, and opium are used for abdominal colics the better will be the results in the treatment of perforative peritonitis. The improvement in the statistics of this condition that has been obtained of recent years is due for the most part to the fact that the practising physicians make the diagnosis earlier and the patients enter the hospital before their condition has become hopeless. An important prophylactic measure is to instruct patients suffering from gastric ulcer in regard to the possibilities of a perforation and warn them of the necessity for hospital treatment at the first suspicion of this complication. He reports ten cases of perforation of a gastric ulcer treated by suture, with six recoveries. The indication is to operate immediately without waiting for symptoms of shock to subside, to find the ulcer as quickly as possible, and close the perforation. He prefers not to excise the ulcer, but simply to suture over the perforation, covering the spot with a piece of omentum. A tampon is then placed at the operative area. The question of whether or not to perform a gastroenterostomy is still in doubt, but the author ordinarily prefers not to do so. Cleansing of the abdominal cavity is best performed by the use of large quantities of saline fluid, for which purpose the author employs from twenty to thirty liters.

Carrier Pigeons in Medical Practice.—The car of Venus is often represented as surrounded by doves, but no such poetic symbols are accorded to Æsculapius. We learn from an English contemporary, however, that carrier pigeons as aids to country doctors are used in the north of Scotland. A doctor who has a scattered practice, when on long rounds takes several pigeons with him. If one of his patients needs medicine immediately, he writes out a prescription, and by means of the birds forwards it to his surgery. Here an assistant gets the message, prepares the prescription, and dispatches the medicine. If after visiting a patient the doctor thinks he will be required later in the day, he simply leaves a pigeon, with which he can be called if necessary.

Book Reviews.

THE MEDICAL AND SURGICAL USES OF ELECTRICITY. Including the *x*-Ray, Phototherapy, the Finsen Light, Vibratory Therapeutics, High-Frequency Currents, and Radioactivity. By A. D. ROCKWELL, A.M., M.D., Neurologist and Electro-Therapeutist to the Flushing Hospital; Formerly Professor of Electro-Therapeutics in the New York Post-Graduate Medical School and Hospital; Fellow of the New York Academy of Medicine; Member of the American Academy of Medicine, etc. With Two Hundred and Fifty-nine Illustrations. New Edition, Revised and Enlarged. New York: E. B. Treat & Co., 1907.

THIS volume is practically the eleventh edition of the work that originally appeared under the names of Beard and Rockwell. It deals most exhaustively with the general subject of electricity as applied to medicine and surgery; it also contains chapters on the *x*-rays, phototherapy, Finsen light, vibratory therapeutics, high-frequency currents, and radioactivity. In the present edition the chapter on high-frequency currents has been enlarged and mostly rewritten; various changes and additions have been incorporated in the chapter on *x*-ray diagnosis and therapeutics; the chapter devoted to phototherapy has been enlarged and partly rewritten, while the subject of radioactivity is considered in an additional chapter. There is a tendency in many books on this subject to exaggerate the value of electricity as a therapeutic agent and also to overestimate the conditions in which it is indicated. Further, what were considered indications twenty years ago may not be so considered to-day. In the present work much of the chapter on midwifery (for example) is of historic interest only; and in a few of the other chapters many of the references are of considerable age, and there is comparatively little reference to the more modern work. The author says with much truth: "Elaborate electric pharaphernalia (static and high-frequency) adorn the consulting room of many a physician who is quite ignorant of the fundamental principles on which is based the use of electricity in medicine, and who would be altogether perplexed if asked to differentiate in the use of electric modalities." Physicians who wish for a thorough understanding of this important matter are recommended to read this book, which since the early editions has been recognized as the standard work on the subject.

THE CHEMISTRY OF COMMERCE. A Simple Interpretation of Some New Chemistry in Its Relation to Modern Industry. By ROBERT KENNEDY DUNCAN, Professor of Industrial Chemistry at the University of Kansas; Author of "The New Knowledge." Illustrated. New York and London: Harper & Brothers, 1907.

WHILE the supremacy of this country in many industrial fields is undeniable, in others we are still far behind our European competitors, and even in those branches in which American manufacturers have been most successful this result has not always been attained through superiority in technology, but rather through more intensive business methods. In addition to its purpose of setting forth in entertaining fashion many of the recent advances in chemical knowledge, it is the object of the present book to emphasize how important an ally scientific research can and should be in commercial affairs, and to point out how frequently neglect of the theoretical aspects of a manufacturing problem leads to financial disaster or at least bars all progress. The managers of the large enterprises are realizing this and making use of every aid that the laboratory workers can give them in testing and selecting raw material, devising more economical methods of production, utilizing what have been regarded as waste products, etc., while the smaller manufacturers, unable to understand the nature of the new industrial power that is being turned against them, have ascribed their commercial downfall to the force of combination, trusts, etc. Professor Duncan urges the manufacturer to avail himself of the forces and abilities modern chemistry places in his reach, and suggests a plan of university fellowship, supported by commercial interests, by which young men may be trained as chemical technologists.

Among the subjects he discusses in order to illustrate the potency of scientific knowledge as applied to practical affairs, are the newer lore concerning catalysis, the problem of fixing the nitrogen of the air and rendering it available for man's use, high temperatures as applied to modern industries, glass making, industrial alcohol, and the chemistry of cellulose. Two chapters are also included which bear directly on medicine, one on the making of synthetic remedies and the other on the opsonins. The former would certainly gain more approval from the medical reader were the identity of the manufacturing firm whose methods it describes more carefully concealed, or else its praises less extravagantly sung, while we are sure that the twenty pages devoted to the latter subject could have been used by the author to much more purpose in discussing some topic more nearly in keeping with the title and general tenor of the book.

Professor Duncan's agreeable style makes the wonders he describes seem doubly fascinating, and it is a pleasure to call attention to a work that no educated layman—and much less a physician—can read without interest and profit.

RATIONAL AND EFFECTIVE TREATMENT OF HIP-DISEASE. By P. BRUCE BENNIE, M.A., M.D., B.S. (Melb.); Honorary Medical Officer, Melbourne Hospital for Sick Children, etc. Founded on Experience of Numerous Cases in Hospital Practice During 28 Years. Compiled by ALEX. B. BENNIE, M.A., M.D., B.S. (Melb.) New York: William Wood & Company, 1907.

THIS little book seems to be a plea for the use of the Thomas hip splint in tuberculous coxitis in preference to any other mode of treatment. The writer has used the appliance in a large number of cases and claims that in this method the joint can be absolutely fixed with the slightest degree of inconvenience to the patient. He insists that the apparatus be made in general after the model devised by Dr. Thomas, but recommends several minor modifications. Bennie also advocates the use of the double form of the splint in the treatment of Pott's disease, not only of the lumbar, but of the dorsal and cervical varieties as well. An interesting point to which the author calls attention is the value of stereoscopic skiagraphs in interpreting the degree of ankylosis in a hip. In the case reported, one of eight years' standing, the supposed bony ankylosis was shown by this means to be entirely fibrous.

CHEMICAL PATHOLOGY. Being a Discussion of General Pathology from the Standpoint of the Chemical Processes Involved. By H. GIDEON WELLS, Ph.D., M.D., Assistant Professor of Pathology in the University of Chicago and in Rush Medical College, Chicago. Philadelphia and London: W. B. Saunders Company, 1907.

THIS is a very timely presentation of a subject that is constantly gaining in importance and that even threatens in some of its phases to overshadow the study of morphological pathology itself. The work is characterized by a very logical plan of arrangement and facile style that render its perusal a pleasure. It opens with an introductory chapter on the physics and chemistry of the cell which summarizes in easily intelligible fashion the intricate lore of the newer conceptions in this field, and is followed by an equally illuminating exposition of the nature of enzymes and their manner of action, including the subject of autolysis. The succeeding seven chapters are devoted to various phases of bacterial action and the means of defense against poisons of bacterial, chemical, and animal nature. The subjects of inflammation and hematology are next discussed and then the various cellular degenerations and metamorphoses. The little that is known of the chemistry of the tumors is brought well up to date and the last hundred pages of the volume are devoted to the disorders of metabolism. The value of the book is much enhanced by the very numerous references and by an unusually voluminous index. The difficulty of producing so satisfactory a treatise on this fascinating but unfortunately still rather inchoate subject can be appreciated only by workers in the same field, and the author is to be highly congratulated on the success with which he has performed his arduous but beneficent task.

A TEXT-BOOK OF PHYSIOLOGY for Medical Students and Physicians. By WILLIAM H. HOWELL, Ph.D., M.D., LL.D., Professor of Physiology in the Johns Hopkins University, Baltimore. Second Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1907.

THE author of this book wastes no time or space with any introduction or general remarks—subjects more or less remote from the one in hand, but begins at once with the physiology of muscle and nerve, the opening chapter being on the phenomenon of contraction. He differs from many writers on physiology in getting down to the level of the average student of this subject, who starts usually in absolute ignorance of its most fundamental and commonplace facts. The language is clear and nothing is taken for granted; lucidity has not been sacrificed to brevity on the one side nor to a vain desire to embrace the entire subject on the other. This is not an encyclopedia of physiology nor is it a compend, but a text-book in which the student will find the main facts of the science presented in an easily comprehensible manner. The second edition differs but little from the first, only such additions and changes having been made as were rendered necessary by the normal progress in physiological knowledge

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

210th Regular Meeting, Held on October 11, 1907.

THE PRESIDENT, DR. ROBERT ABBE, IN THE CHAIR.

A Consideration of Esophageal Stricture.—By Dr. ROBERT ABBE. (See page 890.)

Dr. WALTER B. JAMES said that last winter he saw a patient who had been under the care of a surgeon for a fusiform dilatation of the esophagus resulting from a stricture which was treated by the so-called string method. The patient would swallow ten or more feet of a strong silk cord, which apparently had no difficulty in passing the esophageal obstructionn, and would then enter the stomach and intestines, at times even emerging from the anus. With this string, which was firmly held in the intestinal canal, serving as a guide, an olive-tipped bougie was passed which acted as a dilator.

Dr. JOSEPH D. BRYANT said that about ten years ago, when treating a case of esophageal stricture, it occurred to him that possibly it might be wise and feasible to attempt dilatation from above by a string-cutting process, and with that object in view he devised a bougie with a tiny wheel at the end over which a string was drawn back and forth with the idea of sawing through the stricture at either side at the same time. He employed this device in one instance with very satisfactory results. He realized, however, that it was necessary for the purpose of carrying the dividing mechanism through the constriction to provide a stiffer instrument than that which he had first employed. He regarded it better and safer that the constriction be equally divided at two aspects than wholly divided above.

Dr. ABBE, in closing, said that strictures of the esophagus were exactly like those of the urethra; there were some that could not be treated by the string method, and there were many that could not be stretched by sounds with any degree of satisfaction. After a urethral stricture had been cut, and dilatation had been persisted in for three or four years, the urethral canal might retain its patency, and the same was true of esophageal strictures. A certain number of esophageal strictures could be dilated easily, but there were some cases in which the obstructions were so dense, gristly, and numerous that the only result of persistent dilatation was to set up an inflammation of the parts and aggravate the condition. It was in those instances to which the method he had shown was applicable. When the stricture was once cut widely open it remained patulous. The speaker said he did not regard gastrostomy in these cases as a serious operation if it was done carefully.

Two Cases of Primrose Poisoning.—Reported by Dr. WALTER B. JAMES. The speaker said he had recently seen two patients who suffered from this unusual form of poisoning, which manifested itself as an acute dermatitis. Both had suffered from recurrent attacks of the affection for many years, and had been in the habit of going to the Hot Springs of Virginia for what was supposed to be gouty eczema. In one case, the history of the attack which he obtained was as follows: The patient was a woman who had worn a bunch of spring primroses in her corsage during the evening. On the following morning she observed an eruption on the chest, which soon spread to the arms and neck. It became infected by scratching and persisted for several weeks. She subsequently observed that each time she handled primroses she became subject to these attacks of intense dermatitis of a moist, oozing variety, with intense itching and some swelling. In her case the cause of the trouble was discovered by accident, as her daughter was subject to the same affection, and wrote to her mother regarding it. The second patient gave the history of having suffered from several violent attacks of dermatit's affecting the face, neck, hands, and arms, for which she had undergone various methods of treatment without avail. When Dr. James saw her, the eruption did not look like an ordinary eczema, but had more the appearance of a toxic dermatitis. This attack occurred in the middle of winter, and the history obtained from the patient was that while out driving she had seen a particular variety of primroses in the florist's window, and had purchased a bunch of them and carried them home in her lap. On the following day she had developed this dermatitis. She was warned against handling this flower, and since that time had had no further trouble. The eruption is these cases, Dr. James said, bore a fairly close resemblance to ivy poisoning, but the edema was more intense and the blebs extensive, with oozing and the formation of crusts. In both cases the diagnosis had been made of gouty eczema and angioneurotic edema. Primrose poisoning, Dr. James said, was far from unknown in literature. Some of the dermatological works spoke of it, as well as some of the books on toxicology. It was an exceedingly violent form of toxic dermatitis, and it was pretty well recognized among florists, who were aware of the fact that some men were unable to handle primroses without subjecting themselves to this danger, while others were apparently immune. One florist suggested that it was due to the insecticides, such as hellebore, that were applied to the plants by the growers.

Dr. S. GREIDANUS of The Hague said that in Holland it was a well known fact that certain varieties of the primrose gave rise to a skin affection. The eruption was attributed to the tiny hairs with which the plants were studded, and the speaker said he had seen many such cases. The particular variety of the primrose that was recognized among florists as causing this trouble was known as *Primula obconica japonica*, the blossoms of which were considered dangerous to handle, as they frequently caused inflammation of the skin and eyes.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 24, 1907.

DR. HOWARD C. TAYLOR IN THE CHAIR.

Pregnancy Complicated by a Myofibroma, Obstructing the Pelvic Outlet.—Dr. HERMAN J. BOLDT presented this specimen. He said the various complications connected with myofibromata were of common occurrence. Tubo-ovarian inflammations were among the most common. When pregnancy was complicated by the existence of fibromyomata, the gestation in most instances might be permitted to go to term, it being possible usually to bring about delivery with safety to the mother and child. Occasionally, however, the patient with a myofibroma was not so fortunate, and at the time of termination of pregnancy the outlet was obstructed to such a degree that artificial means must be resorted to. He had on three occasions found it necessary to deliver women at the termination of pregnancy through the abdominal route; the last time three months ago. In all of these three instances he also removed the uterus; first because of the neoplasms and their relation to the uterus, and secondly, to avoid the danger of sepsis after delivery. In the instance from which the specimen was obtained the outlet was completely blocked by the large cervical myofibroma, to such an extent that delivery by morcellation of the child would have been almost a physical impossibility. The operation was undertaken at the beginning of labor. Fortunately for the patient the attending physician realized that there was a serious complication present, and at once requested council, so that the patient had neither been infected nor had she lost strength by long labor pains. Both mother and child were alive and well.

Extrauterine Pregnancy on Right Side; Pyosalpinx on Left Side.—Dr. HERMAN J. BOLDT presented this speci-

men. The patient was thirty-five years old, and had missed her period three months ago; six weeks thereafter she began to have atypical bleeding for which she was curetted, under the supposition that she had an incomplete abortion. Since that time she had cramp-like pains in the lower abdomen. She was again curetted under ether two weeks ago. The pains became worse and the bleeding continued. A few days ago she was seen by Dr. Boldt in consultation. The woman then had a general peritonitis. Inasmuch as no improvement was ascertainable she was operated upon. The operation was unusually difficult because of intimate and diffuse adhesions. The blood that was found in the form of a hematocele was old. The severe bleeding was undoubtedly caused by the curetting. The woman was now convalescing.

Specimen Illustrative of Conservative Surgery Practised upon the Uterine Adnexa.—Dr. Herman J. Boldt said that for several months he had tried more extensive conservatism in instances of inflammation of the adnexa. For instance, in cases of interstitial salpingitis with the tubes nearly an inch in diameter, held to the floor of the pelvis by adhesions, the pelvic organs matted together, all the adhesions were separated, the adherent uterus attached to the parietal peritoneum, and the inflamed tubes and ovaries suspended to the upper border of the broad ligaments by stitching them with one or two stitches to the round ligaments, so that they could not again prolapse and become adherent to the floor of the pelvis. In instances of much purulent secretion, the cul-de-sac of Douglas would be opened and the pelvis drained for a short time with gauze surrounded with rubber tissue. The specimen presented was obtained at an operation performed that morning. The ovaries were so firmly adherent to the floor of the pelvis that it required much force to separate the adhesions. The tubes were likewise adherent. It was an inflammation probably caused by a former gonorrheal infection; the woman, however, never had the acute symptoms of gonorrhea. In this instance conservatism was practised only on one side so that he could show the condition of the adnexa which were treated conservatively by him, in the hope that others might make a study of the subject, and try it on a certain class of hospital cases, keeping them under observation for a couple of years, and then report the result. Undoubtedly in his opinion some would require subsequent operation for the removal of the adnexa, but he believed that many would be completely cured without unsexing these women. He maintained, however, that vaginal surgery was out of the question in such cases. Much more exact work could be done through the abdominal route. In the case from which the specimen was presented, the Fallopian tube on the side retained was dissected off the ovary as far as necessary and the abdominal opening made widely patent by cutting it open and everting the opening thus made, holding the edges permanently open by stitching them. The ovary itself was halved, a piece taken out of the center to take off the tension from the cortex, and then the gland was brought into apposition. What the eventual outcome of this kind of work would be, remained to be seen, but he proposed to thus treat 100 cases, and after three or four years he hoped to come to a definite conclusion.

Dr. Charles Jewett discussed these specimens.

Uterine Fibromyoma Complicated by Acute Pyosalpinx.—Dr. Herman Grad reported a case of fibroid of the uterus complicated by an acute pyosalpinx because of the symptoms presented and the difficulty of diagnosis. The patient was seen in consultation July 7. The attending physician said that twenty four hours previous the patient was taken with severe abdominal pains. The attack came on when the patient was apparently in good health. Morphine had to be given and repeated. No diagnosis had been made. The temperature was 101°, and pulse 140. She had an anxious expression and extreme pallor. There was nausea and vomiting. The urine was drawn by catheter. The bowels were moved by a cathartic. She never had a similar attack. She was forty-five years old, and had one child three years old. She never had a miscarriage, and her menstruation was normal. The flow was excessive, lasting eight to ten days, and she always passed large clots. She had cramps with her periods. Her last menstruation was one week ago. She had been conscious of some enlargement of the abdomen for several months, but did not consult about it, because she had no pain. She attributed her pallor to the excessive loss of blood during her menses. Even the slightest palpation of the abdomen was resented on account of the extreme hypersensitiveness, necessitating an examination under an anesthesia. An abdominal tumor was discovered reaching up to the umbilicus. It was immovable, felt hard, and had a smooth outline. It filled the pelvic cavity completely, so that the appendages could not be palpated. A tentative diagnosis was made of twisting of the pedicle of the pelvic tumor. She was sent to the hospital and kept under observation for forty-eight hours. Leucocytosis was moderate. Her temperature was 100°, and pulse from 120 to 130. The nausea and vomiting was considerable. On July 10, the abdomen was opened. A few recent adhesions were found. The bowels and omentum were adherent to the tumor, which was a myoma of the uterus. After liberating the tumor, a large pyosalpinx of the left side came into view. The tumor, uterus, and pus tube were removed in one mass. The patient made an afebrile recovery. While pyosalpinx complicating a fibroid of the uterus was not uncommon, it was rare enough to mislead one in diagnosis.

Rupture of the Uterus after Cesarean Section.—Dr. George L. Brodhead said that the patient was a Russian, thirty-five years old, and pregnant for the fifth time. Her first and second were long labors, and she was attended by a midwife, and no instruments were used. Both were stillbirths. The third and fourth were difficult labors, instruments were used, and these were stillbirths. In each instance the fetal movements persisted up to the last day. The pelvis was the typically flat one, with an internal conjugate of eight cm. On December 31, 1904, cesarean section was performed, the mother and child doing well. The uterus was sutured in layers with No. 1 (ten day) chromicized catgut. The peritoneum was sewn with plain catgut No. 2, and the fascia with No. 2 chromic gut. In August, 1906, the patient was seen for the first time in her sixth pregnancy. She gave the date of her last menstruation as April 1, and she supposed she was about four months pregnant. No life had as yet been felt, and the uterus appeared to be of four months' size. It was decided to perform cesarean section again during the latter part of December, at about full term. On November 26, at about eight P.M., a physician telephoned that he had seen the patient and that she was having "false pains," with a slight bloody discharge from the vagina. The patient was advised to enter the hospital at once, and she was admitted about eleven P.M. She was very restless, and very thirsty. The skin was cold and clammy. Her pulse was 104 and of poor quality. Her respirations were forty-four. The cervix admitted one finger. The abdomen was distended with fluid, and the fetus was felt freely movable in the abdominal cavity. Laparotomy was at once performed, but the patient soon died after the incision was made. The child weighed 7 5-16 pounds and was stillborn. The rupture was at the site of the old scar. While he did not feel certain that the continuous layer sutures were responsible for the weakness of and rupture of the uterus, he had, since that time, repaired the uterus by passing interrupted sutures of No. 2 (twenty day) chromic catgut through the inner two-thirds of the muscle, down to but not including the mucous membrane. A second set of interrupted sutures closed the outer portion of the muscular coat. The peritoneal in-

cision was then closed and its raw surface covered with a continuous suture of No. 1 plain catgut.

Dr. J. Clifton Edgar said that he used twenty day chromic catgut in these cases.

Dr. Charles Jewett asked Dr. Brodhead what proportion of the cases of cesarean section was followed by rupture of the uterus. He had never had the misfortune to meet with but one case. A recent German writer had proposed in all cases where a cesarean section was to be performed, that the woman should first be sterilized. One hour later the operation was performed.

Dr. A. Sturmdorf called attention to one point in the technique which Dr. Stone had brought up in a similar discussion. It did not make so much difference whether one used interrupted or continuous sutures, but it did make much difference how they treated the lining membrane. If the uterine membrane was caught in the suture, it would in some cases proliferate. The line of rupture was along this line in the endometrium.

Dr. W. S. Stone said that rupture might occur no matter whether a longitudinal or transverse incision was made. The transformation of islands into decidual tissue was the cause of these ruptures. He had always used plain catgut. He recalled one case of rupture which occurred a few days after an operation; here the omentum filled in the chink in the uterus. The woman recovered although the uterus became firmly attached to the abdominal wall. Before she left the hospital it was thought best to open the abdomen when the omentum was found filling in the hole in the uterus. In that instance there was a poor line of union. The incision, whenever possible, should be made in the median line and slightly obliquely. The uterine muscle would retract unevenly. In some cases one side would be thin, while the other would be thick. Therefore, it was difficult to make a nice line of union.

Dr. George L. Brodhead said he could not furnish any statistics as to the frequency of rupture following cesarean section, but a considerable number of cases had been reported. They had occurred often enough to make them feel that, if cesarean section was to be performed, the matter should be laid before the woman, telling her of the frequency of rupture, etc. In one or two instances cesarean section had been performed four times on the same woman. In a case Dr. Stone referred to the rupture occurred through the fundal incision.

Placenta Prævia; Remarks on Its Frequency and Mortality, with Report of Eight Cases.—Dr. I. L. Hill read this paper, and gave the following summary: Among multiparas, placenta prævia could hardly be called a rare complication. In 1,800 cases, of which 87 per cent. were multiparas and the average number of pregnancies four, he found the ratio to be 1 to 225. The mortality had been understated recently because of too broad generalization upon a few highly favorable series of cases reported. There had been very little reduction in the fetal death rate, which was still from 40 to 50 per cent. In the presence of hemorrhage in the last third of gestation, the cervix should be dilated sufficiently to allow a diagnosis by the finger, and if placenta prævia was present, the uterus should be emptied without delay. Tamponade of the cervix and vagina was useful as a preliminary step. The Braxton-Hicks version was effective in controlling hemorrhage and was the safest procedure for the mother, but it did not give satisfactoryy results for the child. When the dilatability of the cervix made them positive that delivery could be effected with little or no tearing of the cervix, they might elect rapid delivery by version and forceps, packing the uterus and vagina if there was bleeding after the third stage. In cases presenting long, rigid cervices, complete prævia and a viable child, if the surroundings of the case were favorable, cesarean section should be chosen in the interests of the child. The advance in the treatment of placenta prævia had been remarkable in reducing the maternal death rate even though the saving of the patients had not been brought so near an exact science as some suggested. It would seem that progress must be directed to decreasing the fetal mortality.

Dr. Charles Jewett, speaking of the mortality in cases of placenta prævia, said that methods of treatment which were best for the mother were worse for the child, and conversely. His own mortality he had not by any method been able to keep down to 1 per cent. In any large number of cases taken as they go so low a mortality was impossible. One or two weeks ago he lost a case; there had been considerable hemorrhage when the patient entered the hospital. This was controlled and he was about to take steps for immediate delivery when the woman was seized with eclampsia. She was delivered easily under chloroform. Catharsis, hypodermoclysis, and other measures were used, but the patient died of exhaustion a few hours after delivery. With reference to treatment before the period of fetal viability he formerly advocated an expectant course except when the hemorrhage was profuse. He was now inclined to think that in most instances such cases should be treated by immediate evacuation of the uterus. Exceptions might be made when the blood loss was very moderate and the case could be closely watched. But the prospect for a living and viable child was so small that the attempt was seldom advisable. The choice of procedure at delivery was pre-eminently a matter of judgment in the individual case. In marginal or very partial placenta prævia with good pains rupture of the membranes had in his hands been entirely satisfactory. With much bleeding before the cervix had fairly begun to dilate a firm vaginal pack with wet strip gauze supplemented by a tight abdominal binder had served him well and it had a good record in other hands. Still better, when beginning dilatation permitted, was the vaginal tamponade together with a water bag in the cervix. The Pomeroy bag was free from the objections to other bags for this purpose. Sometimes, after labor was well established, manual dilatation and extraction might be carried out safely in the exceptional cases in which the woman had not bled much. When the cervix would admit two fingers, and the membranes were unbroken there was perhaps no quicker or better method for the control of profuse hemorrhage than bipolar version without extraction. Extraction immediately following version he thought was in most instances an unfortunate mistake. The half exsanguinated woman succumbed very easily to superadded shock. Cesarean section he granted might be justified in rare instances, but as a rule the usual obstetric procedures were better, as figures would show. He certainly would not perform a cesarean operation on a woman who had recently lost much blood.

Dr. J. Clifton Edgar said the fetal and maternal mortality must be considered in such cases. They took certain risks in order to give the child a chance and, at the same time, they lessened the chance for the mother. Looking at placenta prævia from a practical standpoint, it seemed to him that the cervix was the interesting part and should be an object for consideration. It was a significant fact that of the cases reported there was not one primipara among them; all the cases occurred in multiparas. It seemed to him that where the woman had had several children the chances were favorable as regarded the prognosis for the mother. This led them to consider the statement hinted at by Dr. Jewett, that cases of placenta prævia would rarely require cesarean section. Occasionally one met with a case with a long cervix where suprapubic operation undoubtedly gave better chance for the child as well as for the mother. Dr. Edgar confessed that he had not the fortitude to use bags in a cervix covered by placenta; introducing a bag under those circumstances, and injecting water into that bag, gave him the feeling that he would be separating the placenta further. But where a finger or two could be placed in the cervix, he did not hesitate to use one

of the smaller bags. After one or two sharp hemorrhages in placenta prævia the fate of the child was sealed. But an ordinary birth under such circumstances gave a high mortality. Bossi's dilator had a place in placenta prævia. It started dilatation, when manual dilatation could be proceeded with. The slow extraction of the child had not been brought out. A gentleman in Philadelphia favored the Braxton-Hicks method of extraction in these cases.

Dr. George L. Brodhead said that in all cases of placenta prævia, whether the child was viable or not, pregnancy should be terminated unless the woman was in a hospital where she could be closely observed. Allowing these patients to go on without careful watching was a bad procedure. With regard to the mortality rate he agreed with Dr. Hill, that where the treatment was instituted promptly after the diagnosis was made, the mortality should be small. When the diagnosis was established, and measures instituted to empty the uterus, the chance for the mother was good, although there was a high mortality for the child. One of the most important points brought out in the paper he believed to be the statement that after version had been done, with the cervix only partially dilated, extraction should be made slowly. He could recall a number of cases where the child was saved by rapid extraction, but the mother died. He thought the mother should be saved even though the child was lost. A number of women lost their lives through rupture of the uterus, shock and hemorrhage because of the rapid dilatation of cervix and rapid extraction of the child through an undilated cervix. Dr. Brodhead had never had a case of placenta prævia in which it was necessary to do a cesarean section, but he had no doubt that in some of the cases described it would give a living child, and a far better chance than if version and forceps were employed. It seemed to him that in those cases with a long and rigid cervix, the best treatment was packing; he thought the tampon offered the best possible chance where the cervix was undilated. Where the cervix admitted two or three fingers there was no question but that the Braxton-Hicks method was the safest. Podalic version was best for the patient, although it was not so good for the child. Where the cervix was well dilated and the hemorrhage slight, forceps and version. If the cervix was very well dilated, forceps should be the means of extraction. In some cases he advocated the use of the tampon; later on rupture the membranes; or complete the dilatation with the fingers, then later on operation with forceps and version.

Dr. Leonard S. Rau said that in the report of his eight cases the reader of the paper used the bags in none. Personally he favored the bags; this was his favorite method of treatment. In cases where the cervix was readily dilatable delivery should be done as soon as possible. Those who saw many cases realized the danger to the mother. Unfortunately the mortality for the child too was high. He did not know why he examined all the cervices of women after delivery, because in many cases one would find that, although forceps had not been used, there would be a tear, quite a marked tear, in the broad ligament and sometimes in the uterus itself. These were the cases in which the women did badly. Dr. Rau's method was, if the cervix was sufficiently dilated, to introduce the bag. This checked the hemorrhage, and gave the woman a chance to regain her strength and produced dilatation. He then did a Braxton-Hicks, bringing the foot down; then he allowed nature to do the rest. With regard to the long rigid cervix, he did not see how the diagnosis could be made of a complete placenta prævia because one could not get the finger through. That was simply presumptive.

Dr. H. N. Vineberg said that he had seen a number of cases where the bleeding occurred from the uterus and not from the cervix. He had allowed cases to go to full term with no hemorrhage and no evidences of placental detachment. He had known of cases with slight bleeding where it was not deemed necessary to do anything, and they were delivered all right. But where there was active bleeding there was nothing to do but go ahead and deliver as soon as possible. He had seen cases in the hospital under the expectant treatment, being closely under observation; then there would be a scurrying to and fro, and death of the patient before delivery. In cases with a low placental detachment and profuse hemorrhage delivery should be accomplished as soon as possible. If the cervix was dilatable and you could introduce three or four fingers, the rest would be easy; the rest of the dilatation could be done without difficulty. The child then could be turned and delivered without fear of rupturing the uterus. The great difficulty was encountered in dilating sufficiently to get in two or three fingers not only in primiparas, but in multiparas as well.

Dr. John O. Polak wished to called attention to the extreme friability of the cervix in these cases of placenta prævia. The last speaker had just stated that when three or four fingers could be introduced into the cervix, the rest of the dilatation was easy; but that was just how the tear took place. He had rapidly dilated cervices and with a tenaculum brought down the cervix and had found a tear in one or the other fornix. Multiparas had scarred cervices and increased friability of the parts, and he wished to say that Dr. Rau's treatment was one form of treatment which saved the most lives. With regard to cesarean section he could see theoretically the advisability of doing it; but personally he did not believe in it except in those rare instances of central implantation, with slight bleeding; then one might be justified in placing this extra strain upon the mother in the interest of the child.

Dr. I. L. Hill, referring to Dr. Rau's criticism regarding the difficulty of diagnosing a central placenta prævia in cases of long and rigid os, said that he did say complete, one covering the lumen of the os. If necessary he dilated it as far as was necessary to pass in the finger to make the diagnosis. One could twist the finger around. With regard to Dr. Edgar's statement that hemorrhage caused the death of the fetus and cesarean section later offered little hope of saving the child, it should be remembered that cesarean section, if done at all, should be done as soon as possible, even though hemorrhage was going on. He hoped what he had said might be felt and a greater number of children saved. He had been impressed in studying this matter with the great difficulty of all methods used in reducing the mortality of the child.

Injuries of the Perineum; Their Mode of Formation and Treatment, with Report of Seven Cases.—Dr. Ellice McDonald presented this communication, illustrating his remarks with charts.

Dr. Charles Jewett, Dr. H. N. Vineberg, and Dr. Herman C. Collyer entered into the discussion.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 10, 1907.

Dr. Godfrey R. Pisek in the Chair.

A New Diagnosis of Tuberculosis.—Dr. Louis Fischer said that the diagnosis of tuberculosis years ago, by the Koch method, fell into disrepute because it was necessary to use such large doses. In this present method tuberculin was taken and diluted with normal saline solution 1-4. Three portions of an arm were scarified and to two of these the diluted tuberculin was applied, the other place being used as a control. In tuberculous cases a marked reaction would occur. In the last stages of miliary tuberculosis or tuberculous meningitis there would be no such reaction. This was what Koch found years ago, when he injected pure tuberculin. In one case of marasmus Dr. Fischer had seen, there was a reaction within twenty-four hours, as shown by the amount of inflammation around the inoculated area. In Vienna he was told that the area of in-

flammation following the injection of the diluted tuberculin was about 10 millimeters, and if it was more it should be excluded as a diagnostic point, but Dr. Fischer had seen it even larger in cases of undoubted tuberculosis. Among seven hundred cases inoculated, only three gave febrile reaction. Some had a complication of conjunctivitis, and some a severe type of rhinitis following the injection. Dr. Fischer had seen personally seventy-five or one hundred cases injected with this method, which was a very simple one. A few days ago he used this method and was surprised at the quickness with which it responded. In regard to infants and nurslings, four, five, or six days after the inoculation the condition wore away entirely, whereas in older children it might remain for several weeks, with distinct red streaks about the site of inoculation.

High Frequency Currents in the Treatment of Hernias.—Dr. HERMAN C. FRAUENTHAL showed a child who had whooping cough, which was followed by inguinal and umbilical herniæ. The child was treated with high-frequency currents with apparently remarkable results.

Dr. L. E. LA FÉTRA examined the patient and found evidences of the hernia, and asked Dr. Frauenthal what he considered the condition of the patient to be at present.

Dr. HENRY W. FRAUENTHAL answered that the child had been under treatment but two weeks and, at present, the hernia which protruded was about the size of the thumb. He showed the base because he expected to show it again, and see what the future would bring forth.

A Fatal Case of Hemophilia Neonatorum.—Dr. H. FRED LANGE ZIEGEL reported this case. An infant weighing twelve pounds at birth had tongue-tie and phimosis. The prepuce was retracted over the glans, causing a small laceration on its anterior surface, where a small bleeding area was noticed. To check this oozing a strip of gauze was packed under the preputial tissue. Then the tongue was drawn forward and with the points of the scissors a slit was made through the tight frenum. Six hours later he was sent for, and found that though blood oozed steadily from the cut surfaces of the frenum linguæ, yet no bleeding vessel was to be detected. Various hemostatic agents were applied, with but little effect upon the bleeding. After the application of ice and digital pressure for about an hour the bleeding was apparently controlled. Twelve hours after the operation bleeding was more profuse and, after fruitless efforts to control it, he summoned a consultant, who tried various measures, but without success. The patient was then admitted to Mt. Sinai Hospital, where Dr. Charles A. Elsberg was on duty in Dr. Lilienthal's service. The blood was escaping in a steady flow from the substance of the tissues as a capillary oozing. It was pale, and gave no evidence of normal clotting. Styptics, astringents, ice, pressure, additional sutures, the actual cautery, enemata containing calcium chloride and gelatin, were all employed in vain. The infant died seven hours after admission to the hospital. Unfortunately an autopsy was not granted. The loss in weight from the bleeding was as much as two pounds. The doctor reproached himself for having cut the frenum linguæ as early as the second day, and undoubtedly the procedure was reprehensible; but the intended end seemed to justify the supposedly harmless means.

Some Observations on the Recent Epidemic of Acute Poliomyelitis in New York City.—Dr. J. F. TERRIBERRY said that there had been in this city and vicinity since the beginning of last July an epidemic of infantile paralysis, which in severity and extent exceeded the disease as previously met with. This disease constituted as high as 8 per cent. of all the diseases of childhood, and the limps seen in children were caused by this disease in 50 per cent. of the cases. Notwithstanding the fact that this disease had received the attention of investigators for many years, they practically had no knowledge of its etiology or its management. Dr. Terriberry then referred to an outbreak of infantile palsy, spotted fever, and typhoid fever at Ridgway, a village of 6,700 population in Pennsylvania, lying at the convergence of the Clarion River and Elk Creek. The general drinking supply was from a well, into which drained the excreta from a case of typhoid fever. Of the cases of infantile paralysis, fifty in number, four died. Almost all epidemics of this disease originated in low-lying regions and along coast lines. Again, they occurred at a time when the rainfall was reduced. At Ridgway he was informed that the Elk Creek had ceased to flow last summer for the first time. Most of the cases coming to the hospital were improperly diagnosed. The general practitioner should pay more attention to this disease, because of so many mistakes in the diagnosis. The bacteriological findings so far had been negative. In spite of the study of an immense number of these cases, our knowledge of the cause and treatment had not advanced at all.

Dr. SIMON FLEXNER said he had had an opportunity last week to see a number of these cases, wishing to make bacteriological and pathological study of them. He had been fortunate enough to get the spinal fluid and the blood from some cases in the early stages of the disease, as well as in older cases. But thus far he had no results to offer. He wished to make an appeal to those present, that if they saw these cases early, and if an opportunity was given to get some spinal fluid by lumbar puncture, that he would like to have some for study at the Rockefeller Institute. He also wished to obtain some material at autopsy, especially parts of the central nervous system. He said he would be much indebted to them if they would allow him to be present and secure whatever material possible, as he was particularly anxious to get material in the fresh state. So far as the spinal fluid was concerned, there were no evidences from the histological or morphological standpoint to say that it was of inflammatory character.

Dr. HENRY W. BERG thought that there should be some method by which an epidemic like the one now prevailing, which did not often kill, but maimed, should be recorded. A disease of this nature should be reported to the Health Department, even though the disease did not terminate in a death certificate. He had seen 25 cases, and believed the disease to be quite widespread. He called attention to the peculiar flaccidity of the muscles, which was very characteristic in those cases when seen early. The diagnosis rested upon this and the severe paralysis, with loss of patellar reflex. Kernig's reaction was not present. He then reported some interesting cases.

Dr. L. EMMETT HOLT reported the case of a child who was admitted to the hospital on the fourth or fifth day of the disease with paralysis of all four extremities and the muscles of respiration except the diaphragm. There was complete loss of voice and a moderate amount of temperature. At present the child was regaining power in the extremities, but not in the neck muscles, and there was as yet no phonation. The respiration continued diaphragmatic. He had seen two or three cases of extreme severity; also cases of extreme mildness, cases which presented, after a slight febrile reaction, paralysis of one member, complete recovery taking place at the end of one month or six weeks. The results in each case depended not so much upon the treatment as upon the severity of the infection and the temperature.

Dr. HENRY DWIGHT CHAPIN reported one case with respiratory phenomena. This patient left the hospital and he could not tell how it terminated. In 1900 he was called to Poughkeepsie for consultation as to the nature of an epidemic. There were about 60 cases in which pain in the extremities was the marked feature, and it was uncertain whether they were dealing with a peripheral neuritis or a poliomyelitis. One child died and at autopsy the typical lesions of the latter disease were noted.

Dr. GODFREY R. PISEK said he had seen 12 cases. He wished that more could be said regarding the etiological factor. In eight of the cases there was a previous gastro-enteric infection and it seemed to him quite possible that the bacterial flora were at the basis of the disease. The

feces should be more carefully examined. In six of his cases lumbar puncture, as well as the urinary examination, resulted in negative findings.

Dr. Josephine Hemenway said that there had been 50 cases of poliomyelitis at the Babies' Hospital during the past five years. The cases admitted so far were all severe, involving three or four extremities, and several with neck muscle involvement. All had a sudden onset with rapid recovery. Many of the cases had been diagnosed as cerebrospinal meningitis because of the rigidity of the neck, opisthotonos, and paralysis coming on several days later.

Dr. T. Halsted Myers reported a case which made a remarkable recovery. Within thirty-six hours the paralysis cleared up and in forty-eight hours the coma had entirely disappeared and the child was practically well.

Dr. Charles G. Kerley said he had seen 33 cases. Within the first thirty-six hours of the disease a diagnosis of cerebrospinal meningitis he believed to be quite reasonable. He emphasized the condition of mental apathy, the comatose condition from which it was difficult to arouse the patient, and one case he had seen in consultation had been unconscious for four days. When the patient began to speak it was nearly a week before he could enunciate clearly. He believed the disease to be an infection of some sort.

Dr. Henry Heiman said that of the 36 cases he had seen 11 were hospital cases, 12 dispensary cases, 6 were seen in private practice, and 7 were seen by Dr. Schwarz. The onset was sudden in 30. He believed this to be an infectious disease and therefore vomiting and diarrhea might be expected to be present. Rigidity of the neck muscles was present in 4 of the 11 hospital cases. Blood cultures showed negative results. The blood count showed a leucocytosis. The treatment followed was that advocated by Gibney and Whitman, *i.e.* feet up in the state of flexion and inversion, to prevent the resulting drop-foot.

Dr. Carlton Wallace said that there had been 300 cases of this disease at the Hospital for Ruptured and Crippled during the last few months. In June there were 17 cases; July, 24 cases; August, 86 cases; September, 138 cases; so far in October, 35 cases. According to age, he reported as follows: First year, 24; second year, 80; third year, 77; fourth year, 57; from fifth to eighth year, 41; from eighth to the twelfth year, 17; after the twelfth year, 4, a total of 300 cases. There were 169 males and 131 females. The treatment should be rest during the first three or four weeks; prevent the contractures. Afterwards some sort of stimulation should be employed and the child should be encouraged to use the muscles. He thought the disease to be an infectious one.

Dr. Henry W. Frauenthal presented three photographs illustrating the facial paralysis which occurred in these cases of infantile paralysis.

Dr. Herman Schwarz reported three cases, each representing a type of the disease. In one case, before death, the paralysis of the left lower extremity had disappeared, showing the rapidity with which function might be regained. At autopsy hemorrhages were found in the anterior horns and in the pia mater. In another case, a child of two years had a temperature of 102°. On the following day there was paralysis of all four extremities and of the muscles of the neck. One month later he was completely cured. A third case had rigidity of the neck muscles, temperature, etc., and it appeared as if the child was to be paralyzed. Here were three distinct types of the disease.

Dr. Sidney V. Haas gave some statistics from Dr. Holt's clinic. There were 40 cases, 15 males and 25 females. There was no case under six months of age and none over four years. The onset was sudden in 31 cases. He presented figures showing the frequency of occurrence of certain symptoms.

Dr. I. E. LaFétra believed that a man was justified in being in doubt as to his diagnosis of these cases. The condition from which it must be diagnosed in many cases was cerebrospinal meningitis. In many cases gastrointestinal symptoms preceded the onset. The absence of cellular elements in the cerebrospinal fluid, the absence of leucocytosis in many cases, and the high polymorphonuclear count, made one think that he was possibly dealing with some preceding trouble in the system, or with some atmospheric condition. As to treatment, the spasm should be relaxed by warm baths, and some suggested that they should be given continuously. The application of the ice-bag along the spine was of value. If the temperature was low and there was much pain, the application of a mustard paste along the spine would prove of benefit. In one case he had used chloral with good effect; this relaxed the spasm and quieted the system in general. In cases of severe pain he gave morphine and codeine.

Blood Pressure in Children.—Dr. William L. Stowell read this paper. He said that with the modern sphygmomanometer it was easy to determine the pressure on any vessel under varying conditions. It was found that the carotid of man supported a column of mercury 150 to 200 millimeters high. Blood pressure depended upon many conditions, such as the energy of the ventricular contraction, peripheral resistance, elasticity of the arterial walls, and the volume of blood. The pulse rate and pressure did not necessarily increase together. Some drugs increased the heart's action, as strychnine, while others, like adrenalin, acted chiefly on the vessels and so increased pressure with little or no increase in the number of beats. Increased abdominal pressure raised arterial pressure up to a certain point, but after that point was reached it caused a fall. Stimulation of centripetal nerves caused increased blood pressure; so also did irritation of the cerebral cortex. As a rule, rise in frequency meant rise in pressure. In deep breathing there was an extreme rise in pressure at the beginning of expiration. The tension of the vessels rose and fell with atmospheric pressure. The pressure was low during sleep. Alcohol did not increase the pressure ordinarily, although it increased the pulse rate. Tobacco, on the other hand, had the effect of increasing the pressure through its influence on the vasoconstrictors. It was said that any pressure below 100 millimeters was pathological. After making more general observations, he said that it was evident that vascular tension was lower in childhood than in adult life, his deductions being based on a study of 216 children in health and disease. Seventeen little idiots were examined and exhibited pulse rates and arterial pressure both above the normal. One theory of the cause of epileptic convulsions was disturbance of the vasomotor center in the medulla. Thirty-two of these patients were examined, but the variations from normal were very slight. Very fat subjects had high pressure. Dr. Stowell concluded that blood pressure in the young was low in proportion to extreme youth; its rise and fall was quickly influenced by emotions as in adults; diseases of the nervous system gave high pressure; acute diseases with high temperature might give either high or low pressure; sclerosis of arteries was almost unknown in childhood, so that the use of a sphygmomanometer for its detection was needless; blood pressure readings were of interest physiologically, but had little clinical value in childhood.

Dr. L. Faugères Bishop believed it to be worth while to recognize the mechanism of high pressure because of its important bearing on certain cases. High pressure and cerebral compression was purely compensatory and he referred to Dr. Emerson's experiments at the College of Physicians and Surgeons; a hole was made in the animal's skull and a cannula screwed in. An instrument was introduced into the carotid artery to measure the blood pressure. Whenever the pressure in the cranial cavity was raised the blood pressure in the carotid was raised as well; when it was reduced the blood pressure went down too. The high arterial tension accompanied by cerebral com-

pression he believed to be an attempt on nature's part to maintain the circulation in the brain. When such was the case he did not think it was wise to use nitroglycerine.

Dr. L. E. LaFÉTRA moved that the Chair appoint a committee of three to confer with a committee already appointed by the Neurological Section, that they might take such steps as were necessary in the study of the etiology of poliomyelitis. This was seconded and carried, and Drs. L. E. LaFétra, Josephine Hemenway, and Herman Schwarz were appointed on the committee.

Acute Anterior Poliomyelitis.—Dr. WALTER B. JENNINGS presented this case. A typical history was obtained. The patient was a boy, eight years old, who had always been healthy. On the afternoon of August 29, 1907, the child came to the house from play and complained of being tired. That same night, about 2 A.M., the mother said that the child had an "awful fever," together with a stiff neck. She gave him a hot mustard bath, after which the child went to sleep. The next morning the child appeared to be much better, but remained in bed during the day. There were no gastrointestinal disturbances. Dr. Jennings saw the patient September 6, just one week after the onset, when the patient complained of pain in the left hip and leg, together with loss of function of the entire lower left extremity. Rheumatism was excluded. The skin was cold and had a reddish mottled look. The muscles were flabby and the patella reflex was absent. The boy had as well an enlarged thyroid gland.

NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS.

THE seventh annual meeting of this Association was held at Richmond, Va., October 24, 1907. It was opened with short addresses of welcome by Governor Swanson of Virginia, by Mayor McCarthy of Richmond, and by Dr. Ennion G. Williams on behalf of the medical profession of Richmond. Responses were made for the Association by Dr. Everett Flood of Palmer, Mass., and Dr. Spratling of Sonyea, etc. Reports were read from several States in which there are institutions—Ohio, New York, New Jersey, Massachusetts, Indiana, Pennsylvania, and the Province of Ontario, Canada.

Epilepsy; Its Definition and Treatment.—Dr. J. S. DEJARNETTE of Virginia, offered the following definition, formulated by Dr. Freed and himself: "Epilepsy is a chronic disease, characterized by sudden, occasional, recurring, and involuntary discharges, usually short in duration, from a diseased cerebral cortex; always with psychical disturbance, frequently with convulsions, excluding the diseases paresis, meningitis, and short attacks of mania. The tendency is always towards dementia." He believed that heredity was much more important than generally considered because epilepsy was concealed or undetected in many cases. The writer emphasized the impulsiveness and irritability of the epileptic. Bromide of potassium was advocated most strongly. Colony treatment was recommended most highly because of the control which it was possible to have over the patient.

Alcohol as a Primary and Exciting Cause of Epilepsy.—Dr. THOMAS C. FITZSIMMONS of Wilkesbarre, Pa., said that alcohol was dangerous as a cause of epilepsy not only in the drinker himself, but in his posterity. Especial stress was laid upon the influence of alcohol upon conception. The product of conception when one parent, or both, was under the influence of alcohol at the time, was especially prone to the disease.

The Value of Elimination in the Treatment of Epilepsy.—Dr. J. ALLISON HODGES of Richmond, believed that faulty chemical processes played an important and conspicuous role in the disease; that a hypertoxic condition with inadequate elimination was the underlying basis of the disease. "Clean out, clean up, and keep clean" expressed his idea of the treatment of epilepsy. He reported three cases, in all of which there was an undue proportion of indican and a deficient secretion of urea in the renal secretion. Small doses of strontium bromide were given and dechlorization was secured. General methods for stimulating elimination were employed. The seizures were notably decreased in each case and the general health was markedly improved. In one case there had been up to this time (one year) no return of the epileptic seizures. Their continued improvement for the lapse of a year argued well for the future.

Pulmonary Edema as a Complication of the Epileptic Seizure.—Dr. W. T. SHANAHAN of Sonyea, N. Y., said that pulmonary edema was a frequent and serious complication of grand mal seizures and the status epilepticus. The cause was probably an enfeebled action of the heart. The treatment was the adoption of a posture to aid in draining the respiratory passages, dry cupping, and the use of atropine and strychnine hypodermically, with venesection in full-blooded patients.

Eye Defects in Epilepsy.—Dr. D. D. WILLCOX read this paper, reporting some improvement following work in this direction.

Surgical Intervention in the Treatment of Epilepsy.—Dr. STUART MCGUIRE of Richmond, discussed this subject. His conclusion was that the term "epilepsy" was at present too broad a one on which to base a definite line of intervention. The removal of the sources of peripheral irritation was advised as the first step in the surgical treatment of epilepsy. Direct interference with the brain should be avoided unless there are localizing symptoms.

Surgery as a Therapeutic Measure in the Cure of Epilepsy: a Plea for More Frequent Surgery.—Dr. MATTHEW WOODS of Philadelphia presented a paper with this title. He pointed out the possibility that at times the mere incidents and concomitants of operative procedure, such as disturbance of vasomotor equilibrium, etc., might cause cure, rather than the removal of tumors, cicatrices, etc. While permanent recovery had occasionally followed the removal of abnormal tissues, nevertheless there seemed to be many recoveries when the operation resulted in the removal of either nothing or of such parts as were now believed to have no causative bearing on the disease.

Dr. WHARTON SINKLER presented a case of epilepsy of the family type in which a considerable number of the members of the family were epileptic.

The Heart's Action Preceding the Seizure.—Dr. MUNSON of Sonyea, N. Y., discussed this point. In several cases of epilepsy he found the rate practically unchanged, usually slightly accelerated, before the onset of the convulsion.

The Committee on the Prize Essay reported that no award would be made, but that honorable mention should be made of the essay of Dr. E. E. Southard of the Department of Pathology of Harvard University.

It was the sense of the meeting that every effort should be used to bring about the public care of epileptics in States where no effort is being made at present, and that the facilities in States already having institutions should be greatly increased. This was necessary, not alone because the epileptic was dangerous to himself and to the public at large, but also because under proper regulation of life and habits his condition could be greatly improved. The lot of an epileptic outside of an institution was at best a hard one. He was an object of curiosity, of scorn, of pity. No one would employ him; there was no place for him. In the properly constructed institution he found a place in life where he could work to the best advantage and have all the social privileges he was capable of enjoying, together with the best medical care.

Officers.—The following officers were elected: *President*, Dr. H. M. Weeks, New Jersey State Village for Epileptics, Skillman, N. J.; *Vice-Presidents*, Drs. W. F. Drewry, Petersburg, Va., and Thomas C. Fitzsimmons, Wilkesbarre, Pa.; *Secretary and Treasurer*, Dr. J. F. Munson, Sonyea, N. Y.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 23, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	345	154
Diphtheria	282	31
Measles	293	5
Scarlet Fever	278	17
Smallpox	..	..
Varicella	136	..
Typhoid Fever	86	12
Whooping Cough	27	1
Cerebrospinal Meningitis	4	5
Malarial Fever	..	..
Totals	1451	225

Cancer of the Rectum.—O. Laurent gives the etiological factors in rectal cancer as constipation, traumatism, and hemorrhoids. Age, after fifty-five years in general, but sometimes twenty to thirty. It is localized, especially at the points at which the feces are retained, the cecum and rectum. There are three types: at the anus, in the ampulla, and in the sigmoid flexure. The growth may be pavement epithelium when in the rectal region; it may be of cylindrical epithelium, or the cells may be transformed into muciparous cells. It may be nodular and vegetating, infiltrating, annular, or massive, propagated to the peripheral tissues. It extends into the ischiorectal fossa, the bladder, uterus, or vagina. The neighboring glands are infiltrated quickly. The three cardinal symptoms are pain, severe or heavy bearing down feeling; hemorrhage, profuse or slight and mixed with purulent materials; and constipation, with obstruction at times. Its course is from one and a half to six years. Operation is indicated by mobility. If firmly adherent to the sacrum, excision will be useless. The method may be perineal, vaginal, or abdominoperitoneal. The rectum must be emptied and fluid diet used for a day or two. An artificial anus must generally be made a week before. Schlange's tegumentosacral operation is the best when the growth is at all extensive. By this method the growth is operated on by way of the sacrum with an osteoplastic procedure. Complications are septicemia, gangrene, fistula, and incontinence. The best results are obtained when the sphincter is not involved in the operation.—*La Révue Médico-Sociale.*

Nasopharyngeal Irritation.—J. S. Fraser and J. D. Comrie recently presented to the Edinburgh Medico-Chirurgical Society an interesting paper on the nasopharynx as an infection-carrier in epidemic cerebrospinal meningitis. They pointed out that epidemics of this disease were frequent in seaport and colliery towns. Their investigations were chiefly concerned with the occurrence of the disease in Leith, where up to May 28, 1907, 83 cases have occurred. Most of the cases were found in the densely crowded and poorer parts of the town near the docks. Eighty per cent. of the cases were under 16 years of age, at the period of life when adenoids and nasopharyngeal catarrh were common. The *Micrococcus intracellularis meningitidis* was found in 2 out of 13 cases of epidemic cerebrospinal meningitis examined. This small proportion was due to the fact that isolation of one bacterium was very difficult in the case of patients who were extremely ill and whose nasal cavities swarmed with germs of different kinds. The micrococcus was present in 10 out of 60 contacts; and of those 10, 5 were fathers of patients; and of the 60, 14 were fathers of patients. The organism was present in only 0 per cent. of the mothers, brothers, sisters, and other relatives, but in 33 per cent. of the fathers of the patients. Five of the 14 fathers worked on a particular ship, and on exposing Petri dishes containing ascitic agar in various parts of this ship the micrococcus was found to be present in the air of the engine room. Twenty three controls who had no evident connection with the disease were examined, and in none was the micrococcus found to be present in the nasopharynx. The authors thought the usual methods employed in stopping epidemics were useless when applied to outbreaks of acute cerebrospinal meningitis. Their investigations and those of Ichle pointed to the spread of the disease by the fathers of the patients, causing infection of the nasopharynx by kissing or by expectoration; therefore, all contacts should be isolated and a bacteriological examination of their nose and nasopharynx should be obtained. Those cavities should subsequently be disinfected by very dilute solutions of formalin or other antiseptic.—*British Medical Journal.*

New Method of Reducing Dislocation of the Thumb.—L. B. Burnett states that in view of his failure in a recent case to reduce a dislocated thumb by ordinary methods and in view of the fact that the tension of the flexor longus is one of the chief hindrances to reduction, he made a further attempt at reduction with the wrist completely flexed and he applied the two half hitches of bandage, with which he grasped the thumb to the first phalanx so as to allow the second phalanx to flex and so still further relax the flexor longus tendon. He then pressed the metacarpal bone firmly into the palm of the hand to relax the short flexor; having thus relaxed all the muscles that were opposing reduction he then made traction in the usual way, first backwards, and by the time he had got the thumb straight the dislocation was reduced. He admits that the result may have been a pure coincidence, but believes that the method deserves a further trial.—*The Lancet.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending November 22, 1907:

SIX CASES OF MALIGNANT ENDOCARDITIS.*

BY ALFRED MEYER, M.D.,

NEW YORK.

ATTENDING PHYSICIAN MOUNT SINAI HOSPITAL

IN making a study of the following six cases of malignant endocarditis observed at Mt. Sinai Hospital, I have had a considerable hesitancy as to how to designate them. In spite of a few interesting differences, which will be commented upon later, there are clinically many points of resemblance, and they belong to a class of cases which for many years have been designated as ulcerative endocarditis. My first intention was to call them all malignant *bacterial* endocarditis. Firstly, because they were malignant in their course and ended fatally with septic symptoms more or less acute and pronounced; secondly, because I believe the evidence is strong that they were all of bacterial origin, yet bacteriæ were present in the blood cultures of only three of them. In two the blood cultures were negative, and in one, unfortunately, no blood culture was made, and no postmortems were obtained in the cases with negative findings. Five of these cases occurred in my own service. The case E. B. I had seen privately in consultation, and am publishing through the courtesy of Dr. Brill, into whose service she was subsequently admitted.

CASE I.—H. E., male, seventeen years old, single, schoolboy; streptococcus endocarditis, embolic aneurysm of the ulnar artery; admitted April 11, 1906; died July 2, 1906. Has suffered from cardiac palpitation since his second year. Has also had an ear discharge of many years' duration.

Present Illness.—Sudden onset eighteen hours before admission, with loss of power in his left arm, inability to walk, loss of speech during half an hour. No loss of consciousness. Does not know whether he has had any fever, but sweats profusely.

Physical Examination shows (1) facial paralysis on left side; (2) left-sided paresis; (3) *a*, a loud, rough blowing systolic murmur at apex transmitted all over the precordium and to axilla; *b*, systolic and diastolic murmur in aortic area, the systolic murmur transmitted into vessels of the neck; *c*, systolic murmur in pulmonic area; *d*, thrill at apex; (4) pulse Corrigan in type; capillary pulse present and Durozziez murmur present; (5) spleen palpable two fingers below the free border; (6) liver palpable two fingers below the free border, slightly tender; (7) marked cyanosis and clubbing of fingers and toes with incurvation of nails; (8) no petechiæ.

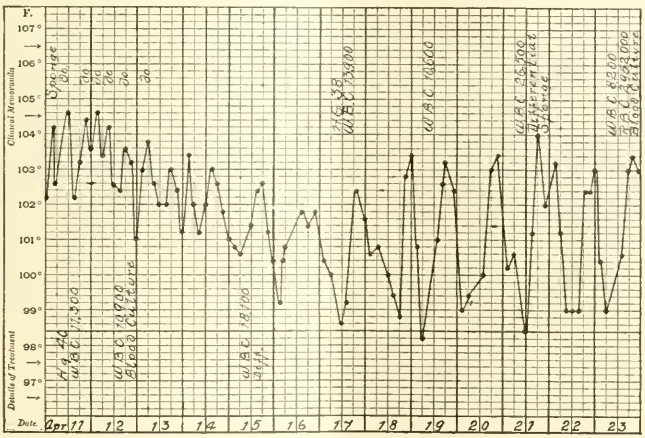

CHART 1.—Patient H. E., Case I.

Fever on day of admission ranged between 102° and 104.6°, pulse between 100 and 132, respiration between 24 and 30. The urine contained a trace of albumin. On May 3 a fusiform swelling was first observed over upper part of left forearm with expansile pulsation, and in which a systolic diastolic murmur could be heard. On May 6 this swelling was the size of a robin's egg. On May 7 and 8, petechial eruption was observed for the first time on lower right lid, on the floor of the mouth, and in the right conjunctival sac. The first blood culture was taken on April 13, amounting to 10 c.c., and streptococcus grown in three days. Subsequent cultures on April 24, 13 c.c.; May 15, 10 c.c.; June 3, 7 c.c.;

*Read at a stated meeting of the New York Academy of Medicine, November 21, 1907.

all showed no growth, but the urine of April 26 showed streptococci. The temperature chart of the first two weeks is shown herewith.

From the third week, and subsequently to the end, the temperature was mostly under 102°. There was progressive anemia with 40 per cent. Hgb. on admission, which gradually fell to 28. The leucocyte count varied between 11,300 and 26,500, with the polynuclears about 55 per cent. The amount of the albumin in the urine gradually increased, and there were varying numbers of red blood cells and casts.

Autopsy.—Lungs: Brown induration; emphysematous. Heart: Right auricle and ventricle enlarged; left ventricle hypertrophied and dilated; old aortic insufficiency with recent friable vegetation on the center of flaps and extending down over entire surface of anterior flap of the mitral valve and chordæ tendineæ; mitral shows moderate o¹d thickening; coronaries negative; heart muscle cloudy. Slight changes at arch of aorta. Spleen congested, fatty. Adrenals, pancreas, and mesentery negative. Kidneys enlarged; capsules slightly adherent; few yellow infarcts. Left ulnar artery: About 6 cm. from

There is headache and anorexia. There was a chill last night, another one this morning, followed by high fever and profuse perspiration.

Physical Examination.—General condition rather poor, complexion pasty. Eyes: Petechiæ in both upper eyelids and right lower lid. Thyroid: Isthmus palpable. Glands: General slight enlargement except the epitrochlears. Lungs: Negative. Heart: Upper border at third space, left border 14 cm. from median line at fifth space, right border 4½ cm. from median line; apex beat 8½ cm. to left of median line; faint thrill palpable; action regular, forcible, and normal in frequency. Murmurs: Prolonged, rough presystolic murmur at apex, followed by accentuated first sound and blowing systolic murmur with faint second sound; the systolic murmur is transmitted into left axilla; the presystolic is well localized; second pulmonic is accentuated; both sounds at the aortic orifice are muffled. Pulses: Equal, small, compressible, no capillary pulse. Liver: Not palpable. Spleen: Just palpable, fairly firm. Abdomen: Negative, save for palpable and somewhat tender right kidney. Extremities: No edema.

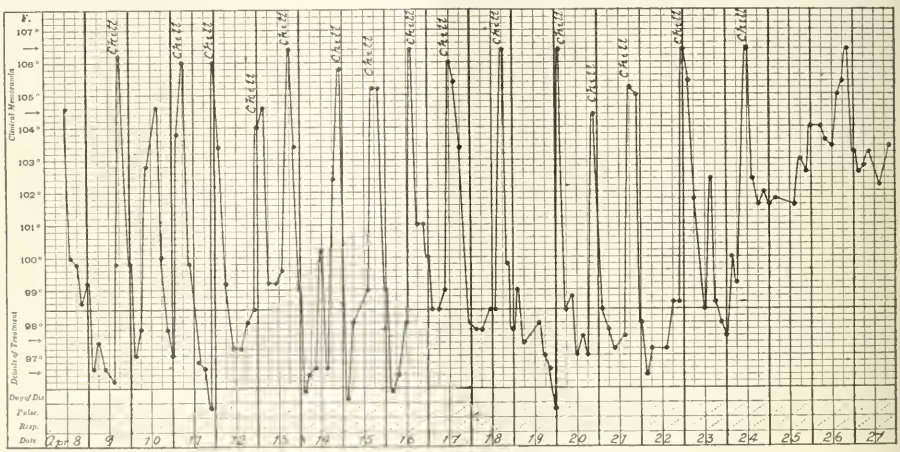

Chart 2.—Patient E. B., Case II.

its origin there is an aneurysm (about the size of a cherry) of the ulnar artery containing dark red clot. Bacteriology of the heart blood: *Bac. muc. capsulatus* and *coli;* no streptococci found.

Case II.—E. B., female, twenty-one years old, single, stenographer. Tricuspid stenosis, mitral stenosis, aortic insufficiency, acute (pneumococcus) endocarditis, chronic nephritis, bladder hemorrhage. Admitted April 8, 1904; died April 27, 1904. Had measles and mumps as a child. No other exanthemata or acute trouble of any kind. No cardiac, pulmonary, nephritic, nervous, or gastrointestinal symptoms; was told, however, that she had had heart trouble when a child. Menstrual history negative.

Present Illness.—Six weeks before admission patient claims to have "caught cold," was sick for five days, and then went to work. A week later she had a chill, followed by headache and fever, and has been in bed most of the time since then, with recurrent chills, slight cough, occasional dyspnea and cardiac palpitation, edema of the feet, and precordial and abdominal pains. No epistaxis or hemoptysis. Has vomited several times in the course of the week. There are three or more loose movements per day.

Fever on the first day ranged between 96.9° and 104.5°. Subsequently, with few exceptions, she had daily chills, the temperature range being between 7° and 10°, on one occasion nearly 11° (95.2° to 106°). The pulse rate varied until the time of her death between 80 and 120, occasionally 70. The last week of her life 40 to 50 (cerebral embolism). Respirations were mostly between 22 and 30. During her last week between 45 and 50. Fresh crops of petechiæ appeared from time to time on both eyelids, on palm of right hand, both lips, and fingers of left hand. Two days before death they appeared over body, including thighs, legs, and dorsum of feet. Three days before death, hemorrhages in both fundi. On April 13 the blood culture showed the pneumococcus 220 colonies to the c.c. The leucocyte count varied between 11,000 and 21,000. The auscultatory evidence in the heart showed no changes in the sounds and murmurs with the exception of the development of a slight diastolic murmur over the aortic orifice. On April 13, five days after admission, patient did not respond to questions, and it was found that she had aphasia and complete right-sided hemiplegia and facial paralysis. She was wholly

unconscious between April 21 and April 23, with but slight improvement before the final coma and her death. The urine, which in the beginning had only traces of albumin, subsequently showed considerable amounts with occasional hyaline casts and some red blood cells.

Autopsy.—Pleura: Some adhesions. Lungs: Right lower lobe congested; upper lobe emphysematous, edematous; middle lobe, emphysema; left lung, brown induration. Heart: Weight, 405 gms.; right auricle dilated; tricuspid flaps show old and recent vegetation; left auricle dilated; sclerotic and calcareous patches; aortic orifice shows marked insufficiency; mitral flaps shortened; yellow-red vegetations in flaps; a few yellow-red vegetations on auricular surface of valve; left ventricle evidences of old dilatation; heart muscles soft, cloudy, interstitial myocarditis; aortic flaps marked thickening and some calcareous deposit. Spleen: Chron. interst. splenitis, anemic infarcts. Kidneys: A few petechiæ on surface; markings poor; few small anemic infarcts; some petechiæ in pelves. Aorta: Fatty degeneration; just above bifurcation, and extending up one-half cm. and into each of iliacs, a firm, granular, thrombus, gray throughout, slightly adherent. Liver: Recent perihepatitis over both lobes; nutmeg. Intestines: Small hemorrhages in wall. Bladder: Hemorrhagic areas. Ovaries: Negative, right tube petechiæ. Bacteriological of spleen: *B. coli, staphyl. aureus, pneumococcus.*

Case III.—E. D., male, twenty years old, single, tailor. Admitted March 24, 1906; died July 31, 1906. Mitral stenosis and insufficiency, aortic stenosis and insufficiency; streptococcus endocarditis. Had measles as a child. Has had a chronic cough without expectoration. No acute illness of any kind, except some slight sore throat.

Present Illness.—Of two weeks' duration prior to admission. Sore throat, night sweats, cough, edema of the face, and weakness.

Physical Examination.—General condition poor, marked pallor. Heart: A presystolic systolic thrill at apex; a slight diastolic impulse is felt at third left intercostal space; a presystolic, systolic diastolic murmur at the apex; at the base a loud systolic diastolic murmur; in vessels of the neck a blowing systolic murmur. Spleen: Just palpable below the free border of the ribs. Liver: Not palpable. Abdomen: Fluid wave present. Glands: General slight enlargement.

The temperature during the first week was nearly normal. Subsequently it was of a septic type, fluctuating mostly between 98° and 102°, but mostly with a range of 6° (98°-104°) in the eighth, eleventh, thirteenth, and sixteenth weeks. The pulse rate varied between 90 and 130 and the respirations between 24 and 40. The first blood culture was made on April 19; 12 c.c. were taken and showed streptococci in seventy-two hours. Petechiæ appeared on April 20 in left lower conjunctival sulcus. Subsequent cultures on May 15 (11 c.c.) and June 13 (1.5 c.c.) were negative. Fresh petechiæ in the lower lid were seen on April 27, May 17, 24, and 29, June 17 and June 22. They were not observed on any other part of the body. On June 26, after the patient had been out of bed for three days walking about, a profuse hemorrhagic eruption appeared on both legs, extending in a day or two above the knee. The spots were the size of a pea and dark in color. July 2, fresh petechiæ in left lower lid and on left upper jaw and behind last molar. July 4 and 5, new spots on conjunctivæ, also on July 11, and on the legs July 20 and 26. Hgb. 60 per cent. on admission, afterwards 45 per cent. Highest leucocyte count, 7,400. The endocardial murmurs underwent no change during the course of the disease. Liver and spleen both increased in size in the course of a few months. On July 19 the liver was palpable 7.5 cm. below free border in mammary line. On April 23 the edge of the spleen could be felt at the crest of the ilium. On July 2 it was palpable in the anterior axillary line 9.5 cm. below the free border. No crepitations audible over it. On April 7, both kidneys were palpable. Red blood cells were found in the urine from time to time, although guaiac reaction was negative throughout. Albumin was only present in faint traces, also an occasional hyalogranular cast. No autopsy.

Case IV.—A. S., male, twenty-three years old, single, tailor. Admitted June 9, 1906; died July 16, 1906. Aortic stenosis and mitral insufficiency. At age of fifteen years had an attack of chorea following trauma on back, and repeated attacks of subacute articular rheumatism, followed by cardiac disease. Then there succeeded palpitation, shortness of breath, and edema of legs. Each winter he would have an attack of fever with temperatures of 100° to 102°, and an exacerbation of these symptoms, occasional attacks of rheumatic pains with swelling and impairment of function in joints of hands, feet, ankles, knees, elbows, and shoulders.

Present Illness.—Of seven weeks' duration, with an increase of the above symptoms associated with a reduction in the amount of urine, ascites, edema of legs and face; tenderness in right hypochondrium.

Physical Examination.—On admission there were no joint symptoms, nor did any develop subsequently. Heart: The heart was enlarged to the right and left; apex beat 12.5 cm. from median line; there was a loud, rough systolic murmur at apex transmitted to the left axilla; pulmonic second markedly accentuated; aortic second accentuated, a systolic blow in aortic area. Liver: Pulsating and enlarged. Spleen: Enlarged, no clinical evidence of infarcts.

Temperature on admission 100° plus, afterwards varying between 97° and 102°. Pulse on admission was 90, respiration 38. Pulse afterwards varied between 80 and 90, excepting for a short time, when it dropped to 36 after the use of digitalone (10 minims q. 4 h.). The slow pulse rate was in part due to imperfect systole, so that at times the apical impulse would be 112 and the radial pulse 90. Respirations ranged mostly from 26 to 28. Petechiæ first appeared on June 26, seventeen days after admission. A blood culture taken on the following day (14 c.c.) proved negative. Second crop of petechiæ appeared two weeks later on the hard palate, abdomen, and retina (the first crop having appeared on back, thighs, and elbow). In neither crop were the eyelids involved. On admission the Hgb. was 72 per cent. and the leucocyte count 13,400. The highest leucocyte count was 18,600 one day after the appearance of petechiæ. At no time did the urine contain any red blood cells; no autopsy.

Case V.—M. H., male, twenty-eight years old, single, tailor. Admitted December 31, 1905; died February 7, 1906. Mitral stenosis and insufficiency. Had measles, scarlet fever, and smallpox in childhood, cardiac symptoms some years before admission, dyspnea, muscular pains, edema of legs one year before admission. First chill six months before admission.

Present Illness.—Probably dates from first chill

six months ago; complains of pain in his joints; took to bed six weeks ago.

Physical Examination.—Marked pallor; fairly well nourished; slight general enlargement of glands. Heart: Apex beat forcible, diffuse and heaving in fourth and fifth spaces; right and left ventricle both enlarged; thrill felt over entire precordium. Murmurs: Presystolic systolic murmur at apex, second pulmon. accent. Veins: Pulsation visible in the neck. Liver: Enlarged and tender. Spleen: Hard and large. Extremities: Slight clubbing of fingers.

Temperature was normal for the first week. In the second and third weeks normal, with single sudden rises to 101° and 102°. In four and fifth week, nearly normal, interrupted by a single chill in each week, and followed by a rise to 104.8° and 103.8°, respectively. No acceleration of pulse or respiration

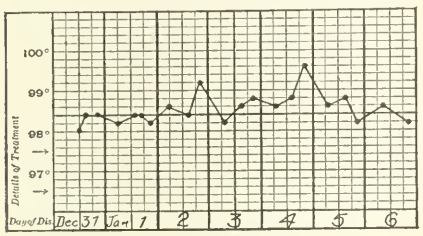

Chart 3. —Patient M. H., Case V.

during whole disease. January 13, pain in right knee, which is hot and red; ankle also painful. February 2, petechiæ in palpebral conjunctiva and skin. Few small hemorrhages in right fundus. Blood culture February 3, 5 c.c. negative. February 3 and 4, pain and tenderness over spleen with friction sound. Urine always contained albumin and casts. Red blood cells not always present, but showing a tendency to reappear after chills. The Hgb. varied from 60 to 35 per cent, white blood cells 7,500 to 7,800. Sudden death, preceded by bradycardia (48) with severe precordial pain not previously noted, except once before, during a chill. These agonal symptoms lasted about four hours. (Embolism of the coronary artery?) No autopsy was performed.

Case VI.—M. F., female, thirty-one years, single, domestic. Admitted October 1, 1902; died October 4, 1902. Mitral stenosis and insufficiency. Had measles in childhood. Acute articular rheumatism one year ago. Fracture of left wrist and left leg by falling down a flight of stairs about same time.

Present Illness.—Of indefinite duration; chief complaints shortness of breath, cough, palpitation, bloody expectoration, swelling of legs, vomiting and chills.

Physical Examination.—Heart: Thrill at apex, presystolic-systolic murmur at apex and in pulmonic area. Petechiæ: On conjunctiva and soft palate day of admission. Liver: Tender.

Temperatures 101° to 104.4°. Red blood cells in urine. Hgb. 72 per cent., white blood cells 21,600. No autopsy was had.

Other authors have had trouble with the nomenclature of cases similar to the six here briefly narrated. Bouillaud (1824-1832) spoke of acute endocarditis with pyemic symptoms. In 1880, Wilkes spoke of arterial pyemia. Osler, I believe, introduced the term malignant endocarditis, because of the proneness to a fatal issue (Goulstonian Lectures, *British Medical Journal*, 1885). Other names applied to such cases have been infective endocarditis, diphtheritic endocarditis, mycosis endocardii, malignant ulcerative endocarditis. Dreschfeld, in "Allbutt's System of Medicine," places them among the septic diseases, yet Litten very pointedly asks (*Deutsche medizinische Wochenschrift*, May 22, 1902), "Are we justified in calling an endocarditis septic because microorganisms are found in the blood?" He thought not, and inquired "What would become of this view if a bacterial basis were established for acute articular rheumatism?" I might add that a possible source of error may lie in the fact that a patient with an old valvular lesion may acquire a bacteriemia from some intercurrent disease entirely independent of the heart condition and without fresh involvement of its structures. On the other hand, it must be admitted, that with the introduction of new and more favorable media, organisms may be found in blood cultures of cases of malignant endocarditis in which at present the results are negative. This may have applied in the past to cases of gonococcal endocarditis.

An exceptional attitude is taken by Gibson ("Diseases of the Heart and Aorta"). He does not discuss the malignant or septic type as an entity at all, but classifies all types clinically into three groups: acute, subacute, and chronic. He believes that most cases of acute endocarditis are of "septicemic origin." Adams, in the *Jacobi Festschrift* (p. 432) also bemoans the confusion in the classification, "the descriptive adjective being subject only to the license of the author." Dreschfeld has described four varieties of infective endocarditis: the septic, the typhoid, the cerebral, and the cardiac. Broadbent ("Heart Disease," third edition, p. 29) protests against this classification as misleading and unsuitable. He says that in the first three types the *essential feature* is the presence in the circulation of pyogenic microorganisms sufficient in number and virulence to destroy their host, and that the affection of the endocardium is secondary and of minor importance and the cardiac symptoms usually ill-marked. He deems it advisable, therefore, not to include these types of septicemia under "infective endocarditis." He wishes the term restricted to cases running a more chronic course, in which the microorganisms attack a valve already diseased and the cardiac symptoms are prominent. To me this protest does not appeal, because it accentuates a difference in the severity, duration, and extent of the infection rather than any difference of underlying cause. This classification makes for convenience of observation, study, and instruction, just as classification into salient types of typhoid fever, pneumonia, and other diseases serves a similar purpose.

Etiology.—A list of different organisms actually recovered from the blood during life, and from the heart lesions (?) after death, is a long one. The most frequent appear to be the pyogenic organisms: Staphylococcus, streptococcus, pneumococcus, meningococcus (Warfield and Walker quoted in the Medical Record, February 20, 1904, p. 302). *Bacillus coli, Gonococcus, Bacillus typhosus, Micrococcus aureus*, and *Streptococcus mucosus capsulatus*. It must have been an oversight for Gibson to say in 1898 (*l.oc. cit.* p. 305) "That it appears doubtful whether diphtheria can give rise to endocarditis," when Howard had already published in 1893 a fatal case of "ulcerative" endocarditis of the mitral valve due to the diphtheria bacillus (Johns Hopkins Hospital Bulletin, Vol. IV). In the discussion which followed the presentation of the case,

Welch characterized it as the first recorded case of "diphtheritic endocarditis." In fact, Gibson contradicts himself on a subsequent page (405) when he says: "The Klebs-Loeffler bacillus may be present in those out-of-the-way cases of endocarditis appearing during the course of diphtheria."

Etiology.—In studying the etiology of my cases the most striking feature is the predisposing influence of preexisting chronic endocardial disease.

Case I.—Cardiac trouble from infancy, clubbing of fingers and toes.

Case II.—Cardiac trouble in childhood, hypertrophied dilated heart.

Case III.—Uncertain.

Case IV.—Chorea, acute articular rheumatism, and cardiac trouble eight years.

Case V.—Blood-tinged sputum four years before, dyspnea, and edema of legs one year, slight clubbing of fingers.

Case VI.—Acute articular rheumatism one year before, uncertain.

This agrees with the experience of other observers. In Kanthack and Tickell's eighty-four cases with autopsies observed in St. Bartholomew's Hospital from 1890-1897, 85 per cent. had old cardiac lesions.

In this connection I would mention the experiments of Wyssokowitch, made under the guidance of Professor Orth, which have been referred to by most recent writers on the subject. He produced endocarditis in animals by injecting staphylococci and streptococci into the blood *after injuring the aortic valve* by introducing a sound into the carotid. I must mention, however, that Ribbert succeeded in producing myocarditis and endocarditis in the rabbit by injecting a potato culture of *Staphylococcus aureus without previous injury*. In both series of experiments the microorganisms appeared to infect the valves directly from the blood current—a type of mechanical inoculation—though Köster had shown (*Virchow's Archiv.*, Bd. 72) the great probability of the *embolic* origin of the process in the human subject when he saw groups of capillaries stuffed full of micrococci and could follow them into the arterial branches.

Age.—All of my cases were young individuals between seventeen and thirty-one years. This is not entirely explained by the fact that I have only an adult service, cases over 14 years of age, for there are many cases of old people with valvular lesions, and they give no contingent to the acute infective type. My experience is also in agreement with that of other writers. I will only mention Dreschfeld's forty-five cases (Allbutt), average age equaled 33 years. Adams (*Loc. cit.*) was able to collect only 47 cases in the whole literature of the subject affecting children under 14 years of age.

In the children's service at Mt. Sinai, out of a total of 527 cases of all kinds in the year 1905, there were 43 cases of endocarditis, and only 1 of these was a malignant endocarditis.

To fix the *cause and time of infection* is attended with a great deal of uncertainty and in many cases it is an impossibility. This is partly because hospital cases come under observation long after such infection has taken place, because the causes of such infection are so manifold and have so many possible portals of entry and because in many cases the infecting lesion is a very slight one.

In Case I. the otitis media may have been the source; in Case II. possibly a slight pneumonia; in Case III. possibly a slight tonsillitis two weeks before admission; in Case IV. unknown; in Case V. unknown; in Case VI. unknown, unless it be fracture of wrist and leg.

Of the symptoms the most interesting are the fever, the petechiæ, symptoms due to infarcts of internal organs, and the glandular enlargements.

Fever is almost always present, sometimes with wide daily ranges. (See chart E. B.) Still exceptional cases occur in which there may be no fever during part of the course, as during the first week in M. H. Fazio reports a case fatal in six weeks without fever (*Gazzetta degli Ospedali*, 1903, XXIV., No. 29). The chart of Case H. E. is probably more characteristic than either of the other two. It is worthy of note that the three cases in which the blood cultures were positive (H. E., E. B., E. D.) were the ones with the most striking septic or pyemic curves, though I do not wish to say that this is always so; in fact in the case H. E. the blood finding was positive at a time when the curve was not pyemic and negative when the curve was pyemic in character.

The *pulse-rate* as a rule varied with the temperature, and no diagnostic and prognostic hints could be obtained from it.

The presence of *petechiæ* in the skin, however, very much strengthened the diagnosis of malignant endocarditis. They were present in all six cases at one time or another. In several cases they appeared in successive crops. They were not always present on admission. In three cases they did not appear until 17, 26, and 28 days later (Cases A. S., H. E., E. D.). There was no regularity in the appearance of successive crops. Thus in one case, E. D., there were intervals of 1, 6, 7, and even 20 days. The presence of conjunctival petechiæ has been mentioned by various authors. The importance of this observation is increased by the fact that sometimes petechiæ are found in the conjunctiva before they occur elsewhere. This was so in Cases E. D. and E. B. In fact, in Case E. D. the eyelids were the only site involved for 2 months and 5 days, at which time they first appeared on the skin.

Relation of Petechiæ to Culture Findings.—Contrary to expectations, blood cultures made 24 hours after fresh crops of petechiæ proved negative on two occasions (Cases A. S., E. D.). It may be that cultures taken immediately upon their discovery might have given a different result. In one of these cases (E. D.) the culture was positive (streptococci) on April 19, a day *before* a fresh crop of petechiæ. Repeated negative cultures (three times each) in two cases (H. E., E. D.), in which the findings had previously been positive, suggest caution in laying too much stress upon negative cultures.

Retinal hemorrhages were found in three cases, once not until three days before death (E. B.). Their presence seems to forebode an early dissolution. Death occurred in five and six days respectively after their discovery in the other two cases.

Proof of *splenic infarcts* from the presence of a perisplenic friction sound was found but once (M. H.). The enlargement of the spleen found in three cases was in all probability mainly due to the old valvular lesion.

The *urine* of five of the cases contained red blood-cells at various times. In one case (E. D.) their appearance coincided several times with that of the petechiæ in the skin—they were probably of embolic origin; in the other cases they may have been due to the accompanying nephritis.

Other Embolic Complications.—Two of the cases were complicated by cerebral emboli, and one by embolic aneurysm of the ulnar artery (H. E.), prob-

ably bacterial in origin. That these aneurysms need not always be of bacterial origin has been shown by Libman in a case occurring in the hospital. Repeated blood cultures had been negative—the autopsy showed no acute endocarditis, but a large mass of calcareous vegetations and a piece of lime in an aneurysm of the iliac artery.

Enlargement of Lymphatic Glands.—This is a symptom not generally mentioned in connection with malignant endocarditis; its occurrence in three out of my six cases (E. B., E. D., M. H.) justifies a more frequent searching for this sign. As a rule the glandular enlargement does not appear to be accompanied by a leucocytosis, as the highest count in one case was 7,400 (E. D.), in another 7,800 (M. H.), and in a third (E. B.) varied from 11,000 to 21,000.

Diagnosis.—Just a few more words about diagnosis. By reference to the histories it will be observed that in all of the six cases here reported there was plain evidence of cardiac involvement. This naturally made the diagnosis easier. But all authors agree that there may be neither auscultatory nor percussion evidence of cardiac disease, and the diagnosis may thus be rendered more difficult. I have seen such cases myself. Romberg says the heart can act quite normally (as it did in 16 out of 42 cases), in spite of enormous endocarditic deposits on mitral, tricuspid, and aortic valves, and offers the interesting explanation that the excrescences are so soft in these cases that they do not disturb the opening and closing of the respective orifices. On the other hand the gradual evolution of a murmur, with progressive changes in its character from day to day and week to week, has been looked upon as strong corroborative evidence of cardiac involvement in cases giving other evidences of sepsis. But this is not always so. I had striking proof of that fact this winter. In a case of cryptogenetic streptococcemia in a girl of 16 years, with chills, fever and sweats, jaundice, repeated positive blood findings (streptococci), multiple thrombophlebitis, and suppurating joints, there was such a progressive evolution of a bleating murmur in the pulmonic area, and at the autopsy the heart and valves were found to be normal. The murmur had been of purely hemic origin.

Elimination of Bacteria.—Churchman has written in *American Medicine* (Vol. XI., No. 3, p. 111) a very complete review of the literature of the bacteriology of the urine in relation to surgery, and concludes that "the normal kidneys, while possibly not absolutely impermeable to bacteria, play a very unimportant rôle in helping to rid the body of organisms. Only when they or their vessels have been injured do the bacteria escape in any quantity. Organisms brought to the normal kidney meet their fate, for the greater part at least, by passing into the gland substance rather than through it into the urine." I am sorry that this question of elimination in the urine was not studied in a routine way; I have only one positive case to report, that of H. E., in which streptococci were found once. This limited finding is, under the circumstances, no criterion of the frequency of excretion of bacteria by the kidneys in such cases.

Treatment.—Most writers agree that at present cases of malignant endocarditis are beyond our control. Treatment was of no avail in any of my cases in averting the fatal issue. Besides the use of a variety of cardiac stimulants (caffeine, digitalis, strychnine, sparteine, digitalone, and camphor), which entered more or less into the treatment of all the cases, sodium salicylate was given to three cases—in one of these as high as 25 grains every 2 hours for one day, in another 20 grains every 2 hours for four days. Broadbent considers salicylates as "worse than useless." To me, however, there appears justification for their use in the fact that they are valuable in benign endocarditis, and in the beginning the differential diagnosis may be uncertain. In two cases inunctions of ungt. Crede were employed—in the case of E. D. b.i.d. for 17 days, then once daily for 30 days, making the whole inunction treatment cover a period of eight weeks. In one case (E. B.) an intravenous injection of 1 c.c. of a 10 per cent. silver nitrate solution mixed with 500 c.c. of water was tried. A number of writers refer to the use of quinine. Romberg (p. 365) mentions prompt improvement after the use of this drug, and ultimate recovery. He is careful to accentuate, however, that this was after and not necessarily because of its use. I believe that a more extended trial of this drug ought to be made in carefully observed cases. It was used in but one of those here reported (E. B.), and it did not appear to be of service; but the administration was not begun until six weeks after the onset of acute symptoms, and this can scarcely be regarded as a fair test.

Much was expected by the profession from the various sera. Thus far the results have been very disappointing, and my personal experience with them in the mixed infection of tuberculosis, in sepsis without endocarditis, and in a private case of pneumococcus endocarditis have not impressed me with their value. Still, Nathan Raw reported recovery in two cases of malignant endocarditis with polyvalent antistreptococcus serum (*Lancet*, April 21, 1906). Theoretically intravenous injections of dilute formalin solutions might have promised some favorable results, but W. H. Park's conclusion that they were dangerous in septicemic rabbits discouraged me from their employment.

For the culture methods employed in these cases I must refer the reader to the report of Dr. Libman of the pathological department, published in Mt. Sinai Hospital report for 1905 and 1906.

785 Madison Avenue.

PERFORATED GASTRIC AND DUODENAL ULCER; A REPORT OF EIGHT CASES.

By CHARLES H. PECK, M.D.,

NEW YORK.

ATTENDING SURGEON TO FRENCH HOSPITAL; JUNIOR ATTENDING SURGEON TO ROOSEVELT HOSPITAL.

The present series of eight cases of perforated gastric and duodenal ulcer, operated upon during the past four years at the Roosevelt and French Hospitals with six recoveries and two deaths, illustrates some of the practical clinical aspects of the condition. Seven of the cases presented acute perforation with more or less extensive peritonitis at the time of the operation, and of these five recovered. Four of the patients are in good health at the present time, the fifth I have been unable to trace. Two died, one having had perforation three days, the other fifty-three hours prior to operation, the cause of death in each case being the extensive generalized peritonitis present at the time of operation. The five acute cases which recovered were operated upon at four, six, eight, thirteen, and twenty-nine hours respectively after the onset of acute symptoms of perforation. In all five there was a more or less extensive escape of the gastric contents with a cor-

responding degree of peritoneal effusion and peritonitis.

The clinical picture presented was quite typical in four of the seven acute cases and the diagnosis was made without difficulty prior to operation. In cases 4, 6, and 8 the signs of diffuse peritonitis, located chiefly in the right half of the abdomen, were thought to be due to appendicitis, the escaped gastric contents having followed the colonic gutter downward.

Case 7, perforation with inflammatory adhesion to the abdominal parietes preventing escape of gastric contents, is of a different type, as the history which is given in detail will show. In six cases the perforation was situated on the anterior wall in the pyloric half of the stomach. In case 6 it was posterior, discharging into the lesser sac, and in case 8 it was in the duodenum, less than half an inch from the pylorus. In case 1 it seemed to be immediately at the pylorus, the dense mass of inflammatory exudate making it almost impossible to definitely locate the pylorus. In the six cases in which the perforation was on the anterior wall, it was usually about midway between the greater and lesser curvatures and always within the limits of the pyloric half.

The size of the perforations varied from that of a pencil point to an opening sufficient to admit the index finger. Leakage of stomach contents had occurred in all seven of the acute type, and except in case 8, where the exudate was chiefly in the right half of the abdomen, all parts of the peritoneal cavity contained particles of food and seropurulent fluid.

Inflammatory infiltration of the stomach wall surrounding the perforation, usually for a radius of 1 to 1½ inches, was marked in all except cases 6 and 8, and rendered closure of the perforation by suture difficult, both on account of the rigidity of the tissues preventing infolding, and the tendency of sutures to cut out.

In spite of this fact, no leakage or gastric fistula occurred in any of the cases. Six of the eight cases gave a distinct previous history of pain after eating, and vomiting, for periods ranging from three weeks to seven or eight years, but only one had ever vomited blood. In six cases the onset of the symptoms of perforation came suddenly and except in case 1, without any immediately preceding exacerbation of the gastric symptoms, while the patients were following their usual occupations. In two cases (2 and 8), the perforation seemed to be caused by lifting a heavy weight; but in none of the others was there any history of unusual muscular effort or of any particular indiscretion in diet. I distinctly recall a case occurring in my service when a hospital interne, in which symptoms of acute perforation followed the passage of a stomach tube by myself. The patient, who was not operated upon, died within a few days of diffuse peritonitis.

As previously stated, the clinical picture in four of the seven acute cases was typical and the diagnosis was made prior to operation. The other three were mistaken for appendicitis with peritonitis. The symptoms were a sudden onset with violent epigastric pain, vomiting, and collapse; progressively increasing pain, tenderness, and board-like rigidity, most marked in the upper half of the abdomen, with a rising pulse and temperature, and in the later cases (3, 4, 5, and 6), abdominal distention. Complete loss of the area of liver dullness was noted in cases 2 and 4; it was absent in cases 1, 5, and 8, and not noted in the other two. Signs of fluid (shifting dullness in the flanks) was noted in all the acute cases except 1 and 8.

Six of the patients were males, and two females; their ages ranged from 22 to 45 years.

The operative procedure followed was similar in all of the cases, and briefly, consisted of closure of the perforation by suture, without attempt to freshen the edges or to excise the ulcer. The friability of the inflamed stomach wall surrounding the ulcer made careful closure difficult, but it was successfully accomplished by using a mattress or purse-string suture passed deeply into the tissues at some distance from the edge of the perforation, and tied just tightly enough to bring the edges of the opening together. The entire area was then infolded by Lembert sutures, which were placed beyond the area of greatest infiltration, and in less danger of cutting out. No leakage or gastric fistula occurred. Black silk was the only material used.

Gastroenterostomy was not performed in any of the cases. The peritonitis was treated by flushing with salt solution through the Blake tube, which was passed to the pelvis, both flanks, the subdiaphragmatic space, and all parts of the peritoneal cavity to insure thorough cleansing. No attempt was made to drain except at the site of the sutured perforation, which was protected in all of the acute cases by one or two cigarette drains.

It is worthy of note that in spite of the fact that gastroenterostomy was not performed nor was any attempt made to excise the ulcer in any of the six cases which recovered, four of them have been followed for periods ranging from eight months to nearly four years without recurrence of serious gastric symptoms. Case 1 was also free from symptoms during the few months in which he was under observation and case 8 is well, but just out of the hospital. While there are too few cases in the series from which to draw definite conclusions, it is at least demonstrated that a certain number of patients suffering from ulceration extensive enough to infiltrate a large area of stomach wall, and to perforate, can make a good recovery without excision of the ulcerated area or the performance of gastroenterostomy. That such is the case is an important fact to bear in mind, for patients with perforated gastric or duodenal ulcer, when presented to the surgeon for operation, are as a rule in no condition to bear protracted operation or prolonged manipulation of the abdominal contents. In my opinion it is preferable to make the operative procedure as simple and short as possible, leaving the question of future trouble, should it occur, to be dealt with by secondary operation, and concentrating our efforts on the immediate recovery of the patient.

Case 1.—Perforated gastric ulcer; operation four hours after perforation; recovery. (History No. 69, 1904, First Surg. Div., R. H.) J. R., male, 23 years of age, teamster, had been troubled with indigestion for two years or more, frequently having about an hour before eating, or two or three hours after, severe knife-like pain in the epigastric region with vomiting. Would produce vomiting by putting finger in pharynx to relieve pain. Never vomited blood nor passed blood by the bowel. Five months before admission was in a hospital for about a week under medical treatment for the pain. Quite marked alcoholic habit. On the evening before admission he ate a light supper about 9 P.M. and had some abdominal discomfort. At 2 A.M. he was awakened by a violent cramp-like pain in the epigastrium and a desire to defecate. He drank a

large amount of water which was at once vomited, and the vomitus contained blood. About two hours later he was brought to the hospital in the ambulance.

On admission, temperature was 98.4°, pulse 124, resp. 28; no leucocyte count was made. There was extreme tenderness and board-like rigidity in the epigastric region. No loss of liver dullness was detected; the breathing was shallow; expression anxious. A diagnosis of perforated gastric ulcer was made, and operation was performed at 5:50 A.M., a little less than four hours after the onset of the acute symptoms.

A median incision was made above the umbilicus, and gas and turbid fluid escaped on opening the peritoneal cavity. The perforation was found on the anterior aspect of the pylorus itself, as nearly as the exact site could be determined, for the surrounding tissues were much thickened and infiltrated, and bound down to the under surface of the liver and the region of the gall-bladder.

The perforation was closed as well as possible by two tiers of silk Lembert sutures, the closure seeming unsatisfactory on account of the friability and thickening of the adjacent stomach and duodenal wall. The turbid fluid and gastric contents were then washed from all parts of the abdomen and pelvis by flushing with salt solution through a Blake tube. A large cigarette drain was placed down to the site of the perforation emerging at the upper end of the abdominal incision, and the remainder of the wound was closed by layers, in the usual way.

Convalescence was rapid and uneventful. There was some vomiting on the second day, and a few saline and nutrient enemata were given. Fluids by mouth were commenced on the third day and soft diet about the eighth day. The drain was removed on the fourth day and all stitches on the ninth day. He left the hospital, cured, on February 1, twenty-two days after the operation. He was followed for some months, remaining well, and was then lost track of. The probability of the development of pyloric obstruction from stricture, owing to the site of the ulcer and the surrounding inflammation, was considered, but there was no evidence of such a result when last seen.

Case II.—Perforated gastric ulcer; operation six hours after perforation; recovery. (History No. 101, 1904, 1st Surg. Div., R. H.) H. Z., male, 22 years of age, had been troubled with pain in the left inguinal region and anterior aspect of left thigh for some months, and had been under medical treatment for it. He had never complained of symptoms of indigestion until about three weeks before admission to the hospital, when he began to have pain after eating and occasional vomiting. He worked as usual on the day of admission, January 21, 1904, until 4 P.M., when, after lifting a heavy weight, he was seized with violent abdominal pain. He was given a drink of brandy, which he promptly vomited. He was brought to the hospital in an ambulance, and on admission had a temperature of 102.2°, pulse 124, resp. 28, leucocyte count 16,000. There was marked general tenderness with rigidity over the entire abdomen, somewhat greater above the umbilicus, but not distinctly localized. The greatest pain was in the left inguinal region, and anterior aspect of thigh, the site of his old pain. There was complete loss of liver dullness and shifting dullness in the flanks; no distention. A diagnosis of perforated gastric ulcer was made.

Operation was performed at 10 P.M., six hours after the onset of the attack. Gas and turbid fluid escaped on opening the peritoneum, and a perforation about a quarter-inch in diameter was found in the anterior stomach wall about two inches from the pylorus, midway between the greater and lesser curvatures, from which stomach contents were escaping. The surrounding stomach wall was much indurated. The perforation was closed with two tiers of silk Lembert stitches, the peritoneal cavity thoroughly flushed with salt solution, removing turbid fluid and particles of food from the pelvis, both flanks, the subdiaphragmatic space, and all parts of the peritoneum, except the lesser sac. A large cigarette drain placed down to the suture line was brought out at the upper angle of the wound, the remainder of which was closed by layers in the usual way. The patient made a good convalescence sitting up on the nineteenth day, and leaving the hospital on the twenty-second day after operation.

Milk and lime water by mouth was commenced on the fourth day and soft diet on the eighth day after operation. There was no leakage from the stomach on removal of the drain, which was done on the fourth day. The last report received from him was in June, 1907, three and one-half years after his operation, at which time he was free from gastric symptoms and in good health.

Case III.—Perforated gastric ulcer; operation 53 hours after perforation; death. (History No. 6, 1905, Surg. Div., French Hospital.) J. L., male, 34 years of age, had suffered from pain after eating, vomiting, and loss of weight for about six months. He was seized with violent epigastric pain and vomiting at about 10 A.M. on December 10, 1904, for which morphine was given hypodermatically.

The seriousness of his condition was not recognized until December 12, at which time he was brought to the French Hospital with signs of advanced general peritonitis. On the typical onset, followed by the rapidly advancing peritonitis, a diagnosis of perforated gastric ulcer was made, and, in spite of the patient's critical condition, an operation was performed fifty-three hours after the onset of the attack. A large perforation on the anterior wall of the stomach, easily admitting the finger, was found, and the peritoneal cavity was filled with purulent serum and escaped gastric contents with many recent adhesions. An advanced stage of general peritonitis was present everywhere. The perforation was closed by silk purse-string and Lembert sutures, the abdomen flushed with salt solution in the usual way, cigarette drains placed down to the suture line, and the wound closed. The patient survived for a few hours only, death being caused by shock and the preexisting peritonitis.

Case IV.—Perforated gastric ulcer; operation 29 hours after perforation; recovery. (History No. 64, 1906, 1st Surg. Div., R. H.) E. B., female, 23 years of age, had been troubled with symptoms of indigestion for several years. In one attack, two years ago, she vomited some blood. There had been no recent exacerbation of her symptoms of indigestion up to about 6 P.M. on the day before her admission to the hospital, when she was suddenly seized with violent epigastric pain, vomiting, and collapse. There was no blood in the vomitus. Symptoms of peritonitis steadily increased from that time up to her admission to the hospital the following evening about 10 P.M.

The abdomen was then greatly distended, there was complete absence of liver dullness, a tympanitic note all over the front of the abdomen with shifting dullness in the flanks. The respiration was rapid and shallow, pulse 138, small and thready, tempera-

ture 102.5°, facies anxious. No leucocyte count was made. A diagnosis of perforated gastric ulcer, with generalized peritonitis was made, and she was prepared at once for the operation, which was performed at 11 P.M. on December 17, 1905, twenty-nine hours after the onset of symptoms of perforation.

On opening the peritoneum through a median incision above the umbilicus, there was a gush of gas and turbid fluid. A perforation large enough to admit the little finger was found on the anterior aspect of the stomach, midway between greater and lesser curvatures, not far from the center of stomach. The perforation was closed with a silk mattress suture, imperfectly buried by Lembert stitches, which were placed with difficulty owing to the friability of the tissue. The peritoneal cavity was then rapidly flushed with salt solution through a Blake tube. Purulent fluid, flakes of fibrin, and particles of food were washed from the pelvis, flanks, subdiaphragmatic space, and every part of the peritoneal cavity except the lesser sac. The abdomen was unusually long and capacious.

Two large cigarette drains were placed down to the site of the perforation and brought out at the upper angle of the wound, the remainder of the incision being closed in the usual way. The patient's condition was critical for some days and the pulse remained high, 115 to 130, for more than a week. There was a rather profuse discharge from the drainage tract for about two weeks, but never any escape of food or gas. Milk was given by mouth at the end of forty-eight hours and soft solids at about ten days. Convalescence was slow, but satisfactory, and patient left the hospital on January 24, 1906, thirty-eight days after the operation. There was still a shallow, unhealed sinus at the site of drainage, and three weeks later a small abscess developed in the abdominal wall, but was soon healed. She has remained in good health up to the present time.

Case V.—Perforated gastric ulcer; operation 8 hours after perforation; recovery. (History No. 479, 1906, 1st Surg. Div., R. H.) J. F., male, 42 years of age, was operated upon five years previously for an abscess in the epigastric region of unknown origin, the operation being performed in one of the large hospitals of this city. He had had more or less trouble with indigestion both before and since this operation, but had not been ill in bed at any other time. There was a moderate, periodic, alcoholic habit. He was taken suddenly ill with violent abdominal pain while walking in the street at 10 A.M. on the morning of the day of his admission to Roosevelt Hospital, June 9, 1906. Signs of diffuse peritonitis were present at 5 P.M., the time of his admission, the tenderness and rigidity being greatest in the right half of the abdomen, and right iliac region. A diagnosis of appendicitis with spreading peritonitis had been made by his family physician, and was confirmed after hasty examination by my house staff and myself.

Operation was performed immediately, eight hours after the onset of the attack. The appendix was removed through an intermuscular incision, and found practically normal. The peritoneal cavity was filled with a milky fluid of aromatic odor containing oil droplets. (Later questioning developed the fact that an aromatic preparation of castor oil had been taken shortly after the onset of the pain.) The incision was closed and a median incision in the epigastric region at once made. There was a perforation on the anterior wall of the stomach about two inches from the pylorus, from which stomach contents were escaping. The perforation was fully a quarter of an inch in diameter, and the surrounding induration had a radius of at least one inch. The pylorus was bound down by old adhesions. The perforation was closed by a silk purse-string suture, buried by two tiers of silk Lembert stitches. The peritoneal cavity was thoroughly flushed with salt solution through a Blake tube. Turbid fluid was washed from the pelvis, both flanks and all parts of the peritoneal cavity except the lesser sac. A large cigarette drain was placed down to the site of the perforation and the remainder of the wound was closed in the usual way.

The patient made an uninterrupted convalescence; the drain was removed about the sixth day; there was no leakage of stomach contents. Signs of peritonitis rapidly subsided, and he left the hospital, cured, on June 28, 1906, nineteen days after the operation. He has remained in good health up to the present time and does not suffer from symptoms of indigestion except when he oversteps the bounds of prudence in his diet.

Case VI.—Perforated gastric ulcer; operation 3 days after perforation; death. (History No. 822, 1906, 1st Surg. Div., R. H.) F. D., male, 36 years of age. Admitted October 27, 1906, and operated upon immediately. Died of general peritonitis on October 30 about sixty hours after operation. Had been ill for three days before admission with abdominal pain, vomiting, fever, and distention. Was too ill when brought to the hospital in the ambulance to give a satisfactory history, and presented signs of advanced generalized peritonitis, thought to be due to appendicitis. Temperature on admission 103°, pulse 132, resp. 32. Under ether an intermuscular incision was made over the appendix, which was removed and found practically normal. The peritoneal cavity contained much free purulent fluid, which seemed to come from above. The wound was covered and a median incision was made above the umbilicus. The anterior surface of stomach, duodenum, and gall-bladder were normal, but much pus was escaping from the foramen of Winslow. The patient's condition prevented prolongation of the operation sufficient to find and suture the perforation. Drains were hastily inserted into the lesser sac through an opening in the gastrocolic omentum, and in Morrison's pouch, and the wounds closed, after flushing the peritoneal cavity with salt solution.

The patient rallied somewhat during the first twenty-four hours, but then failed rapidly. Death occurred on October 30 from generalized peritonitis. As no autopsy was obtained the exact site of the posterior perforation was not determined.

Case VII.—Perforated gastric ulcer; perforation sealed by inflammatory adhesions; recovery. (History No. 1503, Surg. Div., French Hospital.) A. C., female, 32 years of age, had had symptoms of moderate indigestion for seven or eight years. She seldom vomited but had more or less distress after eating. About five weeks before her admission to the French Hospital on February 8, 1907, she was seized with an attack of violent pain in the left upper abdomen, which required morphine for its relief. She did not vomit. Since that time she has had exacerbations of the pain of varying severity, always in the left upper quadrant, one attack requiring a total of 2¼ grains of morphine by mouth for its relief. She had no vomiting and did not think that the pain bore any relation to the ingestion of food. She was confined to her bed for part of the time only, but was unable to attend to her work.

There was some loss of weight, no febrile symptoms, moderate constipation. About five or six days before her admission to the hospital she first noticed a lump in the left upper abdomen. On admission the patient was rather emaciated, abdomen flat and somewhat retracted. Temperature and pulse rate normal. Leucocytes 7,500, polynuclear cells 74.5 per cent., hemoglobin 80 per cent., red cells 4,704,000. Examination of stomach contents showed free HCl 20, combined acid 43; there was no lactic acid, no excess of mucus, and no evidence of food retention.

In the left upper quadrant of the abdomen, two inches above the level of the umbilicus beneath the left rectus muscle, a mass about half as large as a hen's egg was distinctly felt. It was quite fixed, slightly tender, and pulsated so strongly that some of the physicians who examined the patient felt sure that the pulsation was expansile. No diagnosis was made prior to the operation, which was performed under ether anesthesia on February 11, 1907.

Through a 4-inch median incision above the umbilicus, the tumor was found to consist of a mass of inflammatory adhesions, fixing the anterior stomach wall to the anterior parietes beneath the left rectus. Separation of the adhesions revealed a perforation large enough to admit the finger, surrounded by an area of infiltration and thickening of the stomach wall having a radius of 1 to 1½ inches. The perforation was closed by a purse-string suture of heavy silk, buried by two tiers of Lembert sutures. The pylorus and other portions of the stomach wall seemed normal. The lumen of the stomach did not seem greatly enough encroached upon to endanger hour-glass contraction, and gastroenterostomy was not performed. The abdominal wound was closed without drainage. Peptonized milk was given by mouth in thirty-six hours; soft diet commenced on the eighth day. There was no vomiting.

The wound healed by primary union and convalescence progressed without incident. The patient was discharged, cured, on March 4, 1907, twenty-one days after operation. She has been obliged to be careful of her diet since that time, indiscretions being followed by symptoms of indigestion, but with that exception has remained in good health, and has gained a few pounds in weight.

Case VIII.—Perforation duodenal ulcer; operation 13 hours after perforation; recovery. (History No. 851, 1907, 1st Surg. Div., R. H.) B. McA., male, 45 years of age. There was no history of previous gastric trouble except an attack of abdominal pain two years ago, which laid him up for a few days. On the morning of his admission, about eleven o'clock, while lifting a heavy tank of gasoline in the garage where he worked, he was seized with severe abdominal pain. He turned pale, felt nauseated, but did not vomit, and in a short time attempted to go on with his work. The pain continued, however, and he was soon obliged to go home.

On his admission to the hospital at 11 P.M., November 1, 1907, his temperature was 101°, pulse 90, leucocytes 27,000, polynuclear cells 93 per cent. Tenderness and rigidity was general, but most marked in the right half of the abdomen and right iliac region. There was no loss of liver dullness and no free fluid in the peritoneal cavity. The abdomen was not distended. A diagnosis of appendicitis was made, and under ether the appendix was removed through an intermuscular incision and found practically normal. There was a considerable amount of free purulent fluid coming from the upper abdomen. The wound was closed and a median incision made above the umbilicus. A small perforation the size of a pencil point was found on the anterior aspect of the duodenum less than half an inch from the pylorus. There was remarkably little infiltration of the surrounding duodenal and stomach wall, and the pylorus was quite free from fixation. The perforation was closed without difficulty with a purse-string and continuous Lembert suture of black silk.

The peritoneal cavity was flushed with saline solution, the purulent exudate being chiefly in the right colonic gutter and Morison's pouch. A cigarette drain was placed down to the suture line and the wound closed by layers in the usual way.

Convalescence was uneventful. Water by mouth given at the end of thirty-six hours, peptonized milk after sixty hours, soft diet on the sixth day. The drain was removed on the sixth day; there was no leakage; the wounds healed by primary union. About three weeks before the perforation the patient was burned about the face by an explosion of gasoline, but the burn was of the first degree, slight in area, and it seems unlikely that it could have been responsible for the ulcer.

Conclusions.—(1) Perforated gastric or duodenal ulcer should be curable in a good percentage of cases if promptly recognized, the mortality being in direct ratio to the time allowed to elapse prior to operation. (2) Perforation is apt to occur without any especial warning or exacerbation of gastric symptoms, and often without any previous history of such symptoms. (3) The operative procedure should be simple, quick, and accompanied by as little manipulation of intraabdominal contents as possible. Closure of the perforation by suture without attempt at freshening the edges or excision of the ulcer is generally sufficient. Gastroenterostomy is better held in reserve as a secondary operation, and may never be required.

TUBERCULINS AND SERA;

A SYNOPSIS OF THE DIFFERENT PREPARATIONS IN USE.

By WILLIAM MEYER, A.B., M.D.,

WEST HOBOKEN, N. J.

The recent publications on the subject of tuberculosis concern mainly the prevention of the white plague. We shall endeavor to approach the subject from another standpoint, one more useful for those who are afflicted.

Koch, Behring, Maragliano, and Trudeau have from time to time called attention to the specific treatment of tuberculosis. A decided advance has been made in the immunization of animals against tuberculosis, while in man the question of both toxin and bacterial immunization is still *sub judice*. The first preparation to effect immunity was the old tuberculin, which is prepared as follows: The bacilli are cultivated on bouillon with peptone and 5 per cent. glycerin for about three to six weeks, depending on the process of the growth. Shortly there will be formed an abundant, thick, dry, white crumbled layer, spreading gradually over the entire medium. After the growth ceases this layer sinks to the bottom of the flask and breaks up. The fully developed cultures, when microscopically pure, are evaporated on a water bath to about one-tenth of their original bulk; then the mass is filtered through porcelain, and the crude tuberculin thus obtained may be standardized, and contains from 40 to 50 per cent. glycerin, while the medium contained only 4 to 5 per cent. This product retains its activity for an indefinite period of time. Now, when we inject small, increasing doses of this or any other tuberculin, there will come

a time when the patient no more reacts to the tuberculin, and he is said to be immune. This immunity is only a toxin-immunity, not an immunity against the bacillus itself. When this state is reached further injections would be useless until this artificial immunity has passed off.

The reaction which followed the indiscriminate use of old tuberculin lingers still with some of the profession, and no doubt there is some justification in the sceptical view they entertain. Tuberculin in inexperienced hands is more dangerous than any other drug or agent we use. The diagnostic value has been settled in favor of tuberculin by almost all authorities; the therapeutic value may be seen from the fact that the O. T. has been used from the day of its discovery, and is still used, as for instance by Trudeau in Saranac, and in a number of German Sanatoria. However, the dose has been diminished considerably, and the selection of the patient has been carefully attended to.

The next preparation is Koch's new tuberculin, or T. R. In 1897, Koch obtained this product while experimenting to obtain a new immunizing tuberculin. He found a number of tuberculins, an alkaline one (T. A.), an upper or original tuberculin (T. O.), and a residual tuberculin (T. R.). This T. R. is prepared as follows: The bacilli are so pulverized that only the smallest number remains intact. Distilled water is used to make an emulsion which is centrifugated for thirty to fifty minutes. The emulsion separates in an upper, white, opalescent, and translucent layer, containing no bacilli (T. O.), and a lower muddy sediment adhering to the bottom of the vessel (T. R.). The latter is dried, again triturated, emulsified, and finally centrifugated, in order to obtain again a supernatant liquid and another sediment. This second sediment is treated again as before, and so on until the whole mass is an opalescent liquid. The muddy mass was originally called the true tuberculin. By adding enough glycerin to make a 20 per cent. solution, it is ready for use. In order to obtain an active product very virulent cultures are used, and as young as possible, dried rapidly *in vacuo*, and ground only after complete drying.

The initial dose should not exceed 1/800 of a milligram, given three or four times a week, increasing slowly, and avoiding a serious reaction. It is a diagnostic and therapeutic agent.

In 1900, Landmann obtained a tuberculin called tuberculol. This is more powerful than any of the others and free from all by-products. It produces a certain kind of toxin immunity. Tuberculol represents tuberculous toxin quantitatively unchanged and includes the poisonous substances of culture fluids as well as those of the bacterial cells. The dose is variable, as some patients will react to a small dose.

Tuberculol is a tuberculous toxin free from secondary products. It contains the culture fluid and the bacterial cells. It is a powder and diluted with water, used hypodermically in dose of 1/500 mg. to 20 mg. and more; reactions take place sometimes after one dose.

In 1891, Hunter made an analysis of Koch's tuberculin and obtained a series of five precipitates, calling them A, B, etc. The albumoses which he separated by ammonium sulphate were taken up again in water, dialyzed, and washed. This product he called modification B. This preparation was used in several sanatoria, among them in Saranac Lake, with about equal results as the other preparations. Dose from 0.0001 to 0.02 mg.

In 1898, Buchner obtained a substance by hydraulic pressure, which was called tuberculoplasmin. It is obtained as follows: The bacilli are grown on pepton-bouillon; the media are drained off, and the bacilli are washed slightly in water to remove an excess of culture fluid. Next they are mixed with quartz sand, placed in a small bag, put into the hydraulic press, and subjected to fifty tons pressure to the square inch; the resulting fluid is filtered through porcelain. The preparation is variable in strength, and hence in action. Dose from 0.001 to 0.03 mg., but more has been injected at times without untoward effects.

In 1901, Koch produced the *Bacillen-Emulsion*, Tuberculin "New," Koch, *Emulsio Bacilli*. This is a suspension of pulverized bacilli in water, to which an equal quantity of glycerin has been added. This preparation I have used mainly for the last two to three years, both as a diagnostic and as a therapeutic agent, with excellent results. It is used widely to-day all over the world.

A specific tuberculin is obtained from the patient's own bacilli. It was first employed by Haentjens-Putten in Europe. The success with this preparation has been excellent in the few cases where it has been used by the discoverer and by Dr. Krause of Hanover, Germany. Both these gentlemen have used the preparation in third-stage cases that found no relief by sanatorium or other treatment, and who had continuously a rather high temperature. All symptoms improved in a very short time after its use.

Dr. Allen in Saranac Lake prepared a standardized vaccine for tuberculosis; it is called tubercle vaccine, resembling an emulsion very closely. It is prepared as follows: Fresh sputum is washed through six normal salt solutions, then homogenized with an ordinary egg-beater. Now the bacilli are separated from the cells as far as possible, centrifugated and filtered through many grades of filter, cloths, sands, wool, etc. After the homogenization the foam is collected, which is rich in bacilli and relatively poor in cells. The foam is liquefied by means of an exhaust pump then centrifugalized. Now the emulsion obtained is standardized by a modification of A. E. Wright's method. The most concentrated product contained 175,000,000 bacilli per c.c. Then the emulsion is sterilized. This vaccine contains the constituents of the sputum. The bacteria are homologous and noncultivated, and include probably all bacteria of the individual lung. This vaccine avoids the great variety of tubercle bacilli and is restricted to the particular bacilli the body is fighting. It has the advantage of being a vaccine for all the different bacilli present, that is, for mixed infection.

There are a number of other tuberculins on the market, but since their value is not known positively, we shall omit a consideration of those preparations, and go on to describe the most important sera now in use.

Von Behring's Tuberculase.—Preparation: Preparation of tubercle bacilli (RI) into Z and RII. Take of the moist bacilli a fraction with 10 parts of alcohol (96 per cent.); let the same digest twenty-four hours, stirring occasionally. Drain off the alcohol and add fresh alcohol. This is done for four days. The alcoholic fluids are collected and steamed, then their dry substance (Z) is determined at 110°. The bacilli free from Z are washed on a large filter with 96 per cent. alcohol, then with absolute alcohol, and lastly with ether. The substance free from alcohol and ether is dried *in vacuo*. It consists of V, Gl, and C. It is dried as follows: RII is freed from ether between two filters, the residue

collected, pulverized, and spread in glass vessels or containers, and now made air dry and finally *in vacuo* over calcium chloride, 2 or 3 days longer.

Preparation of RII into V and RIII. The dried mass RII is weighed, mixed with distilled water to thirty times its weight, digested with water twenty-four hours, then centrifugalized, when a watery solution of V and a residue consisting of Gl and C are obtained. The liquid containing V is pressed to 1/6 its volume then we add fifteen times its volume of alcohol, dry *in vacuo*, weigh by excluding air, and preserve in a cool place. The residue is washed with distilled water; the water is removed by the centrifuge until the fluid, when boiled with citric acid, gives no opalescence. The dried and weighed residue RIII must be protected against air, humidity, and light.

Preparation of RIII into Gl and C. Digest RIII with 10 per cent. NaCl solution for twenty-four hours. Remove the liquid and weigh the residue. Separate the undissolved residue from the liquid by the centrifuge and 70 per cent. alcohol. Continue thus using stronger alcohol each time, until no chlorreaction takes place. Dry *in vacuo*. The 10 per cent. sodium solution (LIII) contains now the Gl substance, which is liberated by 80 per cent. alcohol and dried. The purified residue contains the residual bacilli, which are converted into TC by pulverization, washing, and extraction.

The C substance immunizes animals against the tuberculous virus. This preparation is used in animals in doses of 0.025 c.c., five days later 0.05, and after five more days O. I. In human beings a modification of this preparation is used in smaller doses.

Thamm's tuberculoalbumin is very much similar to v. Behring's preparation. It is taken by the drop or used as an ointment in tuberculous ulcerations. The results are not sufficiently known to form any definite conclusions.

Von Ruck has a preparation which is closely allied to that of v. Behring. He published his results lately in the MEDICAL RECORD (September 7, 1907).

Denys' tuberculin is about identical with Koch's T.O. It is called *Bouillon filtré*. He had very excellent results.

Klemperer uses a P.T.O. (animal tubercle bacilli prepared) with good results.

Marmorek's serum is prepared by cultivating bacilli upon a medium which contains leucolytic serum and extract of liver tissue to augment the virulence of the bacilli. Marmorek supposes that the presence of leucotoxic serum stimulates the toxin production of the bacilli. Leucolytic or leucotoxic serum is obtained by injecting pepton-bouillon into the abdominal cavity of guinea-pigs and washing the same after twenty-four hours with physiological salt solution. The milky liquid thus obtained is injected into a calf, each calf receiving thirty injections. These bacilli so grown are easily digested by the leucocytes, and cause thus no local abscesses. Horses are made immune in about eight months; the reactions are severe. Dr. Feldt of Russia and many French and German physicians have had excellent results with this remedy in man.

Technique: 5 to 12 c.c. is injected daily for five successive days; then, after three days' rest, again five injections in five days; then comes a pause of three weeks; or inject one dose every other day until ten injections have been made; then stop three weeks and begin again. It may also be employed per rectum. Prof. Hoffa had good results with this method. In mixed infection, Mamorek made a double immunization in horses; then used the serum thus obtained in man with very good results.

Maragliano's serum is prepared by mixing tuberculous toxalbumin (the toxin proper) with watery tuberculin (endotoxin) in the proportion of 1 to 3. Then inject this mixture into horses in increasing doses of from 5.0 to 50.0. The process of immunization lasts from four to six months, after which 3 liters of blood is withdrawn from the horse and examined for the presence of specific bodies. This serum is theoretically ideal. Its content of tuberculous agglutinins is small. The serum further contains agglutinins which are adapted to the human tubercle bacilli, as is seen from the following: When we suspend a four weeks' old culture of tubercle bacilli on glycerin-agar in 5 c.c. antituberculous serum, and remove after some time the bacilli by centrifugation and again test the serum for agglutinins, it will show an agglutination in a solution of 1 to 15. It is therefore evident that the bacilli bound 2/3 of the agglutinins during their stay in the serum. The original dilution was 1 to 50. This preparation is extremely poisonous. It excels TR because it is a chemical preparation absolutely sterile and very active. It is hardly used to-day.

The serum of immunized rabbits has also fallen into disuse, since the effect was not as expected. It is prepared along similar lines as the preceding serum. Among other preparations we may mention PT, TOA, and PTO, all of which have been employed more or less.

DOSES, SELECTION OF PATIENTS, TECHNIQUE, AND DILUENTS.

Tuberculin, Koch (T. or T. O.), a glycerin extract from cultures of the tubercle bacillus. The apparatus needed for its use in hypodermic medication are: A pipette of 1 c.c., graduated to 1/100. A hypodermic syringe, preferably one graduated in the metric system. And, lastly, a good antiseptic solution and distilled water, as well as a 0.5 per cent. carbolic acid solution, containing 0.8 per cent. sodium chloride.

Sterilize both pipette and syringe thoroughly. Then take a sterilized dish or glass jar about 1½ inches in diameter and 1 to 2 inches high. Dip the pipette into the bottle containing the tuberculin, draw the liquid up to the desired mark, in this case to 0.9; drop the contents into the dish until the liquid in the pipette reaches the mark 1 (which is approximately two drops). The rest is thrown away and not returned to the bottle for fear of infecting the contents. To this 0.1 of T. in the dish add 100 c.c. distilled water; stir well, and inject of this dilution 0.5 c.c. (the initial dose), or 0.0005 of pure T. There are three methods of procedure: (1) Give three or four injections one after the other, with intervals of from three to seven days between the injections, and increase the dose from the first initial dose of 0.0005 to 0.001 in the second injection to 0.002 in the third, and to 0.005 in the fourth injection, or even to 0.008 or to 0.01 in the fifth injection; this procedure applies to diagnosis only. (2) One may begin with an initial dose of 0.005, a second of 0.01, and a third of 0.025 (Maragliano). (3) Use but one large dose of from 0.005 to 0.008 (v. Jaksch). All these three methods are used in diagnosis only.

In the treatment of tuberculosis it is best to begin with a dose of 0.0005 and increase the dose every four days by one in the last decimal place, for instance: the first dose being 0.0005; the second would be 0.0006; the third 0.0007, etc. In that way we may avoid a severe reaction, but as soon as a reaction is obtained, even if it be only a mild one, we should go back at once four to five numbers, i.e. if a re-

action takes place with a dose of 0.0008 we must go back to 0.0003, lengthen the interval, and begin again to increase the dose gradually. The maximum dose is about 0.02.

Before the treatment is begun the patient's temperature and pulse should be taken for three days about two or three times a day. I generally take it at 8 A.M., at 1 P.M., and at 6 P.M. Often it is advisable to teach the patient to take his own temperature, especially in private practice. When the patient cannot read the thermometer, let him get two good thermometers and have him insert one into the rectum in the morning for about two minutes, and the other in the evening, and let him keep them until the physician calls to read the temperature. After the injection the temperature should be taken every two hours for 10 to 12 hours, then every four hours for two or three days.

The injection may be made in any part where the skin can be grasped in folds; the interscapular region is as good as any, if not the best. Wash the site with soap and water, then rub in with alcohol or a good antiseptic, and cover the area with cotton, upon which a little chloroform has been dropped, until ready for injection. These precautions are to be observed in all injections and we need not repeat them when considering each tuberculin or serum. The same routine also holds as regards temperature and pulse and pipette and syringe.

A reaction consists of distinct symptoms. In the majority of cases there is a rise of temperature from 1½° to 3° or even more within 24 hours after the injection; a delayed reaction is not infrequently met with, perhaps 30 or 40 hours later. The pulse rate varies, but generally is high and not in accord with the temperature. At times, especially after large doses, a distinct chill occurs, almost immediately after the injection. I had this experience in 6 out of 25 cases. Another accident that may happen is this: When the needle perforates the wall of a vein, a decided cyanosis with dyspnea may set in at once, but this will pass off in a few minutes. To avoid this accident it is well to insert the needle alone and if no blood oozes out to attach the syringe and inject. Other symptoms are: headache, malaise, anorexia, at times vomiting and even diarrhea. Sometimes a distinct pain in the ends of long bones is observed, a constriction in the chest, and pain at the seat of the trouble; local redness and a sore feeling are almost universally noted. The reaction symptoms are, as a rule, the symptoms of rheumatic tonsillitis, minus the throat symptoms.

Selection of cases: Whenever a positive diagnosis can be made, tuberculin should not be used as a diagnostic agent; the presence of bacilli in the sputum, for instance, will establish the diagnosis, without the aid of any other means. In obscure cases or in cases where there is justifiable doubt, tuberculin will give positive signs in 90 per cent. A negative reaction is of as much value as a positive one, for the former excludes tuberculosis in 99 per cent.

Third stage cases should not be treated by tuberculin, unless the physician has had considerable experience in the use of the remedies. It is not altogether contraindicated, but more caution is required. High temperature is, as a rule, a contraindication. If, however, tuberculin is used and the temperature falls, it indicates an amelioration and its use may be continued, but if no fall occurs it is best to leave the case alone.

Second stage cases are very doubtful and do not often receive much benefit, especially if the general condition is bad; but there are some second stage patients who may be greatly benefited. Those who are fever free, who are well nourished, and whose disease runs a rather slow course, may be cured; but harm may be done, especially when too large doses are used. The kidneys and bowels should be in a good condition.

First stage patients are benefited in 90 per cent. of the cases, provided there is no other serious lesion. The heart of the consumptive is generally small, and in 60 per cent. is affected, but it has no bearing on the use of tuberculin. Anemic persons in tuberculous families should receive a diagnostic dose and if the test be positive the treatment will cure them. I have had ten such cases and all of the patients to-day are well and working. These patients had, besides the anemia, a poorly developed chest, were stunted breathers, had lost weight lately, and always felt tired; six hacked now and then, three had moderate expectoration in the morning.

The rules here given are not exhaustive, by any means, and the judgment of the physician is called acutely into play in each individual case. A safe rule to go by is this: "What I am going to do now to my patient, I would also do to myself or to mine." When this rule is followed out conscientiously, and the necessary skill and tact are used, there will not be many failures to record.

Tuberculin "New," Koch (T. R.). This is a real immunizing agent. Koch discovered that the bacilli are covered with a fatty-acid coat which is not easily removed or absorbed. In the process he instituted he succeeded in practically clearing away this layer and thus rendered the bacilli easily digestible. Two products were obtained in doing this, viz., T. O. (tuberculin oberst, upper tuberculin) and T. R. (rest or residue tuberculin). This T. R. is very easily absorbed and produces no abscess or ulceration at the site of injection. The T. O. acts more like the T. A., but the former causes no suppuration, while the latter does quite often.

T. R. has an immunizing effect, even if the patient does not react, while the old tuberculin requires a reaction in order to immunize. When an individual is immunized by T. R. he is also immunized against the action of T. A. and old tuberculin, which proves the immunizing effect positively.

T. R. is used as a curative and immunizing agent. The initial dose is 1/800 mg.; the diluent is 0.8 per cent. sodium chloride solution. No acids or chemicals must be used in diluting T. R. Take 1 c.c. T. R., mix it with 499 c.c. 0.8 per cent. salt solution well sterilized, inject 0.75 c.c. of this as an initial dose, and increase gradually as in T. O. These dilutions should be made daily as they will not keep well longer than 12 to 24 hours. The injection may be made three times a week and increased gradually by 0.05 and then by 0.1. For instance, 0.75 is the initial dose; this increased by 0.05 would make the second dose 0.8, and this increased by 0.1 would make the third dose 0.9, etc. The highest dose is about 20 mg., very often less, occasionally more. If no reaction occurs when 20 mg. is given, it is best to pause for two or three months and then begin a second course. A reaction must not be regarded as necessary for a cure.

New Tuberculin, Koch (Bacilli Emulsion). This is at present my favorite preparation and has been so during the last three or four years. This preparation contains in 1 c.c. 0.005 mg. pulverized bacilli. The initial dose is 0.000,001 mg. of powdered bacilli. (Formerly I gave 0.0025 mg. or 0.000,012.5 mg. of pure substance. This dose is increased by one or two every four to five days; for instance: First dose, 0.000,001, the second would be 0.000,002, the third 0.000,003,

the fourth 0.000,006, etc., until 0.020 mg. is reached or until a reaction sets in; then decrease about five numbers and proceed anew but more cautiously and at longer intervals. The dilutions are made as follows: Take 0.1 c.c. from the original bottle, add 9.9 c.c. salt solution of 0.8 per cent. strength containing 0.5 per cent. phenol or carbolic acid; stir well and take from this dilution 1 c.c., drop into a second dish, and add 9 c.c. of the diluent-salt and phenol solution; of this take again 1 c.c. and place in a third dish and add again 9 c.c. of the phenol and salt solution; stir well, and the preparation is ready for use. Now take 0.2 from this third dish, drop it into the open syringe, and enough salt and phenol solution to make 1 c.c., then inject. When the quantity taken from the third dish has reached 1.0, no more salt-phenol solution is needed to give it quantity, but it may be injected directly from the third dish. Again, if the quantity is large enough, after a while the third dish may be dispensed with and the injections made directly from the second, and so on, finally from the first, but rarely quite pure, as it is always best to dilute somewhat. Should we reach the 20 mg. mark, it will be well to inject in several places instead of one.

Tuberculol. Here dilutions are made with distilled water, sterilized water. The minimum dose is 0.0001 mg., the maximum dose 20 mg. The increase is gradual but more rapid than in the other preparations. The reactions are sometimes quite severe and great care is essential.

Modification B. The dose is begun with 0.0001 and gradually increased to about 18 mg. Injections are made two or three times a week. Dilutions are made as in the preceding case. The increase is made by two and three each time.

Tuberculoplasmin. The dose of this preparation is in the beginning 0.001 mg. and slowly increased to 30 mg. unless a reaction takes place, when, as in all other cases, the dose must at once be reduced considerably. The average injection is every two or three days with the smaller doses, but as soon as larger doses are administered, the interval should be lengthened to once a week or once in two weeks; this rule applies to all preparations more or less. We generally lengthen the interval as soon as a mild reaction is reached, let us say of half a degree to one degree.

The vaccines. The dose of the vaccines depends largely on the amount of bacilli, but is generally larger than that of tuberculin. The doses resemble very much those of the bacterins. In these latter preparations we may give a dose from 20,000,000 to 50,000,000 dead bacilli.

Deny's tuberculin (*bouillon filtré*). The dose is pretty near the same as that of T. O., but it is best to begin with a dose a little smaller than that of T. O.

Klemperer's P. T. O. is used in doses of the T. O.

Timotheus' paratuberculin. Minimum dose 1 to 2 c.m., increased to 10 c.m. or higher. The reaction with this preparation varies somewhat from the other preparations; it manifests itself as follows: Headache, increased cough, dyspnea, rise of temperature and pulse, and quite often a transient cyanosis.

Thamm's tuberculo-albumin. Minimal dose 2 drops per os, gradually increased to 20 and 30 drops and more.

Marmorek's serum. Dose, 1 c.c. to 20 c.c. and more. It is injected undiluted once or twice a week. Symptoms of reaction: Considerable pains in the joints, local erythema, and the symptoms of the other preparations. Its benefits are: Fall of temperature, cessation of night-sweats, and increase in weight.

Maragliano's serum. Minimal dose, 1.0 c.c., increased to 50.0 c.c. and more.

P. T. E. 0.001-0.05; P. T., T. O. A., and P. T. O. 0.01-20.0 and more, vary in their doses. They are diluted with distilled water, salt water or phenol-salt solution, as a rule. The dose being from 0.001 to about 20 mg.

T. P. O., 0.01-100.0; T. Pasteur, 0.1-10.0.

Those are the most useful preparations, and it is needless to enumerate the rest, as they are mostly uncertain and not well tried. There is one more American preparation, the one of v. Ruck, which has been described by v. Ruck in the MEDICAL RECORD of September 7, 1907.

ALCOHOLIC DELUSIONAL INSANITY.

By L. F. LA PIERRE, M.D.,

NORWICH, CONN.

ALCOHOLIC delusional insanity is a psychosis occurring on a basis of chronic alcoholism presenting a course of varied duration, and characterized by delusions of persecution based upon hallucinations of the special senses of which those of hearing are constant and the most prominent. The above definition is incomplete and imperfect, yet it conveys a fairly accurate idea of the form of insanity included in the series of 104 cases treated at the Connecticut Hospital for the Insane, Middletown, Conn., which form the basis of this paper.

The etiology of alcoholic delusional insanity is alcohol. In some cases an inherited weak, nervous system, sunstroke, or injuries to the head may act as predisposing causes. In these cases the psychosis often develops from a minimum amount of alcohol. In this series of cases the friends gave the following causes in addition to the excessive use of alcohol: sudden withdrawal of alcohol, three; worry, six; injury to head, eight; sunstroke, five; disappointment in love, three; jealousy, two; shock, one; domestic troubles, four, and menopause one; a total of thirty-three. Hence in about one-third of the cases other factors were given as the cause of insanity besides alcohol. These above-named factors when present may have acted to some extent as the cause of the insanity, but the mental symptoms were those of the alcoholic delusional type.

Usually in typical cases of alcoholic delusional insanity there is a history of the abuse of alcohol for years, with marked excess just prior to the onset of the hallucinations. The duration of the alcoholic habit often dates from youth. In this series of cases the following history was obtained: eighteen had used alcohol twenty to thirty years; ten, fifteen to twenty years; fifteen, ten years, and eight for six to eight years. Others stated that they had used alcohol "since they were young," or "many years." In only a few cases was the duration of the habit given as one or two years. In women it was difficult to obtain reliable histories.

In regard to the form of alcohol taken it was commonly noted that beer was used in youth, the stronger spirits being gradually added as years went by. The history of the use of these stronger spirits or mixtures containing them was almost universally present. In an occasional case a mixture of cider with whiskey or rum was the favorite beverage.

Concerning the amount of alcohol necessary to produce mental symptoms no definite statement can be made. It is well known that the amount of alcohol which an individual can bear varies in each case. This is evident both in nonalcoholics and in alcoholics. Some persons by constant use are able to consume the strongest distilled spirits in large quanti-

ties for long periods, and, although they are often in an alcoholic stupor and present the signs of chronic alcoholism, they may never develop an attack of delirium tremens or alcoholic delusional insanity. Others are more susceptible and develop mental symptoms on the minimum amount of alcohol, each attack weakening the resistance and predisposing to subsequent attacks.

An inquiry into the heredity of this series of cases developed the following figures: Insane heredity, 34; alcoholic, 13; unknown, 16; excellent, 41. In the cases with an insane or alcoholic heredity, the course of the disease was essentially the same as in the ordinary case, and there was the same percentage of recoveries. Stigmata of degeneration were noted in 20 per cent. of cases. About 90 per cent. of these patients were men.

In regard to birthplace the following history was obtained: forty-six were born in the United States, twenty-nine in Ireland, eight in Germany, five in Russia, three in Italy, and eleven in various other European countries. Nearly 50 per cent. were of Irish, and over 75 per cent. of foreign parents.

Concerning station in life: forty-eight were married, forty-five were single, seven widows or widowers, and five divorced. Their ages ranged as follows: 16 between 20 and 30 years, 43 between 30 and 40, 27 between 40 and 50, 13 between 50 and 60, and 5 between 60 and 70 years. As is evident from the above figures, the greater number of cases occur during the prime of life, when the individual should be most capable and of use to the State and society. Instead he becomes incapacitated and a burden.

The employments of the patients were varied: machinists, six; laborers, twenty-five; factory employees, sixteen; blacksmiths, three; moulders, four; farmers, nine; housewives, eleven; stonecutters, two; hatters, two; cigarmakers, two; manufacturers, two; letter carrier, boiler maker, teamster, carpenter, wire maker, saloonkeeper, painter, prostitute, sailor, tramp, druggist, butcher, cook, hostler, plumber, gardener, mechanic, tailor, and barber, each one.

An analysis of the above shows nothing remarkable except that those persons who have hard physical work are well represented. Possibly from statistics of private institutions one might draw different conclusions.

It seemed of interest to note the residence of the patients previous to their admission to the hospital, and I find they were divided as follows: forty-five came direct from home; forty-six from jails and almshouses where they had been temporarily confined; ten came from other hospitals, and two from State's prison.

A history of previous attacks of some form of alcoholic psychosis was present in twenty-nine cases, and alcoholic multiple neuritis was associated with the psychosis in two cases. These previous attacks were divided as follows: twelve had delirium tremens once; three, twice; three, three times, and two, four times. Seven had had one previous attack of alcoholic delusional insanity, and two, two previous attacks.

The prodromes of an attack may or may not be present; in the former case they are as follows: The person becomes restless and low-spirited; headache, loss of appetite, and in some cases nausea and vomiting are present. There is extreme nervousness and indefinite pains throughout the body, which are relieved temporarily with alcohol. The person is often suspicious, irritable, and as night approaches is fearful, sleep being disturbed by dreams of a terrifying character. Insomnia is often present, and instead of normal sleep there is a semiconscious state throughout the night with free perspiration from fear.

Daybreak often brings relief, but as night approaches the above named symptoms return again, the person taking more alcohol to keep up his courage and strength, the appetite usually being lost at this period. Even at this early stage temporary disturbance of perception often occurs during the night, disappearing in the morning. The patient may have insight into his mental condition at this time.

The usual physical symptoms of chronic alcoholism are exaggerated tremors of the hands and lips, with tremulous, flabby, furred tongue, and foul breath. The person may continue in this condition for days or even weeks when the onset occurs. It is more usual for it to be sudden (05 per cent.) and manifest itself by a marked disturbance in perception.

Auditory hallucinations appear and are prominent. They are usually condemnatory in character. Voices threaten and curse them; accuse them of various crimes, and especially of unnatural sexual acts. These voices say: "thief," "burglar," "liar," "scab," "sucker," "you are no good as a man," "you have lost your manhood," "you have improper relations with your children," "kill him," "burn him," "crucify him," "you have got to suffer," "your wife is unfaithful." Hears voices balloting his life away. Voices say, "shoot him," "tar and feather him," "bastard," "you have ruined your sister," "you will be electrocuted," "cremated," "tortured," "he drinks pretty heavy," "make him marry a nigger," "we know your record," "he has appendicitis." Rarely, instead of the voices of his persecutors, he hears the voice of God. He is addressed as Christ and has a mission to perform in the world.

Visual hallucinations occur in more than half of the cases, and they are of a terrifying character. They see their friends being killed by electricity. Dead bodies are laid out upon the floor. The devil moves along the wall and peeps at them from behind chairs; see angels and feel them touch their arms. Faces, snakes, the Virgin Mary, appear to them. See their enemies following them and assuming threatening attitudes. Black dogs surround their bed and wink at them.

Olfactory and tactile hallucinations are present in some cases; electricity is used upon their body, gases are forced into their rooms, *x*-rays are played upon them, feel the sheet move under them in bed.

Concerning the source of the hallucinations of hearing, they most commonly ascribe them to their fellow workmen or associates. Sometimes, however, they say the voice seems to come from the top of their head, their chest, or stomach. The latter is the most common, and is quite characteristic of alcoholic delusional insanity.

Illusions of hearing may also be present, especially in the early stages of the disease. The air going in and out of the nose whispers words to them. The sound of footsteps is a curse to them. The sound of a ringing bell or passing train curses them over and over.

Consciousness is usually clear and orientation but little disturbed. About 30 per cent. of this series of cases showed partial clouding of consciousness at the height of the excitement.

In nearly one-half of the cases there is some clouding of memory for events at and following onset. This rapidly disappears. Permanent impairment of

memory is unusual, and only occurs in chronic cases to a moderate degree.

The train of thought is coherent and relevant. Judgment is much impaired. The patient entertains numerous delusions of a persecuting character based upon the disturbances in perception. He thinks that his persecutors are after him constantly and that he is soon to be tortured and put to death. The character of the delusions depends entirely upon the character of the hallucinations. As the voices say they are to be burned at the stake, etc., they have delusions to that effect. Delusions of infidelity are fairly frequent, occurring in about 15 per cent. of this series of cases. Think their wife is unfaithful because voices tell them.

In an occasional case delusions are of a religious character, based upon the like disturbance of perception. Think that they are Christ and have been sent to redeem the earth. Are inspired and all-powerful.

Somatic delusions are present in about 18 per cent. of cases, but are not prominent. It is worthy of note also that in women at the menopause the delusions may have a self-accusatory tinge. The delusions are without system and do not tend to involve the surroundings.

The emotional attitude is one of fear and apprehension. The constant hallucinations keep them in terror both day and night, but especially so at night. Some are profoundly depressed, and seem to have given up all hope of ever being free from their tormentors.

The volitional impulse is increased in practically all cases, the exceptions being those cases which are most depressed.

In conduct these patients are inclined to violence to themselves or others in reaction to their hallucinations and delusions. They are often defiant, and are frequently noticed answering their auditory hallucinations. A few cases appear depressed and resigned to their fate.

In this series of cases suicidal attempts were present in 15 per cent. and attempts at homicide in 20 per cent. Patients suffering from this psychosis are among the most dangerous of the insane. They frequently seek the police for protection from their supposed persecutors, and occasionally, when the hallucinations refer to some disease, they go to the physician for treatment. I recall one case who entered the accident room of a city hospital declaring that he had appendicitis. Upon examination, no objective symptoms being found, he was asked why he thought he had appendicitis. He replied that everywhere he went upon the street people looked at him and remarked, "He has appendicitis." Under restraint at home, with removal of alcohol, this patient quickly recovered.

The cases with delusions of infidelity are often responsible for the wife murders which have become common. Sometimes the hallucination is in the form of a command which goads them on either to commit assaults upon themselves or others, or to destroy property.

As the disease progresses the illusions and hallucinations of sight are apt to disappear, while the more prominent aural hallucinations and delusions continue.

The course of this disease varies. There may be attacks lasting for only a few hours or days and recovery taking place. Cases often exist for a considerable time at large without being detected. Many tramp about, serving frequent terms in jail for breach of peace. As no systematic examination of the mental condition of disorderly persons is carried out, many insane are unjustly punished. Undoubtedly many persons have brief attacks and recover in jails or at home without treatment. The histories given by the patients themselves bear out this statement.

Of the cases admitted to an institution, most recoveries take place during the first year, and it is exceptional to have a recovery after the fourth year. It happened only once in one hundred and four cases.

The following will give an idea of the duration of those cases which recover: five recovered in one month, seven in two months, three in three months, four in four months, one in five months, one in six months, two in seven months, ten in twelve months, seven in eighteen months, four in two years, two in three years, four in four years. Thus 66 per cent. of recoveries occurred during the first year.

Cases with a sudden onset usually run a shorter course and tend more to recovery. Cases which have a gradual protracted onset run a slower course, and there are fewer recoveries. In general it may be said that the prognosis is fairly favorable, and it is especially so in selected cases.

In cases with a sudden onset the result was, expressed in percentages: Recovered, 60; discharged improved, 12; discharged stationary, 4; stationary in hospital, 12; died of intercurrent disease, 2.

In cases with a gradual onset the result was, in percentages: recovered, 16; discharged improved, 4; discharged stationary, 16; stationary in hospital, 60.

In the whole 104 cases the result was, in percentages: recovered, 38; discharged improved, 8; discharged stationary, 10; stationary in hospital, 41; died, 3.

In those cases which have had previous attacks the prognosis is less favorable, and was as follows, expressed in percentages: recovered, 26; discharged improved, 10; in hospital stationary, 54; died, 10.

In those cases which recover the hallucinations become gradually less prominent until they finally disappear altogether, the patient eventually having insight into his past condition. The hallucinations usually first disappear during the day, often returning for a short time each night. Any return to alcohol is almost certain to cause an exacerbation of mental symptoms.

Concerning the 41 per cent. of patients who do not recover and remain in the hospital, a few words may be written. In many the mental symptoms disappear enough so that they are able to be employed upon the farm. Some have, however, exacerbations and periods of excitement at irregular intervals. Nearly all of these patients show gradually increasing deterioration of the mental powers to a limited extent as years go by.

Of those who leave the institution recovered, improved, or stationary, recurrent periods of excitement are frequent, as they usually return to their alcoholic habit. In others there is retention of peculiarities and eccentricities throughout life.

The diagnosis of alcoholic delusional insanity is usually not difficult, for the symptoms of chronic alcoholism, prominent auditory hallucinations of a condemnatory character with delusions based thereon, and retention of clear consciousness form a clear picture.

In the acute period we have to differentiate alcoholic delusional insanity from delirium tremens. First, it is to be noted that in delirium tremens the clouding of consciousness is more marked than in alcoholic delusional insanity. In alcoholic delu-

sional insanity hallucinations of hearing predominate, while in delirium tremens visual hallucinations are the most prominent.

Treatment.—For the benefit of the person affected, and for the safety of the public at large, it is essential that cases of alcoholic delusional insanity be recognized early and placed in hospitals for treatment. These cases are ideal ones for treatment in acute psychopathic wards of general hospitals, if such wards existed. Many cases would abort if treatment and restraint were early applied. The delay too often occurs and the person is allowed to go his way till it becomes absolutely necessary to secure commitment papers and commit him to some State institution. This delay is fatal, and many cases become chronic and many crimes are committed which could easily be prevented.

It is best to withdraw the alcohol immediately, and improvement usually takes place rapidly. Chloral and the bromides are useful in the early stages, and opium and hyoscine may be added at times with advantage. It is best to humor the patient in regard to his hallucinations and delusions. These patients are dangerous, and great care must be used.

After the acute period is passed, employment of some kind is a benefit. Later, in chronic cases, outdoor employment upon the farm will improve their physical condition, and they often become valuable help. Any return to alcohol will almost certainly cause an exacerbation of the mental symptoms.

THE TREATMENT OF JOINT TUBERCULOSIS IN CHILDREN.*

By LEONARD W. ELY, M.D.,

NEW YORK.

This may seem a broad subject for a paper of this nature, and yet possibly, within the limits allowed, we may not only obtain a general oversight of the principles underlying the treatment of tuberculous joint disease, but also consider some of the finer details. If, in the consideration of the treatment of any disease, we can lay hold on the essential idea of procedure, we shall often find our path much smoother than if, starting at the other end, we encumber our minds with a mass of details, and then try to adapt these to a particular case.

Now, such a main essential idea we have in the treatment of joint tuberculosis in children, and that idea is *rest*. We put the joint at rest in the position which experience has taught us is the best one, and keep it in this position until Nature has had time to effect a cure. Various complications may arise, and various circumstances may render necessary a modification of treatment, but this rest is the main idea that we keep always in mind.

Let us now see how this principle is applied, and take up the consideration of the various joints most frequently involved, beginning with the spine.

Tuberculosis of the Spine, Pott's Disease.—The best routine treatment for spinal caries in young children is by the Bradford frame. The frame is made of gas-pipe, covered tightly with canvas laced up the back. It is built six or eight inches longer than the child. To the canvas, in the region of the buttocks, is sewn rubber sheeting, for cleanliness. The child is strapped to this frame by means of an apron across the chest and abdomen. From the apron run straps which fasten to buckles sewn on the sides of the canvas cover. Two felt pads are then sewn on the front of the cover, so that the kyphosis will fit down between them and relieve the spinous processes from direct pressure. The frame is bent backward to provide for superextension of the trunk. The head and legs of the child are left free. A bed pan can be slid under the child as it lies on its back. The parent or nurse is instructed to place the frame, once or twice a day, on a table, to unbuckle the apron, to roll the child off the frame, to clean the back well with alcohol, to powder and dry carefully, and then immediately to replace the child and buckle it back in place. Scrupulous cleanliness is enjoined. When the treatment is begun the parent is warned that the child is never to sit or stand for an instant unsupported. Often we soon hear that the little patient has learned to roll the frame over and goes crawling about on its hands and knees. A small piece of board about two feet long fastened at right angles to the top of the frame will prevent this.

This is the ideal treatment for young children, or for older ones whose parents are able to afford the luxury of a special nurse. Under it less deformity takes place than under any other. The force of gravity aids us in preventing a hump, whereas with any form of appliance in the erect position we are always working against gravity. Where possible the child should lie on the frame for two or three years. At the end of that time it may be put into some other form of support, and may be allowed to go about.

In older children we have recourse to a plaster-of-Paris jacket or to a brace. Probably the former is better for all-around use, and it has the further advantage that we are independent of the brace-maker—a most important point. The chief opponents of the plaster jacket are those who have had little experience in its use. The more one uses it the better one likes it. The jacket is made as long as possible, reaching from a point just below the top of the sternum to one just above the crest of the pubes, and is trimmed out so as to permit motion of the arms and legs. First, a tight-fitting shirt is applied with a bandage running inside called the scratch bandage, to keep the child's skin in condition. The child is suspended by the head and hands, the bony prominences are padded, and the plaster bandages, wrung out of warm water, are then applied smoothly and firmly, each layer being well rubbed in, so as to make a homogeneous mass. These bandages, from 4 to 6 inches wide, are made of Vigilant brand of crinoline, into which fine dental plaster has been rubbed by hand. Good plaster bandages are not to be bought in the shops, but anyone can make them for himself. The jacket should be about one-quarter inch thick. While the plaster is hardening, the jacket is trimmed above and below, and when it is fairly hard the child is taken down and laid for a while on its side until the hardening is complete. No pain is connected with the operation. A child not used to it cries with fright, but later on is liable to go to sleep in the sling.

The nurse is instructed to keep the jacket clean and dry, and to prevent anything from getting down inside it. She must smell it carefully each day, and with the first suspicion of foul odor must bring the child for inspection. A bad smell means a sore under the plaster, and demands instant removal of the jacket. This removal is done by cutting down the front so as to permit of springing the plaster off. After the sore has been dressed new padding is adjusted to prevent pressure, and the jacket is reapplied and is strapped up the front with adhesive plaster. In this way the excoriation may be dressed

*Read at the annual meeting of the Washington County Medical Society, October 1, 1907.

until it is well. Then a new jacket is applied. A good jacket lasts anywhere from one to eight months. The usual time for change is about two or three months. It is remarkable to see how soon a child who has been suffering intense pain, and has been kept awake with frequent night cries, will quiet down when a jacket is applied.

In case of cervical Pott's, or disease of the thoracic vertebræ above the eighth, the jacket is supplied with a so-called jury-mast or head-spring, which removes the superincumbent weight and transfers it, through the plaster, to the hips.

The usual form of brace in Pott's disease is the Taylor brace, but this needs considerable experience for its application and subsequent care. Here let it be said that no patient should ever be sent to a brace-maker with instructions to "get a brace." The brace-maker must be told exactly what to do, and then must be watched in order to see that he does it. We cannot shift the responsibility to his shoulders. As well send a patient with gonorrhea to a druggist with instructions to get an injection.

A good brace, carefully applied, constitutes an excellent form of treatment, but it needs constant supervision, and is liable to frequent breakage. Besides this, we never can tell, when the patient is out of our sight, just how much time he spends outside of his brace. With a skilled nurse, and under the best possible surroundings, a brace may be said to be as good as a jacket, otherwise it is inferior. There is one exception to this. In cervical or high thoracic Pott's, the brace provided with a chin-piece or head support is superior to the jacket.

Abscesses.—These, if deep and not very large, should be let alone. When they approach the surface, or increase rapidly in size, they may be opened under strict asepsis, wiped out carefully, and then sewn up tight, and dressed snugly. A patient with a good-sized abscess should be kept quiet.

Psoas Contraction.—Rest in bed or on a frame, perhaps, if necessary, with weight and pulley extension.

Paraplegia.—The patient with this complication should be stretched out on a Bradford frame, with his spine in superextension, and should be kept there until the paraplegia has disappeared. This will usually require about a year. Medicines are useless.

Hip-Joint Disease.—Until seven years ago the treatment of hip-joint disease in this country was almost universally by braces. Then, at least in New York, the short plaster spica of Lorenz was introduced in the clinics, and the battle between plaster and the brace was on. It is still raging merrily and bids fair to endure for some time. Let us see what we hope to gain by appropriate treatment, and then we can better make a selection of our weapons of warfare. When we have made our diagnosis, two questions will almost invariably be asked: How long will the treatment take? and What will be its results? Under favorable conditions we look for a cure in three years; that is, at the end of that time the hip will be ankylosed in a position we choose for it, and experience teaches us that the best functional posture is extension and slight abduction. Motion in a cured tuberculous hip is rare. It may occur, and does undoubtedly, but not often under any form of treatment. Good motion in an old tuberculous hip usually means a wrong diagnosis.

The advantages of the plaster spica are numerous. It dispenses with the aid of a brace-maker; it does not require constant supervision; it cannot be removed by the patient; it is not unsightly; it permits the patient to use the limb in walking, and so avoids the extreme atrophy that always accompanies the use of the extension splint. Two objections may be urged against it; first, that it can rarely be used when an open abscess is present with much discharge, and, second, that it requires some skill in its application. But to measure for a brace, and then to apply it, also require skill. In the old days the opinion prevailed that by the use of a traction brace we could pull the head of the femur away from the acetabulum, but now we know that, unless the head has been eaten away, this is impossible. Our experience seems to show us that motion is harmful to a tuberculous hip, but that weight-bearing is not. True, every time a patient with a spica steps on his affected limb he drives the joint surfaces together, but this is only a reversal of what takes place with a traction brace. In case of profuse suppuration the spica is impracticable.

Before a brace or a spica is applied any existing deformity must be reduced, slowly by weight and pulley in bed, or rapidly under ether. Never try to reduce a deformity by any form of appliance. A support, whether metal or plaster, is only intended to hold a position which has already been attained. When the thigh has been brought down into full extension and slight abduction we are ready to put on our plaster or brace.

In measuring for a brace, take the distance from the anterior superior spine to the sole of the foot held at right angles with the leg, and add about two inches for extension. This is the stem. Then measure the distance from the trochanter to the opposite anterior superior spine for the anterior limb of the pelvic band, and add an inch for the posterior limb. If a thoracic extension is required measure the distance from the anterior superior spine to the nipple.

For a plaster-of-Paris spica we need some good plaster bandages, 4 to 6 inches in width, some piano felting or sheet wadding (so-called interlining), ordinary canton flannel bandages, a one-legged pair of pants, so to speak, made out of ordinary shirting, a pelvic rest, and a rest for the head and shoulders that may be easily improvised. The shirting is first applied, and should reach from the ankle to the axilla. Then the child is laid out in the horizontal position on the two rests, with one assistant holding the legs and another the shoulders. The pelvis and the knee are well padded, and the whole dressing is firmly bandaged. Then the plaster bandages, wrung out of warm water, are quickly applied, carefully moulded over the pelvis and knee and covering in the buttocks. The plaster is built up very thick across the lower part of the belly and over the groin where the strain comes. Just above the pubes it should be almost an inch thick, and from this it shades down to about one-quarter inch at the knee. When it begins to harden it is trimmed out at the borders, going wide of the genitals and anus for cleanliness, and leaving the knee free. Above, it takes in the crests of the ilia and is cut concave in front so as to expose the navel. Thus the spine is left almost entirely free and motion in its joints takes the place of that at the hip. Finally the padding is trimmed away, and the shirting is turned down so as to make a covering as well as a lining, and the part so turned down is sewn to the lining near the edges of the perineal border. The whole makes a very neat dressing. If an ordinary bandage is pushed up beneath the spica, or, better yet, is put inside the shirting before the latter is applied, it may be drawn back and forth every day, and so will serve with a liberal use of powder to keep the child's skin

in condition. This is called a "scratch bandage." A spica, if well cared for and kept clean, will last for two to six months, and in it the child walks about comfortably except in the periods of acute exacerbation.

The treatment of hip-joint disease in childhood is always conservative. Resort is rarely had to cutting operations on the bone except to save life. The use of the curette alone is almost invariably a useless and harmful procedure in this as in other tuberculous joints, and may be likened to groping about in a grab-bag. In desperate cases we resort to excision, but, bearing in mind the resulting shortening, we postpone excision as long as possible.

The Knee.—The same general rules hold good for the knee as for the other joints, but here the brace constitutes the treatment of election, and the usual form of brace is the Thomas. This consists of a padded ring to fit around the top of the thigh, and two uprights running from this on the inside and outside and joined together below by a foot piece. It is made about 2½ inches longer than the extremity, and the foot on the sound side is supplied with a high sole. By the use of this brace the leg is swung free of the ground, and the patient bears his weight in walking on his perineum. Plaster-of-Paris may be used instead of the brace, but it has two disadvantages: first, it is applied necessarily upon an inverted pyramid, and so has a tendency to slip down unless made to fit very snugly; and, second, its hold above is only upon soft tissues, and therefore it allows considerable motion. The duration of treatment is, roughly, two years, often longer. On account of the great growth taking place in the ends of the bones forming this joint, no cutting operation should be done on them except to save life.

The Ankle.—In tuberculosis of the ankle and tarsus, the best plan of treatment is by plaster-of-Paris and a brace. The foot is held in proper position by the plaster, and then is swung clear of the ground by a Thomas brace. Suppuration is very apt to occur in tuberculosis of this joint. When it does, a window may be cut in the plaster and the sinuses dressed through this. The temptation to curette this joint is usually strong, but is to be bravely resisted. More harm than good is done by it. Conservatism is the rule here also.

The Wrist and Elbow.—Disease of the wrist and elbow, rare in either joint, is best treated by plaster-of-Paris. For disease of the shoulder joint an excellent appliance is the Ely brace. This consists of a girdle about the chest and one about the arm, joined by two arched flat metal rods. These girdles are provided with laces, and the one about the chest is prevented from slipping down by two straps which, starting in front, pass over the shoulders, cross, and attach to the girdle behind. (*Medical News*, July 23, 1904.)

So much for the local treatment. The general treatment may be summed up under two heads: *Fresh Air* and *Feeding*.

A child with a tuberculous joint should be in the open air during the entire day, and should have the maximum amount of fresh air at night. No particular air is specific. Abroad the present tendency is to regard the seashore as peculiarly adapted to these cases; but this, in my opinion, is incorrect. The seashore is probably the best place for them, merely because children in general thrive best at the seashore.

At the Sea Breeze Hospital, where children with tuberculous joints have been treated for some years, we obtain excellent results. Children sent down there receive the best of care and show the results of this care almost immediately. They gain in weight, and often become fat and rosy while their sinuses are still discharging, but the disease process seems to run the same general course and to take about the same time. With their excellent hygienic condition their abscesses are not so apt to be troublesome, and probably heal more quickly; but this is merely a supposition on my part. To establish the value of seaside hospitals, as compared with those in other country places, would require an analysis of very voluminous statistics. The personal element of those in charge would also enter into the calculation. With all our care cases have been admitted which have healed up promptly under potassium iodide and mercury. It is the writer's opinion that, in contradiction to the general idea, syphilitic bone and joint disease in children is rather frequent, and often very difficult to diagnose off-hand, especially as many children with unmistakable tuberculous joint disease show the notched teeth and other stigmata of hereditary syphilis. If these and other mistakes were included in our cures we should show an excellent record. In due time we shall have some records that will be of value.

The day's routine at Sea Breeze is as follows: The children rise at 6 A.M., the little ones retire at 6 P.M., and the older ones at 7:30. During the school term lessons are held from 9 to 12, with three-quarters of an hour intermission, which is spent out of doors. In the schoolroom the windows are always open. Kindergarten is held from 9:30 to 11:30, with thirty minutes' intermission. In the afternoon, classes in carpentry, sewing, cooking, and raffia work are held for one hour. The bed cases are given instruction while the other children are playing. All the older children have certain tasks to perform. Those who are able are given an ocean bath daily from the middle of June to the middle of September.

The following is a typical diet sheet for one day:

Breakfast, 7 A.M.—Cereal, milk, toast, bread and butter.

Lunch, 10 A.M.—Bread and butter and milk.

Dinner, 12 M.—Beef, lamb, or chicken, vegetables, bread and milk, dessert.

Lunch, 3 P.M.—Fruit.

Supper, 5 P.M.—Stewed fruit, toast, bread and milk.

During the winter the children have cocoa once a day.

On account of the terror which the hypodermic needle inspires in young children, we have given up the use of tuberculin among them until its value shall have been demonstrated.

THE SURGICAL ASPECTS OF MALIGNANT ENDOCARDITIS.*

BY JOSEPH A. BLAKE, M.D.,

NEW YORK.

It has seemed best to me, in speaking of the surgical aspects of malignant endocarditis, not to treat in detail of the origin and treatment of what may be considered the strictly surgical lesions at times accompanying the disease, but, in view of the shortness of time at our disposal and the comprehensiveness and greater value of the other papers upon the subject, to confine myself to a rather general consideration of some points which have particularly appealed to me.

In the first place, while all forms of acute endo-

*Read at a meeting of the New York Academy of Medicine, November 21, 1907.

carditis may be considered infectious, the so-called malignant or ulcerative is more commonly caused by infection by the pyogenic organisms, including the pneumococcus and gonococcus, and consequently possesses a certain amount of surgical interest, particularly in its etiology and, to a less extent, in its treatment. The treatment of those cases in which the only demonstrable lesion is in the endocardium and which progress with all the evidences of a profound general intoxication, is manifestly beyond the pale of surgery. There are, however, a number of cases in which, as a result of the lodgment of infectious emboli abscesses develop in the tissues or organs, which may be reached by surgical intervention. The more vascular organs are most prone to these invasions, namely, the kidneys, spleen, and parotid. In a number of these cases it may be difficult to decide whether the formation of the abscesses is dependent upon a pre-existing endocarditis or whether the cardiac and other lesions are simply parts of a general systemic infection.

In another series of cases a definite local suppurative process is the point from which the infection of the blood and endocardium originates, and it may be possible, by surgical treatment, to stop the continuous infection of the blood and thus modify the process in the endocardium; for it must be granted that there is in the endocardium, as elsewhere in the body, a definite resistance and effort to overcome infection.

This postulate leads us to the consideration of the possibility of at least a low grade of valvular implication being present in more cases of general pyogenic infection than is usually supposed. During the past summer, I had in my care a young man in whom a gonorrheal prostatitis was followed by a mixed staphylococcus infection. The resulting prostatic abscess had not been drained but had ruptured spontaneously into the bladder. In the week following the rupture of the abscess he was seized with sudden pain in the left hypochondrium and an elevation of temperature. Examination revealed an enlarged, fixed, and sensitive spleen. At this time there was an indistinct systolic murmur at the apex. The splenic abscess was drained and the murmur disappeared. Later, an abscess beneath the right deltoid was opened, and still later an abscess in the right groin beneath the adductor muscles. He finally recovered. The presence of the murmur before the abscess of the spleen was opened led, at the time, to a diagnosis of malignant endocarditis with an embolic abscess in the spleen. Later, the total disappearance of the murmur suggested that there had been only a slight inflammation of the endocardium and that it was simply a local expression of a general infection. It is perfectly possible that affections of the heart valves in the course of a general pyogenic infection oftentimes escape notice, particularly when we consider that surgeons seldom examine the heart repeatedly.

The objection may be made, with perfect propriety, that such slight affections of the cardiac valves do not constitute a malignant endocarditis and that the term is applicable only to those cases in which the lesions in the valves are progressive and produce death either by local elaboration of toxins or by causing infectious processes elsewhere. If we accept this definition, the surgical aspects of the disease are practically nil. If, on the other hand, we take the other view, that suppurative lesions of the endocardium may resolve, provided the initial focus and all secondary foci of infection are removed, there is a distinct surgical aspect to the disease.

Assuming this view to be possible, the term malignant is unfortunate, as it means nothing other than a condition regularly producing death. On the other hand, the term infectious or infective is too broad, inasmuch as it is also used to include the so-called simple forms of acute endocarditis regularly observed in rheumatism and chorea.

In the cases of malignant endocarditis, coming to autopsy, there is, according to Osler, a distinct loss of substance in the heart valves; yet, while ulceration is generally absent in simple endocarditis, it is often present in chronic endocarditis, so that for this reason alone the term ulcerative endocarditis would be objectionable, and, furthermore, in view of the fact that we have no information as to the anatomical character of the lesions in the valves unless death supervenes, we are not in the position to state that necrotic processes occur in all cases. It seems to me that, in so far as possible, the terminology of disease should rest upon an etiological basis and, if a distinct mycotic origin can be proven, as seems to be the case for this disease, it, rather than its clinical or anatomical end results, should be indicated in its title.

601 Madison Avenue.

The Toxin of Dysentery.—In a recent monograph on the "Toxin of Dysentery" (Das Dysenterietoxin), Dr. Robert Doerr draws a broad distinction between the Shiga-Kruse and Flexner types of organisms associated with bacillary dysentery. The former type secretes a genuine soluble toxin, whereas the latter does not. This toxin is found in high concentration in the germ-free filtrates of young broth cultures, the lethal dose being 0.01 c.cm. or less. A toxin may also be prepared from young agar cultures by extraction with salt solution and subsequent filtration. The intensity of the toxin production is dependent partly upon the individual characteristics of the strain of bacilli employed, and partly upon the degree of alkalinity of the culture medium. As the alkalinity of the medium is raised within certain limits, there is a corresponding increase in toxicity, the optimum result being obtained with broth which, after being made neutral to litmus, has received an addition of 3 grams of crystallized soda per liter. Under anaërobic conditions of growth or in albumin-free media no specific toxin is formed. Against heat the toxin is relatively resistant; it withstands a temperature of 70° C. for an hour, but is quickly destroyed by a temperature as high as 80° C. It resists the action of trypsin, bile, and enterokinase. Mineral acids neutralize the toxicity of broth culture filtrates, but though they combine with the toxin they do not destroy it, since the toxicity is again demonstrable when the medium is brought back to an alkaline reaction. The toxin of dysentery is pathogenic for rabbits, cats, dogs, and monkeys, but guinea pigs, white mice, fowls, and pigeons are refractory. In susceptible animals which have been inoculated either intravenously, subcutaneously, or intraperitoneally, there is often produced an inflammatory condition of the intestinal mucosa, characterized by hemorrhagic necrosis. It is also found that the toxin regularly produces lesions of the nerve centers to which the animals succumb. The most useful animal for experimental purposes is the rabbit. In about a third of these animals a hemorrhagic membranous typhlitis is produced, whilst the small intestine, as in man, remains unaffected. The excretion of the toxin takes place through the intestine, and also, though to a relatively small extent, through the kidneys; the liver, on the other hand, appears to take no part in the excretory process.—*British Medical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 7, 1907.

DOCTOR SHRADY, the founder of the MEDICAL RECORD and for nearly forty years its editor, is dead. He had reached the Psalmist's limit of three score years and ten, yet his heart was young, his frame was active, and his mind had lost none of its acumen. Medical journalism had in him a brilliant writer and an editor who had no rival. In his death surgery has lost a wise and conservative counselor, and on occasion a fearless and successful operator; those who knew him have lost a witty and entertaining companion; his friends have lost a comrade, loving and beloved; the world has lost a man who made it better for having lived in it.

SERUM TREATMENT OF TYPHOID FEVER.

AFTER the reintroduction of hydrotherapy, under the influence of Brand, deaths from typhoid fever began to diminish, the mortality varying from seven to twenty per cent. During the past few years army reports from the British and German colonies show a still further reduction of the mortality after the use of typhoid-serum. Similar good results were obtained by Brunon of Rouen, Josias of Paris, and the medical officers at the French military hospital of Val-de-Grâce where the mortality was reduced from ten or twelve to three or five per cent. after the use of the serum.

A recent report by A. Chantemesse in the *Klinisch-therapeutische Wochenschrift* of October 14, 1907, offers a good opportunity for comparing the serum-therapy with the ordinary typhoid therapy. He does not compare the results obtained with serum in one epidemic with those obtained by the ordinary treatment in another epidemic, for such a comparison would be misleading since the mortality varies in different epidemics. His report covers all the typhoid cases in the Paris hospitals for a period of six years, patients in each epidemic having been treated by both methods. From April, 1901, to July, 1907, 5,621 typhoid patients were admitted to the Paris hospitals of whom 960 died, a mortality of 17 per cent. During the same period Chantemesse cared for 1,000 patients in his own hospital, and of these forty-three died, a mortality of 4.3 per cent., their treatment having been identical with that employed in the other hospitals, with the one exception that they also received an injection of typhoid serum.

The clinical course was changed by the use of the serum, the injection having been followed in each case by a stage of reaction, lasting from five to six days, during which the temperature dropped but little or not at all, and by a stage of decline, also lasting five or six days, during which the temperature came down to normal. The general condition improved, and instead of the pale face, cold nose, hands, and feet noted while the temperature was high, these became red and warm, the blood pressure rising to 12 and 15 cm. mercury, so that stimulants were often unnecessary. The fact that the disease is shortened and the mortality is low, no patient having died who was injected during the first seven days of the disease, is in itself proof that the complications are rare. Among the forty-three deaths there were four due to hemorrhage and nineteen due to perforation, showing that the serum is less efficacious in preventing the latter than in preventing the other complications, probably because the ulcers are among the first pathological changes and are usually present before the serum is injected; in no case in which the serum was given during the first seven days of the disease did a perforation occur. Late complications, such as periostitis, orchitis, and mastoiditis, were readily cured by injecting some serum directly into the diseased parts. The serum injected into the veins of healthy animals in doses from thirty to forty times larger than those used in man caused no symptoms. Animals which received two c.c. of the serum subcutaneously and which twenty-four hours later had typhoid bacilli injected into an ear vein, lived while a similar injection of bacilli killed the control animals which had not been previously injected with the serum. The blood in the ear of the serum animals that had been injected with bacilli showed the latter inclosed in phagocytes five hours later, while the bacilli were found multiplying in the ear of animals not treated with the serum, the latter thus acting as an opsonin. But the serum also acts as an antitoxin which Chantemesse proved experimentally by injecting typhoid toxins into animals. After the injection the animals lost weight and displayed a hypoleucocytosis and died if the dose was large enough; if the animals had previously received some serum the toxin had hardly any effect; in fact, it could be given with impunity in doses of sufficient size to kill the control animals in thirty-six hours.

Chantemesse found that the opsonic index rose above normal in every typhoid patient, but that it varied, depending upon the severity of the disease. Taking one as the normal index, it rose to two in mild cases, while in severe cases it rose only to one and a fraction. In patients treated with the serum the index always rose above two and remained so for three or four days after the injection, this observation furnishing another proof of the protective action of the serum. During the three or four days after the injection there is a marked destruction of bacilli causing an increase of toxins in the blood, hence only small doses of serum should be given in severe forms of the disease. The baths are necessary to counteract the reaction caused by the bacteriolysis.

CARCINOMA FOLLOWING X-RAY DERMATITIS.

Since 1896 the literature on the effects of *x*-ray has grown each year. The earliest articles dealt with dermatitis and burns which were found to differ from similar lesions caused by heat in that they were most excruciatingly painful and extremely slow to heal; further experience showed that some lesions closed with great difficulty only to break down again and again, finally forming chronic ulcers. Then came the first report of cancer developing in a chronic ulcer and finally the first death from metastatic cancer. The slowly increasing list of *x*-ray carcinomata emphasizes the great danger of all persistent *x*-ray ulcerations.

In the November number of the *Annals of Surgery* Drs. C. A. Porter and C. J. White have gone into this subject thoroughly and have added another case of multiple epithelial carcinoma to those already published. Their patient was a young man who first began *x*-ray work with a large static machine in 1896, but after a few months used a twelve-inch coil. He exposed himself several hours each day at a very short distance from a low vacuum tube. After eight months his hands became dry, red, painful, and swollen; the dermatitis subsided under treatment and work was continued. Five months later a second attack occurred with the formation of blisters and ulcers. The latter refused to heal and after three months' local treatment, were finally cleaned up surgically and skin-grafted. The majority of these grafts adhered and epithelioma never developed in any graft which completely took at this time. Though all *x*-ray work was stopped for a year, ulcers again developed and refused to heal under ordinary treatment, so that in 1902 they were again excised, but the specimens this time showed unmistakable evidence of carcinoma, requiring an amputation of the fingers involved. During the period from October, 1902, to June, 1905, a dozen or more operations were performed, including amputations and excisions of keratose areas on the dorsum of the hand, until finally in June, 1905, he was, for the first time in eight years, free from pain and dressings. This favorable condition, however, did not last long, for in a few months new lesions had to be excised, some of them again showing typical epithelioma. To-day, after ten years' treatment, the patient has only a few useful fingers left, ten different epitheliomata having been removed during that time. The microscopical examinations were made by White and almost every phase of epidermic deviation was encountered in the several specimens.

This and other experiences have led Porter to believe excision and skin-grafting to be the best treatment in all chronic *x*-ray lesions (keratosis, warts, recurrent fissures), as it relieves pain and results in cure. As his and all other reported cases of carcinoma were always preceded by persistent ulceration for from three to six months, he advises excision and microscopical examination of the ulcers if they remain open after three months of ordinary treatment, the subsequent treatment (skin-grafting or amputation) depending upon the result of the examination.

FORMALDEHYDE DISINFECTION.

Formic aldehyde vapor has long been recognized as one of the most efficient germicides available for disinfecting rooms, but there has always been a difficulty in devising a safe, economical, and effective method for obtaining the gas from solutions or from its dry polymeric form, which would not require expensive apparatus and a skilled operator. G. F. Johnson first drew attention in 1904 to a new means of obtaining the gas without external heat, by the simple addition of permanganate crystals to formaldehyde solution. Since the appearance of his paper many experiments have been made for the purpose of determining the relative proportions of each which will yield the best effect.

E. M. Houghton and L. T. Clark publish, in the *Therapeutic Gazette* for July, 1907, the results of their experiments on this method of liberating formic aldehyde from aqueous solution. They found that when 240 grains of crystals of permanganate of potassium was placed in an ordinary three-gallon pail and 480 c.c. of formol added, sufficient gas was evolved to disinfect 1,600 cubic feet of space. As the ebullition set up was very violent, occasioning much foaming and spattering over the pail, the authors tried various experiments to retard the reaction sufficiently in order to do away with this disadvantage. They eventually succeeded, by mixing the crystals with 15 per cent. of Portland cement and enough water to give sufficient consistency for making small blocks. After being moulded, these briquettes are left to dry, and can then be readily handled. The charge of formaldehyde is poured into the pail, and three briquettes, each containing eighty grams of permanganate crystals, are dropped into the liquid. The reaction is slower and less violent. The authors claim that formic aldehyde disinfection is simply and quickly accomplished by means of the permanganate briquettes; no expensive apparatus is necessary, and no outside heat is employed, thus lessening the danger of fire; more thorough disinfection is accomplished, because the whole volume of gas and moisture is liberated during a very short time. The usual sealing up of the room is necessary, and the operator must leave the room directly after the permanganate is put into the liquid.

Relapsing Fever.

While in this country relapsing fever is so rare that most practitioners have never seen a case, in Russia it is constantly present and more or less widespread outbreaks take place at comparatively frequent intervals. In Kieff, for example, a city of 300,000 inhabitants, cases of the disease have occurred during every year of the decade ending with 1906, the greatest number of cases reported being 489 in the year 1898, and the smallest 8 in 1904. Early in 1906 an epidemic of very considerable proportions began, and up to the end of May, 1907, 4,080 cases had been recorded. This epidemic has been made the subject of investigation by Robinovitch (*Berliner klinische Wochenschrift*, November 11, 1907), who in a preliminary communication expresses the belief that the widely held view that the disease is often transmitted by the bites of insects, notably bedbugs, is erroneous. A number of arguments are advanced by the author, the most

striking being that afforded by his experimental work. Twenty bedbugs were kept without food for eight days in a glass dish which was then tied against the arm of a patient suffering from the disease. An hour later all the insects were seen to be distended with blood and the dish was fastened in a similar way to the author's thigh. In spite of severe bites no infection followed, though living spirilla were still present in the bodies of the bugs five days later. This experiment was repeated several times, and then, in order to afford opportunity for any possibly necessary adaptation in the body of the bug to take place, the insects were kept for seven days before being applied to the test person. Living spirilla were present at the end of this period, but no infection followed. Robinovitch suggests that numerous considerations, notably the filthy habits of the abjectly poverty-stricken classes among whom the disease is most often seen and the fact that physicians are rarely infected, makes it likely that transmission takes place by way of the alimentary canal. This supposition is strengthened by the observation that gastrointestinal symptoms, such as vomiting and diarrhea, are ordinarily the earliest manifestations of the disease. The injection of the spirochetes into the circulation of laboratory animals did not produce symptoms, but severe gastrointestinal disturbances followed when the infectious material was introduced into the stomach. Further investigations in this direction are being carried on by the author.

Apophysitis in Growing Children.

In any child who complains of his knee, or heel, or spine, the last thing usually thought of is apophysitis. It is always difficult to diagnose it from tuberculosis, as the age of the patient, the slow appearance of symptoms, variations in the pain, and its increase after walking, are symptoms common to both diseases. An exact diagnosis, however, is important from the point of view of treatment, and therefore cases of apophysary osteitis are of undoubted practical interest. In *La Presse Médicale* (No. 34, 1907), R. Romme contributes an article on this subject. His patients were anywhere from nine to eighteen years old, owing to the different time of ossification; the most frequent cases were those involving the anterior tuberosity of the tibia. He describes tibial apophysitis as beginning suddenly with pain of variable intensity, but sometimes very acute, in one or both knees. On palpation the pain is found strictly localized to the anterior tuberosity, which is felt to be thickened. General symptoms are absent unless the condition, instead of remaining a hypertrophic osteitis leading to the formation of a hyperostosis, should begin to suppurate. Tibial apophysitis is easy to diagnose, but diagnosis is extremely difficult when the disease affects the posterior part of the os calcis. In this case the patient may have been lame for some time with pain at the back of the heel; some improvement may follow rest and the administration of sodium salicylate, but the pain and lameness reappear, and now the posterior third of the bone is found enlarged and tender at the insertion of the tendo Achillis. Usually the other side is also affected, but to a less degree. It differs from tuberculosis of the os calcis, inasmuch as the latter usually occupies the anterior third of the bone, does not lead to bony hypertrophy, and is generally unilateral. The diagnosis of vertebral apophysitis is more easy. An abnormal and painful swelling is formed by the hypertrophied tuberosity of the spinous apophysis of the vertebra, the pain is strictly localized; the absence of contraction and curvature is sufficient to eliminate Pott's disease. The treatment of all forms is simple, rest with counterirritants generally being sufficient to bring about a quick recovery, unless the apophysitis suppurates, when incision and curettage becomes necessary.

A Diagnostic Aid in Tuberculosis.

The physical signs of pulmonary tuberculosis have been so exhaustively studied that it is interesting to find a new clinical aid described even though it must perforce be regarded with some judicial skepticism. Francke (*Münchener medizinische Wochenschrift,* November 12, 1907) has found that careful observation often reveals in the skin over the apices of the lungs minute striations which are sometimes blue but more often red in color. These he considers are capillaries that have become very much distended as the result of inflammatory changes in their walls. As long as they remain permeable their color is red and they may be obliterated by pressure, but if thrombosis supervenes they become converted into blue markings that do not change on pressure. The striations were present in over 75 per cent. of 200 patients with pulmonary tuberculosis of all grades of severity examined by the author and in 27 per cent. of persons coming under observation for other conditions and not manifesting any evidences of pulmonary changes. Francke believes that these capillary lesions of the skin are the result of tuberculous processes in the pleura and the adjacent parts of the lung and that their absence in cases in which there are signs of pulmonary disease indicates that the lesion is a deep seated one. The number and distribution of the striæ show the extent of the tuberculous focus while their color and arrangement permit conclusions to be drawn regarding the intensity and duration of the process. The detection of striæ in persons apparently not suffering from pulmonary disease points to the existence of latent lesions. It is evident that considerable experience and caution are necessary in interpreting these capillary markings, and as they also occur in other parts of the body such as the face, along the costal borders, and about the ankles, where their formation must be due to other causes, their direct connection with tuberculosis demands rather more convincing evidence than Francke gives in his paper.

Malingering in a New Form.

It has often been pointed out that the advances of practical science are frequently accompanied by corresponding ingenuity in perverting their benefits to illegitimate uses. Thermite and the electric arc aid the up-to-date safe breaker, the modern burglar carries an electric pocket light instead of the traditional dark lantern, the most advanced photomechanical processes are employed by counterfeiters, gambling apparatus is equipped with highly ingenious devices for electrical and magnetic control, etc. Even in medicine the abortionists—at least some of them—have learned the advantages of asepsis, and perhaps certain new anesthetics are destined to supplant the less elegant administration of knock-out drops. The subterfuges resorted to in European countries by those who would avoid military service are many and devious, but perhaps the most ingenious is that of

having artificial new growths produced by the subcutaneous injection of paraffin. Three such cases are reported with photographs by Goldenberg in the *Deutsche medizinische Wochenschrift* of November 14, 1907. In each instance a very good imitation of a mass of tuberculous cervical glands had been produced, though in one case the operator had overshot the mark by adding as a finishing touch a flat subcutaneous tumor of the back that resembled nothing so far recorded in the annals of pathology. Goldenberg brings up the point of whether a surgeon acts properly in correcting such a disfigurement, self-inflicted for an unlawful purpose, and concludes that he is justified in so doing, but is not obligated to, and states that in future any patients of this sort that may present themselves will not be treated at the Breslau Hospital with which he is connected.

News of the Week.

Anniversary Meeting of the Academy of Medicine.—At the sixtieth anniversary meeting of the New York Academy of Medicine on November 29, Col. W. C. Gorgas, Chief Sanitary Officer of the Isthmian Canal Commission, delivered an address on the sanitary problems encountered in the canal zone and the results that had been obtained in practically exterminating yellow fever and reducing malaria to a minimum.

Low French Birth-Rate.—The statistics just published by the *Official Journal of the Republic* show that the birth-rate in France during the year 1906 was the lowest on record. During recent years there has been a steady decline in the number of births and the average yearly figures from 1896 to 1905 were 839,843. In 1906 the births fell to 806,847, while the deaths were 780,196.

Fewer American Students in German Universities.—The number of American students at the University of Berlin has fallen to the smallest figure on record. Only sixty-eight men and twenty-seven women from America are enrolled on the university books, as compared with a total of more than two hundred three years ago and more than four hundred ten years ago. A similar state of affairs is said to exist at Heidelberg, Göttingen, Jena, Leipsic, Halle, and other prominent universities.

County Medical Society.—At the annual meeting of the Medical Society of the County of New York held last week the following officers were elected: *President*, Dr. J. Riddle Goffe; *Vice-Presidents*, Dr. H. Seymour Houghton and Dr. John E. Weeks; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. J. Milton Moffat; *Treasurer*, Dr. Charles H. Richardson.

Cornell University Medical School.—The Faculty of the Cornell University Medical College announces it has been decided that the usual "high school" education, commonly accepted as sufficient preparation for the study of medicine, is inadequate. Therefore, on and after 1908 candidates for admission to the Cornell University Medical College must be (1) graduates of approved colleges or scientific schools; or (2) seniors in good standing in Cornell University or in any other approved college or scientific school whose faculty will permit them to substitute the first year of a professional course for the fourth year in arts and science, and who will confer upon them the Bachelor's Degree upon the satisfactory completion of the first year of the course in the Cornell University Medical College; or (3) persons who, while not possessing a Bachelor's Degree, give evidence by examination that they have acquired an equivalent education and a training sufficient to enable them to profit by the instruction offered in the Medical College. In and after 1909 all candidates for admission to the Medical College must have at least such knowledge of physics and inorganic chemistry as may be obtained in college by a year's course in these subjects when accompanied by laboratory work. In and after 1910 all candidates for admission must possess a similar knowledge of biology.

Medical Society of the County of Dutchess.—The annual meeting of this society will be held in Poughkeepsie on January 8, 1908.

A Health Clearing House for Chicago.—The Commissioner of Health in Chicago is seeking to establish what may be termed a health clearing house for Chicago and all its suburbs. In order to control as far as possible the sources and means of transmission of infectious diseases it is proposed that Chicago and all communities within a radius of fifty miles should cooperate in maintaining necessary laboratories and a smallpox hospital, in obtaining and publishing health data, in purchasing supplies, and in taking precautionary measures, ordinary and extraordinary, against the spread of diseases.

Fire in the New Jersey State Hospital.—A fire in the State Hospital at Morris Plains, N. J., did $20,000 damage and almost entirely destroyed the nurses' building erected six years ago. No lives were lost, but several of the nurses were injured in jumping from the windows of the burning building.

Plague and Religion.—It is reported that the efforts of the Indian Government to stamp out the plague up to the present time have been enormously hampered by the refusal of the Mohammedans to evacuate infected villages, on the ground that they were forbidden by the Koran to "flee from the wrath of God." Fully 250,000 deaths from the plague among Moslems are estimated to have been caused by adherence to this belief. Now the heads of the Moslem faith, urged thereto by the Government, have issued a proclamation pointing out the untenability of this idea and declaring that the Koran expressly enjoins Mohammedans to quit places smitten by Allah with this disease. The Government is publishing the proclamation widecast.

Quarantine in St. Vincent's Hospital.—By order of the Health Department the boys' ward in St. Vincent's Hospital was quarantined last week because of a case of scarlet fever, which developed in a patient who had been in the ward eighteen days before the diseases manifested itself.

Florence Nightingale Honored.—Florence Nightingale, the heroine of the Crimean war and founder of the Nightingale Home for the Training of Nurses in London, now in her eighty-eighth year, has been decorated by King Edward with the Order of Merit. This was founded by King Edward in 1902 for the recognition of especially distinguished services in all walks of life and is regarded as one of the highest honors within the gift of the sovereign. It has been bestowed on nineteen men, but this is the first time it has been conferred on a woman.

Nobel Prizes in Medicine and Physics.—The Nobel prize in medicine is to be awarded to Dr. Laveran of Paris, who is well known for his work on tropical diseases, and Professor A. A. Michelson of Chicago is to receive the prize in physics. Dr.

Michelson is the inventor of a new method for measuring the velocity of light.

Two Centenarians.—Mrs. Margaret Horn, an inmate of the Home for the Aged and Infirm on Blackwell's Island, died last week at the age of one hundred and two years. Her husband died twelve years ago at the age of one hundred and three years. W. R. Chambers, thought to have been the oldest resident of Pennsylvania, died on November 24 at his home in Cecil, Washington County, aged one hundred and five years. Up to the time of his death he is said to have been in full possession of all his faculties. He leaves a sister aged one hundred and three years and over a hundred descendants.

A Fatal Banquet.—Three men have died, four others are not expected to live, and over twenty are seriously ill as the result of eating tainted oysters at a Masonic banquet held in Dover, Mich., early in November.

Society of Sanitary and Moral Prophylaxis.—The next meeting of this Society will be held at the Academy of Medicine on Thursday, December 12. Papers will be read on "Police Methods of Dealing with Prostitution in Germany," and on "Statistics of Prostitution in New York City."

Cincinnati Hospital.—The following appointments have been made to the staff of the Cincinnati Hospital: Dr. R. W. Thomas, pathologist; Dr. D. I. Wolfstein, neurologist; Dr. M. L. Heidingsfeld and Dr. A. J. Markley, dermatologists; Dr. W. H. Lewis, assistant in the laboratory.

The Cincinnati Academy of Medicine passed a resolution on November 25 requesting the city council to take the power of a board of health from the Board of Public Service and place it in the hands of a Board of Health consisting of five members appointed by the Mayor.

Psychiatrical Clinic in Brooklyn.—Dr. O. M. Dewing, superintendent of the Long Island State Hospital, announces that a psychiatrical clinic will be held at the hospital, corner of Clarkson St. and Albany Ave., Borough of Brooklyn, at 9 A.M. every Friday. At this clinic interesting cases will be presented by members of the medical staff and an opportunity will be given for the personal examination of these cases, and for general discussion of them. All physicians are cordially invited to attend.

A Cancer Exhibition in Brussels.—In September, 1908, a cancer exhibition is to be held in Brussels in connection with the Second International Surgical Congress. The exposition is to comprise exhibits of all sorts relative to the nature, occurrence, investigation, and treatment of malignant new growths and will be under the direction of the general secretary of the Surgical Congress, Professor Denage of Brussels.

Smallpox in Iowa.—Eleven cases of smallpox are reported as having occurred among the students in Ames College, Ames, Ia.

Tri-State Medical Association.—At the meeting of the Tri-State Medical Association of Mississippi, Arkansas, and Tennessee held in Memphis on November 22, officers were elected as follows: *President*, Dr. Eugene Johnson of Yazoo City, Miss.; *Vice-Presidents*, Dr. R. E. Howard of Durant, Miss.; Dr. C. M. Lutterloh of Jonesboro, Ark., and Dr. Herman Hawkins of Jackson, Tenn.; *Secretary*, Dr. Richmond McKinney of Memphis; *Treasurer*, Dr. Marcus Haase of Memphis.

Lectures on Orthopedic Surgery.—Dr. Russell A. Hibbs, Surgeon-in-Chief of the New York Orthopedic Dispensary and Hospital at 126 East Fifty-ninth Street will give a course of clinical lectures on orthopedic surgery at the institution, on Tuesday and Friday afternoons, at 4:30 o'clock, from December 3 to January 3. The course will be free to physicians and students.

Meeting of the Red Cross.—The annual meeting of the American National Red Cross Society was held in Washington on December 3, thirteen States being represented. Secretary of State Root delivered an address, in which he paid a tribute to the work done by the Society during the past year. Officers were elected as follows: *President*, William H. Taft; *Treasurer*, Beekman Winthrop; *Counsellor*, Alford W. Cooley; *Secretary*, Charles L. Magee. Mrs. Marshall Field of Chicago and Miss Helen Gould of New York were elected members of the Board of Incorporation of the Society.

Obituary Notes.—Dr. Walter J. Norfolk of Plainfield, N. J., died on November 25 at the age of fifty-nine years. Dr. Norfolk was a native of Salem, Mass., and after his graduation from Harvard University and Harvard Medical College he was a resident of Boston till about fourteen years ago, when he removed to Plainfield.

Dr. William G. Russell of Brooklyn died on November 29 at the age of sixty years. He was born in this city and was a graduate of the Long Island College Hospital. He had practised in Brooklyn for over thirty years.

Dr. Edward S. Gates of Cincinnati was instantly killed on November 27 while on his way to a patient. Dr. Gates was alone in his automobile and in crossing a railroad track the car was struck by the locomotive of a train.

Dr. Thomas Wildes of this city died suddenly of apoplexy on November 29 at the age of sixty-eight years. He was graduated from the New York Homeopathic College in 1876 and was connected with the Health Department.

Dr. William S. Bowen of East Greenwich, R. I., died suddenly on November 24 at the age of sixty-five years. He was graduated from Harvard Medical School in 1867 and served for a time as surgeon in the navy. He then practised for some years in Providence, but later gave up his medical work and became a journalist, serving as foreign correspondent for numerous newspapers.

Dr. Sidney I. Small of Saginaw, Mich., died of apoplexy on November 23 at the age of sixty-five years. He was born in Maine and had been a resident of Saginaw since 1874.

Dr. William H. Lamar of Jasper, Ala., died on November 18 at the age of eighty years. He was born in Augusta and had lived in Auburn for over thirty years.

Dr. James E. Kirkpatrick of Los Angeles, Cal., died on November 19 at the age of eighty-two years. Dr. Kirkpatrick had practised in Oregon for twenty-five years before retiring to Los Angeles ten years ago.

Dr. O. D. Norton of Cincinnati died on November 29 at the age of eighty-six years.

Dr. J. P. Oberndorfer of this city died on December 1 of appendicitis. He was a graduate of the College of Physicians and Surgeons in the Class of 1874 and afterwards spent two years in postgraduate work in the University of Leipsic. Of late years he had devoted himself exclusively to dermatology. He had been connected with the German Dispensary for over thirty years and several years ago was a candidate for the office of coroner.

GEORGE FREDERICK SHRADY, A.M., M.D.

JANUARY 14, 1837—NOVEMBER 29, 1907.

In the death of Dr. Shrady there has ended all too soon a career of full and well-rounded achievement, and there has gone from us a personality quite unique in its type and charm; for there was no one quite like Dr. Shrady in his qualities as a man and companion. His geniality of temper, his ready humor, his curious adroitness of expression, and his surprising feats of mimicry and story-telling made him a distinct character among his fellows. As he grew older these personal qualities became more widely known; perhaps they ripened a little; his friends increased, his enemies fell away, till now that the end has come he will be thought of by all as one with whom it was a joy to have companionship and converse.

But Dr. Shrady did not succeed in his career without showing that he had real strength of character and firmness of purpose behind an engaging exterior. He began life equipped with a sound education and a thorough medical and surgical training in college and hospital. He had a manual dexterity which made surgery attractive and easy to him, but which also through his mastery of short-hand led him into medical journalism. And this latter seemed really to be his gift, for he achieved his great success here only by showing that he had special talent for it, as well as courage and initiative. In his early years, and often later, he was visited by eminent medical men, alone or in bodies, who informed him that the policy he was pursuing was wrong and would end in damage to himself and his journal, but he smiled in his inscrutable way and kept at his purpose. No man was more *tenax propositi* when settled on a course, and no man ever succeeded in worsting him in argument over his policies. He would simply smile and joke, and tell a story, but he never really argued. So he always won. He had thought out his view, and that settled it for him. This constancy of purpose was accompanied with a very wise and even cautious conservatism, but he had also a sound judgment and a very penetrating knowledge of his brother man and of the best way to deal with him; he was a wise man in the conduct of affairs, and he knew how to use his wisdom tactfully. He was a student of human character, and he rather loved to dwell on the weaknesses of his fellows; for he had had occasion to see a good deal of the under side of the medical world; but his policies and ideals were all practically high and good. He never advocated a bad or low cause, and if he showed on rare occasions a personal bitterness, it was but a small thing in his whole career.

Dr. Shrady believed that the doctor should be in a saner and closer relation with the public than professional custom formerly allowed. He was often criticised for his interviews with journalists, but this point was always clearly held in his mind, viz., that he was an interpreter and teacher, and that a doctor of experience and authority ought to tell the public those things about his profession that would be helpful to human progress.

Dr. Shrady's literary work, like that of most journalists, is mainly buried in anonymous editorial writing. Here he was most skillful in presenting his point of view clearly and smoothly, yet with a certain elusiveness that made it difficult to controvert successfully any particular position. He wrote strategically, leaving no point that he could not either strengthen or evacuate according to the needs of the situation. He was a sort of medical Henry James when he set out to do his more elaborate tasks, and he did not lack in a subtle humor. His Pine Ridge Letters must be read with the recollection of the state of medicine in New York twenty-five years ago. Dr. Fordyce Barker said that they were worthy of *The Spectator*. Perhaps the best specimen of his really masterly art was his last contribution, entitled "Professional Reminiscences" and published in "The Charaka Club Book." He wrote easily, yet with corrections; he worked easily also and never with a fuss; he worked with a clean desk.

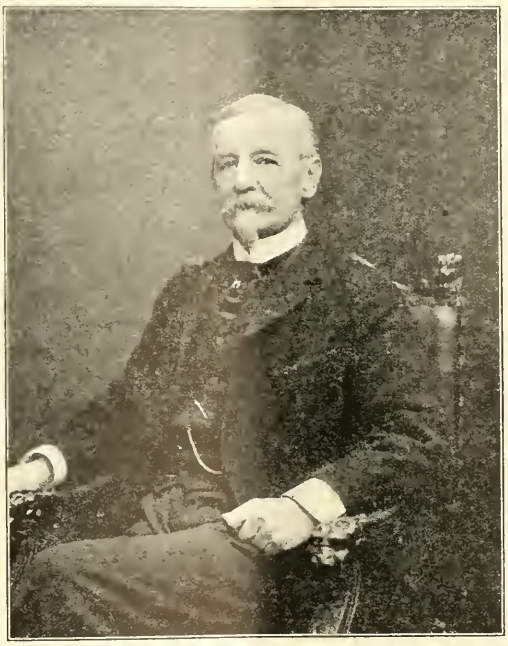
Of Dr. Shrady's surgical achievements I am not competent to speak. He did some excellent plastic surgery; he was skilful as an operator, and the only criticism of him was directed to his conservatism. He was slow to decide on an operation, but when he did decide his work he did it rapidly and well. His contributions to surgery covered a wide field, but had more especially to do with plastic and abdominal surgery and tumors.

After all, Dr. Shrady will be best remembered for the work he did in establishing and maintaining a modern medical journal, which had as its special purpose helpfulness to the general practitioner and the encouragement of whatever was for the best interests of the profession. He always felt that he stood rather as champion of general practitioners, and he tried to do everything possible to secure their interests and promote their welfare. He lived and worked at a time when his policies caused antagonism from some of the medical schools and when an ethical schism disrupted the profession of this State. The problems of the State care of the insane, the sanitary work of this city, and of the State, the questions of medical education, of public schools, the extraordinary developments of laboratory science, all received his sympathetic interest and wholesome support. He stood for high ideals, though he made no parade of such. His achievements as a medical journalist deserve more space than I can give them now. He was listened to by both medical readers and the laity. Before him we had medical journals, but he made them influential and respected, and a force in the community. This distinctive quality of medical journalism is found only in this country and England.

He had a most equable nature, and, though he had many antagonisms to meet, much harsh language to endure, and criticism to overcome, he pursued his way with serene front and ever ready jest. Even in tumultuous times a visit with him was a refreshment to the soul. He was always a lovable man; he grew more so in his age, and it is pleasant to know that in his last years he lived a happy life, and died with the knowledge that he had troops of friends to lament his loss and comment upon a life which gave out much of happiness and was filled with such real achievement.

CHARLES L. DANA.

DR. GEORGE F. SHRADY died at his residence in this city on November 29 of pyemia following an attack of gallstones, after an illness of only two weeks' duration. He was born in the family homestead on Rivington street, New York City, on January 14, 1837. His early training was in the public schools and his academic education was obtained at the Free Academy, which was even then of collegiate rank, but did not until later receive its present title of the College of the City of New York. He was graduated in medicine from the College of Physicians and Surgeons in the class of 1858. His surgical skill was foreshadowed during his undergraduate career by his special predilection for anatomy, and in the same year that he received his degree he was also awarded the Wood Intercollegiate Prize for proficiency in anatomy. After graduation he served a term as interne in the surgical division of the New York Hospital, and in 1859 began the practice of his profession in this city. Upon the outbreak of the Civil War he offered his services to the Government, and was detailed as assistant surgeon in the military hospital in Central Park, in the building now known as the "Arsenal." Later he saw service in field hospitals in Virginia, and on one occasion nearly lost his life in a wreck while in charge of some wounded soldiers who had been sent by sea to hospitals at the north. Shortly before the close of the war he returned to New York and resumed private practice. He was a proficient stenographer, and this led in his early days to employment in reporting the meetings of medical societies for the *Medical Times*, of which journal he later became editor. In 1866 the MEDICAL RECORD was founded with Dr. Shrady as editor, and for thirty-eight years he gave his best thought and his skill as a writer and executive manager to the conduct of this journal. He was an indefatigable worker, and for many years conducted the journal almost single-handed, reporting society meetings, writing editorials, abstracting articles from other papers, collecting news items, and doing whatever the occasion demanded to make the RECORD a worthy representative of medical opinion. One of the "hits" which attracted much attention at the time was the publication of a series of articles, entitled "Pine Ridge Papers," purporting to be written by a country practitioner, in which he treated with the satirical wit of which he was a master, of the foibles and the tendency to charlatanism of certain practitioners of the time. He resigned the editorial management of the journal in July, 1904. In addition to his anonymous contributions to the editorial pages of the MEDICAL RECORD, Dr. Shrady wrote many papers from time to time on surgical subjects, nearly all of which were published in his own journal. The following is a list of these papers, many of which were read at meetings of the Medical Society of the State of New York, and of the Practitioners' Society, of which he was a founder and always an enthusiastic member.



Geo. F. Shrady

"Ligation of the Lingual Artery near its Origin, as a Preliminary Procedure in the Extirpation of Cancerous Disease of the Tongue," September 14, 1878. "A New Subcutaneous Saw, Knife, and Bone Rasp," January 11, 1879. "The Curved Flap in Plastic Operations on the Face," January 25, 1879. "Reproduction of the Shaft of the Humerus, after Excision for Acute Necrosis," April 24, 1880. "Intraparietal Hernia," May 7, 1881. "Surgical and Pathological Reflections on President Garfield's Wound," October 8, 1881. "Removal of a Large Naso-Pharyngeal Tumor, with Extensive Attachments to Base of Skull; Unexpected Brain Complication; Death," September 16, 1882. "Successful Tracheotomy for Diphtheritic Croup in a Child Eleven Months Old," November 4, 1882. "Case of Strangulated Hernia, with Remarks on Treatment," November 29, 1884. When the Medical Society of the State of New York, in 1882, voted to do away with the antiquated Code of Medical Ethics and proclaimed a new emancipation proclamation, Dr. Shrady threw his personal influence and that of his journal on the side of reform, and labored heart and soul for the cause of individual and professional liberty. Intimate friends fell away, for feeling ran high in those troublous times, and influential members of the profession in the city and the State urged him to maintain a position of neutrality at least, even threatening him with professional ostracism and the ruin of his journal if he persisted in his advocacy of independence. Such considerations, however, had no weight with a man of his character, and he refused to swerve from a course which his reason and his conscience told him was right. He lived to witness the triumph of the cause he advocated and to see the American Medical Association itself reject the Code as it then was and adopt as a compromise a revised Code which should be not binding upon any member, but only advisory, in order to win back the allegiance of the profession in New York State, without which its claim to be a national body was untenable. The American Medical Association owes the fact that it stands to-day as the representative of a free and united profession very largely to Dr. Shrady.

Dr. Shrady was also a frequent contributor of papers, of a popular character, to the magazines and other lay publications. He was for many years a member of the editorial staff of the *New York Herald*, devoting his attention especially to matters of public health and to medico-sociological subjects. When the bubonic plague broke out for the first time some years ago in San Francisco, its existence was vehemently denied by the Mayor and other officials. This policy of concealment had its usual effect, and wild rumors were about that an extensive epidemic was raging in Chinatown. That the country might know the facts, Dr. Shrady went to San Francisco, commissioned by the *Herald* to find out the truth and publish it. In spite of the many obstacles placed in his way by the municipal authorities, who had heard of his coming, he made a thorough investigation, going into the infected district and examining the suspicious cases. He announced as the result of his inquest that the disease was actually present, but that the cases were few, and that the small epidemic, if such it could be called, was under control by the health officers. He thereby exposed the duplicity of the men who denied the existence of the plague, and at the same time allayed the apprehension of those who had been led to fear that the situation was more serious than it really was.

As a surgeon Dr. Shrady was a skilful operator, but never achieved the reputation in this respect that he might have done, because of his conservatism. He was conscientiously opposed to the use of the knife when he believed life could be saved by more gentle measures, and never yielded to the temptation to perform a brilliant operation when a cure without mutilation was possible. Perhaps for this reason, as well as because of his reputation as a wise counselor and acute diagnostician, he was frequently sought as a consultant by his colleagues, both medical and surgical. When President Garfield was shot Dr. Shrady was consulted as pathologist, and he was requested to make a report to the profession and the public on the surgical and pathological reports of the case. He was also one of the surgeons in attendance on General Grant during his last illness, and when Emperor Frederick of Germany was suffering from an apparently similar affection of the throat, Sir Morell Mackenzie sought an opinion by cable from Dr. Shrady. In 1890, when Kemmler was put to death by electricity, the first murderer to receive capital punishment by this method, Dr. Shrady was one of the medical experts appointed to witness the execution.

In 1869 Yale College conferred upon Dr. Shrady the honorary degree of Master of Arts in recognition of his eminent services in the cause of medical literature.

Dr. Shrady was visiting surgeon to St. Francis' Hospital for twenty years, and was consulting surgeon there for over six years past. He was also consulting surgeon to the Hospital for the Ruptured and Crippled, the Columbus Hospital, the Fordham Home for Incurables, the General Memorial Hospital, the Red Cross Hospital, the Vassar Hospital at Poughkeepsie, and the Hackensack Hospital, New Jersey, and was at one time attending surgeon to the Presbyterian Hospital. He was consulting physician to the hospitals of the New York Health Department and one of the managers of the Hudson River Hospital for the Insane.

From 1861 to 1879 Dr. Shrady was secretary of the New York Pathological Society and president of that organization in 1883-84. Upon his retirement from the office of secretary in 1881, the society presented him with a silver pitcher and salver in recognition of his unselfish labors, Dr. Jacobi making the presentation speech. He had been president of the Practitioners' Society of New York and of the American Medical Editors' Association. He was a member of the Medical Societies of the County and of the State of New York, of the New York Academy of Medicine, of the Practitioners' Society of New York, of the New York Pathological Society, of the Harvey Society, of the American Medical Editors' Association, and of the American Academy of Medicine; and of the Metropolitan, the Ardsley, and the Jekyl Island (Ga.) clubs. He is survived by his widow, three sons, and a daughter.

OUR LONDON LETTER.

(From Our Special Correspondent)

BRADSHAW LECTURE—SIR JAMES BARR'S TREATMENT OF PLEURISY—PROFESSOR GOLDMAN AT THE ROYAL SOCIETY OF MEDICINE, SURGICAL SECTION—TERRITORIAL ARMY MEDICAL SERVICE—NOTES—OBITUARY.

LONDON, November 15, '07.

THE Bradshaw lecture at the Royal College of Physicians was delivered on the 5th inst. by Sir James Barr of Liverpool, who took for his subject "The Pleuræ: Pleural Effusion and Its Treatment." This he treated with a breadth of view and fullness of knowledge to be expected from one whose clinical experience is so extensive and scientific reasoning exact. As it is impossible to travel over the whole course of his discourse in a letter, it will be best perhaps to note what he had to say respecting the treatment of pleurisy by the method which he has originated of injecting the cavity with adrenalin and sterilized air. This more particularly inasmuch as his method has been misunderstood by some who have followed it imperfectly. In 1903 he exhibited his apparatus for introducing sterilized air and adrenalin into serous cavities and from that time the plan of thus treating pleurisy and empyema has been discussed. In the Bradshaw lecture he told how he came to try it in his first case. That was one of a lady who in 1902 was suffering from secondary cancerous deposits in the pleura, with effusion. The fluid had to be drawn off every four days and reaccumulated so quickly that she had scarcely a day free from distress in breathing between the aspirations. Seeing this could not last long and considering how to lessen the secretion, he came to the conclusion to try injection of suprarenal extract. This was so successful that the remainder of the patient's life was spent in comfort so far as concerned the chest. Since then he has injected 1 dram of adrenalin solution into every pleura which he has tapped and in only two cases has he had to aspirate a second time. So much for this part of his treatment, which is quite original. As to the addition of air to replace the fluid withdrawn, he was led to adopt it by the distress so often caused by withdrawing all the serum; by the rapid reaccumulation, especially when there was negative pressure left in the pleura or a large cavity owing to the lung being unable to expand; by the risk of collateral hyperemia or edema of one or both lungs, and by the fact that in tuberculous cases there is apt to be dissemination through the lung when pleural pressure is removed. The air pad tends to prevent adhesions; the nitrogen of the air is only slowly absorbed. The adrenalin solution is better diluted with two or three times as much normal saline solution.

When to tap is often a rather anxious question. Sir James admitted he was reluctant to interfere unnecessarily with a natural process, which the effusion is, and which if it continue till inflammation has subsided lessens the risk of adhesions and keeps the lung quiet—a very important thing in tuberculous cases, as so many are. In them early tapping causes vascular turgescence of the lung and hastens dissemination—a fatal result. Since he began to replace the serum by air Sir James has become less chary of tapping and now removes the whole of the effusion even in tuberculous cases at an early stage with perfect impunity. The recognized danger of removing all in elderly patients with rigid chest walls he said arose from establishing too great a negative pressure, which led to hyperemia and edema. But this result, he held, can be obviated by the introduction of air. He now recommends complete withdrawal in all cases, but before the negative pressure is established, before the patient feels any discomfort, he introduces an equal quantity of air. Afterwards he re-establishes the siphon and completes the withdrawal. Then he mjects 4 c.c. of adrenalin solution (1 in 1,000) diluted with 8 or 10 c.c. sterile normal saline, and if necessary more sterile air, so as to make the amount equal to half or three-fourths of the bulk of the liquid withdrawn—the larger quantity in tuberculous cases. The siphon is better than the aspirator, as the negative pressure is so much less and therefore the risk of hyperemia or edema. A manometer introduced into the air tube enables the operator to avoid any positive pressure in the pleura. Of course, aseptic precautions are to be taken. The lecturer showed his apparatus. He declared that by his method it is practicable to operate early in any case—even in the febrile stage, and under no circumstances should the fluid be allowed to so accumulate as to cause collapse of the lung. Tap before the patient feels respiratory distress. By the removal of the fluid an enormous number of microorganisms are also removed and by the introduction of sterile air a light innocuous fluid is substituted for a heavy and deleterious one.

Following up my last week's account of the work of the Royal Society of Medicine, the Surgical Section began its work with a most interesting address by Professor Goldman of Freiburg on the growth of malignant disease in man and animals, with special reference to the vascular system, and this was followed by a brilliant demonstration by the same professor on the diagnosis by the help of the *x*-rays of abdominal malignant disease, subphrenic abscess, and appendicitis. Previous contributions to the relation of the vascular system to cancer by Professor Goldman are no doubt well known to your readers. In the present address he gives some deductions from his researches which will give rise to much discussion among pathologists and surgeons. He recalls that tumor cells constituting a thrombus or an embolism might multiply within a blood-vessel and spread along its branches without forming adhesions to the vessel's coat. If such adhesions should form, *i.e.* as soon as infiltrative growth occurs, the mass of cells is organized in the fashion of a blood-clot, the cells often degenerating so far that their cancerous nature is obliterated. From his experience the professor held it to be certain that similar conditions frequently prevailed in lymphatic glands apparently the seat of secondary cancer. Careful examination in serial sections would show that the gland contained isolated cancer cells, but the bulk of the cells had degenerated. These facts showed that the body commands the power of combating and healing cancer. Reference was made to Lomer's collection of above 200 cases of spontaneous cure; in some of these blood changes induced by infectious diseases and other causes preceded the cure; in others the cut surface of the incompletely removed growth was cauterized by heat or chemicals. It would appear that the body's first line of defense is on the boundary of the growth. In some cases the professor suggested that the knife did harm by removing the barrier of defense which the body had raised up during the tumor's existence. In all recoveries there was the same reaction of the body, viz., the formation of a stroma. Extensive local hemorrhage was a common precursor.

Leaving this subject, I turn to Professor Goldman's demonstration on *x*-rays. He regarded the method as a useful aid to the diagnosis of suppuration in the abdominal cavity, of calculus in the appendix, and of cancer in the abdomen. He mentioned two cases of appendicitis complicated with subphrenic abscess which other methods failed to diagnose. In one secondary empyema had already taken place, but did not interfere with the subphrenic shadow. So a pyopneumothorax might exist and the gas in the cavity would modify the skiagram. As to appendicitis, though some pathologists did not consider a calculus important, in 55 per cent. of chronic cases in which perforation or gangrene occurred a calculus was found. The calculus was easily seen, but it was necessary to exclude the "pelvic blotch." It was of the greatest importance to differentiate between calculus in the appendix and in the ureter. To diagnose cancer in the abdomen they must empty the bowels and inflate with air where the cavity became translucent for *x*-rays, and cancer was distinctly shown.

Mr. Haldane, the Secretary of State for War, attended, as I predicted he would, the meeting at the Royal College of Physicians, convened by Sir Alfred Keogh, Director-General of the Army Medical Service. Sir Alfred repeated the account he gave at Manchester of his scheme for providing a medical service for the new Territorial Army. I noticed this in my letter of the 1st inst., so need not add much as to the exposition of his scheme, which elicited the encomiums of the War Minister on Sir Alfred's lucidity, which showed clearly the great strides brought about in the last few months by Sir Alfred Keogh's work. By means of diagrams Sir Alfred explained to the audience the relation which the modern organization of the R. A. M. C. bore to an army in the field. He called particular attention to army hospitals attached to each division, which in war would be at the head of the line of communications. The medical organization of the volunteer army, he added, was very incomplete. There was no hospital organization. Under the scheme the country would be divided into definite areas with medical officers, ambulances, general hospitals, and a sanitary branch. A guiding and directing staff would be provided. Physicians and surgeons were to be asked to lend their aid. About 23 hospitals of 520 beds would be established, each capable of extension. It was also proposed to establish a medical school for the Territorial Army.

Mr. Haldane then made an appeal to the patriotism of the profession as men of science to help them with the

scientific organization. They were trying, he said, to bring the army to the nation, to root it in the nation, to bring the two together, and as part of their plans had come to seek the co-operation of the profession. He ought to be gratified with the success of his appeal, for on the motion of the president of the Royal College of Surgeons, Mr. Henry Morris, the scheme was unanimously approved, and further on the motion by Sir F. Treves, the presidents of the two Royal Colleges were requested to form a small committee to confer with the Director-General on the best way of carrying the proposal into effect.

Some cases of plague are reported as having occurred in Glasgow in the same locality where in 1900-1901 there were 36 cases. Every precaution is again being employed to prevent its spread.

The action brought by Dr. Dakhyl against *Truth* has ended in a triumph for the journal, which had the courage to denounce him as a quack and expose the doings of the notorious Drouet Institute under his direction.

The German Emperor, to whom we are giving a hearty welcome, has conferred on Professor Koch the title of Excellency and Privy Councillor for his work on sleeping sickness. His Majesty's promptitude must be rather a shock to some of our officials, for what honors are bestowed here for scientific work are usually too late to benefit the recipient and are not infrequently delayed until death has stepped in to prevent the recognition.

Among the honors conferred on the King's birthday, Professor Clifford Allbutt is given a K.C.B., Dr. Allchin and Dr. W. J. Thompson of Dublin receive Knighthoods. Dr. Beatson, C.B., of Glasgow is promoted to the K.C.B. Col. F. L. Stephenson, M.B., receives a C.B.

Cinematograph illustrations of various nervous diseases were introduced at the annual meeting of the Middlesex Hospital Medical Society and liquid air experiments were also shown

Haddonsfield has made a successful campaign against infant mortality. For the 39 completed weeks of this year the infantile mortality was 85, as against 138 during the corresponding period last year and an average of 135 for the previous ten years. The ratio is considerably less than in the 76 great towns of the Registrar General's returns.

The death of Mr. Woodhouse Braine, F.R.C.S., removes a pioneer anesthetist, who at one time divided with Clover the practice of this specialty in London. He was one of the first to use nitrous oxide, which he continued to use in combination with ether, of which last he was an earnest advocate. For some 18 years he lectured at Charing Cross Hospital and taught practically the use of anesthetics there and elsewhere. But his interest extended over the whole of medical work. He was a vice-president of the Medical Society of London, which he for a long time served as secretary. He was president of the Society of Anesthetists for its first two years. He was also many years connected with the Royal Dental Hospital. Hosts of friends and admirers will miss him.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 21, 1907.

Underfeeding and Its Associated Ills.—D. Roberts considers this question with reference to gastric, intestinal, anemic, and nervous types of cases. He notes that the matter of underfeeding is generally overlooked. In the first place the present tendency of medicine is toward diagnosis of abnormalities existing in each and every organ. Underfeeding induces innumerable abnormalities of this nature, the fundamental cause of which is not considered. In the second place, underfeeding is corrected in some of our most valued forms of treatment and the true cause of the trouble is thus unknowingly removed. It is a difficult problem to decide just what constitutes underfeeding and what is the best method of determining it. The author has found that the caloric value and nitrogen contents of certain bulks of food as eaten may be accurately determined if the patient can state under cross-examination his usual habits for each meal, using simple units of bulk as measures of quantity. There are three chief causes of underfeeding, effort to save time and money, loss of appetite, and complaints referred to the stomach. The clinical picture of underfeeding is necessarily that of the various functional conditions to which it gives rise. The part of the body most affected by the general undernourishment depends on the constitution of the individual mind and body and on the work each part is called on to perform. The nervous system is most commonly affected as would be expected from its highly organized character. This is shown by deficiency or aberrancy of innervation or by some irritability or weakness

New York Medical Journal, November 23, 1907.

A Study of Sago Bodies and other Vesicular Elements in Massage Urine in their Relations to Diagnosis.—The conclusions of De Santos Saxe's paper are as follows: (1) Neither the occurrence of semi-solid masses nor the increased amount of massage material from the vesicles necessarily indicates the presence of vesiculitis. (2) The semi-solid bodies in massage urine derived from the vesicles include "sago bodies," "sugar granules," "skins," vesicular casts, and vesicular shreds. (3) Sago bodies, sugar granules, and skins occur in normal massage urine, when there is a hypersecretion and a certain (physiological?) amount of stagnation of secretion (spermatostasis) due partly to retention and partly to the absorption of the fluid portion of the vesicular contents. (4) Vesicular casts indicate a more marked degree of spermatostasis in the vesicle, due to an atony of the walls, and favoring infection, but do not indicate inflammation unless they contain pus cells, considerable numbers of vesicular epithelia and bacteria. (5) Shreds from the vesicle containing a mucoid matrix, pus, epithelia, and many spermatozoa occur in chronic vesiculitis. (6) The diagnosis of chronic vesiculitis is incompletely founded unless *stained smears* from the semi-solid vesicular bodies (when such are present) show the presence of sufficient number of pus cells, of vesicular epithelia, and of bacteria. The latter are usually streptococci, less frequently gonococci, occasionally staphylococci, and bacilli resembling morphologically the *Bacillus coli.*

A New Staining Method for Microorganisms.—H. G. Piffard calls attention to the effect of passing slides through a flame, in shriveling bacteria and thus obscuring their detailed structures. He has therefore devised the following method: A solution is made of the following: distilled water 100.0, pure cyanide of potassium 1.0, dry C. P. carbonate of potassium and rectified methylene blue of each 0.5. A small drop of this fluid is placed on the slide and a loopful of the desired bacterial or other culture added. The bacteria are gently mixed with the stain, the drop form of the mixture being preserved as much as possible. At the end of a minute a clean coverglass is laid on and pressed down, the excess fluid being absorbed with blotting paper. The preparation is now ready for immediate examination. Inasmuch as the above solution deteriorates it is better to dissolve the potassium cyanide in one-half of the distilled water and the other ingredients in the other half and mix when wanted. Comparative photographs show the great superiority of the new solution over those in common use.

The Use of the Parathyroid Gland for Paralysis Agitans.—W. N. Berkeley considers this question from the three viewpoints of laboratory work, autopsy findings, and clinical results. Only properly identified glands should be used. Most of the material on the markets is worthless. Human glands gotten at autopsy and ox glands alone are serviceable. Small doses must be given and continued over a long period. The author estimates that some seventy-five patients under his own care or that of his friends have been treated, but he has notes of only thirty cases. Of these two declined to continue the remedy; two have not been heard from; five denied any benefit; three showed temporary improvement only, and eighteen were progressively benefited during the entire period in which they were under treatment. The benefit consisted in diminished rigidity, lessened pain, salivation cured, shaking diminished or cured, voluntary control of the muscles greatly increased, and restlessness and insomnia nearly or quite abolished. The early cases in younger patients responded with more speed and completeness, but unfortunate bedridden patients who had suffered for fifteen years with the disease have quite often been remarkably helped. One man of fifty-five years, with a rapidly progressive type of the disease, bedridden for six months, restless, sleepless, and greatly discouraged, was able to sleep again in three weeks, and is now for nearly a year back at his work, going downtown every morning on the trolley alone.

Journal of the American Medical Association, November 30, 1907.

Opsonins in Normal and Pathological Sera.—N. B. Potter deduces substantially the following conclusions: 1. Wright's method of estimating the opsonic indices in bacterial infections is hardly accurate enough to compensate for the amount of time it requires. There is a general parallelism, however, between the opsonic indices and the clinical course in most cases, so that these determinations should be made when the results of inoculation cannot be controlled by the ordinary clinical methods of observation, when there are several

organisms present, and when the patient does not improve under the usual method of inoculation. 2. Its variations depend on (a) difference in normal sera, so that even with counts averaged from two, three, or more supposedly normal sera, it is not possible to prevent variations of from ten to thirty per cent.; (b) differences depending on the sources of the leucocytes, and (c) differences depending on counting different areas of a slide. 3. The leucocytes from patients, the subjects of bacterial infection, do not always agree in phagocytic activity with those from supposedly normal individuals. During recovery from some infections their activity surpasses that of the leucocytes of some supposedly normal persons, and during convalescence from some infections it falls to or below that of the normal leucocytes. 4. The inoculation of dead cultures of homologous or heterologous bacteria is helpful or curative in many local infections. Some patients with septicemia, however, recover without inoculations, so we must be careful in attributing recoveries to this cause. Some general and local infections are too severe to be thus helped. Some very chronic and obstinate local infections may be helped by inoculations, but it is probable that their response can be easily exhausted by too large, and perhaps by too frequent doses, and it is very doubtful if such advanced cases can be completely cured by inoculation.

Acute Unilateral Ascending Paralysis.—C. D. Camp reports a case of suddenly appearing and rapidly progressing unilateral paralysis in a patient given to alcoholic excesses. The paralysis appeared first in the left leg and passed upward to the arm and face of that side; there was mental confusion, but no aphasia, and the patient died in coma ten days after his admission to the hospital. Sensation seemed to be retained, so far as could be judged in the mental condition. The paralysis was preceded by a temporary spastic state, but later the limbs were flaccid. The patellar reflexes were exaggerated on both sides and tapping the tendon also produced a crossed adductor reflex (later lost on the left side), showing that the sensory routes were intact. The autopsy revealed no lesions to account for the symptoms except degeneration of some of the cells in the anterior horn in the lumbar region of the left side. Though the peripheral nerves were not examined, Camp is inclined to favor the diagnosis of a peripheral neuritis in this case.

A Fatal Liver Affection in Children.—T. D. Parke describes a disease of which he has seen eighteen cases, twelve fatal, within the last four or five years and which he has not seen described elsewhere. The characteristic symptoms were rapid abdominal breathing (air hunger), fast pulse, cessation of bowel movements, enlargement of liver and lowered temperature, restlessness, and expiratory moan. The symptoms were usually preceded for a few days by mucous or bloody mucous discharges. Tympany was marked in some cases, vomiting was present in a good proportion, in only one case was there any loose bowel action without purgatives, the temperature was subnormal at some time after the attack in most of the cases, in some it was at times very high. The only two constant symptoms, save in one mild case that did not show enlargement, were the type of breathing and the liver swelling. The latter was usually very marked. The urine was generally normal. There was no jaundice. A leucocyte count of 25,000 was noted in one case. Convalescence was slow. The intestinal mucosa in autopsy cases was hyperemic, the liver enlarged, and showing fatty degeneration. Bacteriological findings have been negative. Parke thinks that the disease was not confined to Birmingham. The treatment used was eliminative, but it seemed that no treatment was of any avail after the poison had gained a sufficient hold. The patients were apparently all infants. A number of cases are reported in detail.

The Cytology of Gonorrheal Discharges.—R. W. Taylor describes the cell forms met with: the predominant polymorphonuclear neutrophile, the occasional eosinophile which never contain gonococci and which may appear according to him at any stage of the disease, and the comparatively infrequent mast cells and other varieties. He notices the degenerative changes and the peculiar segmentations of lobes of the leucocytes, the "ball nucleated" white cells, the phagocytosis which may occur, etc. Although the literature of the subject is rather extensive, he does not see in these findings anything that is valuable as clinical aid or for therapeutic guidance. The detailed study of the cellular elements of gonorrheal discharges has contributed very little to our practical knowledge of the disease.

British Medical Journal, November 9 and 16, 1907.

Subcutaneous Injections of Air as a Means of Relieving Certain Painful Manifestations.—A. S. Gubb's experience is based on seventy-seven cases of sciatica and several cases of neuritis of the brachial plexus. The summarized histories are given of nine cases of sciatica. In nearly all of them excellent results were obtained. The pumping apparatus consists of the double-bulb arrangement familiar in the Paquelin cautery. Its capacity should be known. The air is pumped through a glass bulb containing sterilized cotton, and enters the tissues through an irido platinum needle carefully sterilized. The skin over the painful area having been sterilized, the needle is inserted through the skin, and as soon as it is evident that no vessel has been punctured, the insufflation is commenced. A rounded swelling forms around the seat of puncture, and when the air reaches a vascular or nervous sheath it rapidly spreads along it, and secondary swellings may form at a distance. These secondary ramifications are specially apt to form in the limbs, where the sheaths are more numerous. The skin at first becomes blanched, but this soon gives place to a pronounced redness, which persists for some hours. The air takes several days to undergo complete absorption, and under the influence of muscular contraction travels far and wide, so that the characteristic crepitation of "surgical emphysema" may be felt at spots distant from the seat of the original injection. No pain whatever is experienced, even when comparatively large quantities of air are injected, at most a sensation of distention, "pins and needles," or pin pricks. Cutaneous sensibility is at once diminished, the skin becoming more or less numb. The needle having been withdrawn and the puncture sealed by a drop of collodion, the next step is to massage the part. The subcutaneous air must be alternately dispersed and brought together again, especially over the painful spots. This massage is an indispensable part of the procedure, and must be conscientiously carried out; indeed, patients should be directed to repeat the process daily as long as any resonance remains. It is believed that the foregoing procedure causes elongation of the finer nerve ramifications, where they leave the subcutaneous tissues to enter the derma proper.

The Origin of the Facial Nerve.—N. B. Harman combats the theory advanced by Mendel in 1887 that the nerve supply of the facial musculature did not spring from the seventh nucleus alone, but contains a partial contribution from the oculo-motorius nucleus as well. The author's anatomical researches show that in the early vertebrates there is no facial musculature. With the development of eyelids and nictitating membrane, first observed in the sharks, the nearest available musculature is adapted for the service of these new eye appendages; this musculature is the muscles of the spiracle (the spiracle is the first gill-cleft behind the eye, and has its representative in man in the ear tube). In those sharks which have a small development of eyelids the filching of the spiracle muscles is of the smallest; in those sharks where the eyelids and nictitating membrane are highly developed, nearly the whole of the spiracle muscles have gone over to the service of these appendages, and the spiracle has become atrophied, and only remnants of the muscles proper to the lost gill can be traced. In these sharks the author traced the development of the spiracle musculature in a series of embryos; it was that common to every gill, and in more developed embryos the growth of the new eyelid musculature from the spiracle musculature was followed. In all these fish the nerve supply could be traced from the conjoined nucleus of seventh and fifth, a nucleus known to anatomists as the facial complex. The progressive growth of the stolen spiracle muscles in the service of the face can be traced to their full development in the facial muscles of man. From earliest to latest conditions they are arranged in two layers, superficial and deep, and there is always a most marked intercommunication of the many muscles of the face; in fact, the facial musculature is not made up of so many distinct muscles, but of two sheets of muscle which have many slips, and to these slips we give, for convenience of distinction, names, for example, orbicularis palpebrarum, levator anguli oris, orbicularis oris, etc. The incorrectness of this separative nomenclature cannot be better shown than by citing the orbicularis oris, which has been demonstrated to be nothing but the interlaced endings of the levator labii superioris, depressor labii inferioris, levator anguli oris and buccinator muscles, and not a separate entity at all. Harman declares that the Mendel theory contravenes the above anatomical findings in three respects: (1) the splitting of the muscular sheets which are a morphological unity into arbitrary areas, (2) the shifting of a primitive nerve sup-

ply, and (3) the shifting of nerve cells from a cranial nucleus of one order to nuclei of quite a different order. He therefore declares that Mendel is wrong.

Pleural Effusion and Its Treatments.—Sir J. Barr enters into an elaborate discussion of the physics of the pleural cavities, and then takes up the etiology of the disease. He believes that every case is due to microorganisms or their toxins. Those cases which follow cold or trauma have only thus been rendered vulnerable. The vast majority of cases are tuberculous, but some are rheumatic, due variably to pneumococci, streptococci, staphylococci, the *B. coli*, *B. typhosus*, or the organisms of influenza. Even cases of dry pleurisy are frequently tuberculous, though not necessarily so. In such cases there is a small effusion of plastic lymph, which is gelatinous in appearance and consistence, and contains a large number of cells with a relatively small amount of fibrin. This effusion quickly organizes, and joins the two pleural surfaces together. In tuberculous cases accompanied by effusion there is not much fibrin, and even the cellular elements may be small in amount. In pneumococcal pleurisy there is usually a large amount of fibrin whether there be much fluid or not. Those cases associated with streptococci, staphylococci, and *Bacillus coli* are frequently purulent or seropurulent, and contain a large number of cells, and in the case of the *Bacillus coli* the fluid is very offensive. In cases of transudation, the liquid contains a few endothelial cells and not much fibrin, and the specific gravity is below 1,018. There are many cases, such as those arising in chronic Bright's disease, when the effused fluid is a mixture of a transudate and an exudate. The questions of symptomatology and diagnosis are passed over, and that of treatment is then taken up. The author is not an advocate of too early tapping, and introduces air to take the place of a certain amount of the fluid—say one-half to three-fourths. He completes the operation by throwing in, to contract the vessels and lessen secretion, 4 c.c. of adrenalin sol. 1-1,000, diluted with 8, or 10 c.c. of normal saline. Salt should be eliminated from the diet. In cases with much effused fibrin, decalcifying agents, such as lemons, the citrates, etc., may be given. Injections of trypsin may hasten the solution and absorption of this fibrinous effusion. Injections of liquid paraffin may prevent adhesions. For empyema, the usual surgical intervention under eucaine anesthesia is commended. The variety of organisms in the pus should be ascertained, and an appropriate vaccine, according to the Wright method, should be employed. Cases of pneumothorax are best treated by drawing off the fluid and filling the cavity with sterile air or oxygen. Tuberculous cases are the most troublesome, and usually when the fluid becomes purulent there is a mixed infection. The paper of Barr is interesting throughout and well worthy the attention of every medical practitioner.

Red Light and Iodine Paint.—J. D. Brunton declares that if iodine be painted on the skin in the dark and only a red light be used, such as is given by an ordinary photographic lantern, there will be quick absorption. The skin will be neither discolored nor blistered even under prolonged use. The part painted should be immediately covered up, as exposure to any white light fixes the iodine in the skin.

The Saccular Theory of Hernia.—R. W. Murray discusses hernia and comes to the following conclusions: When absolute demonstration is impossible our opinion should be guided by what is most probable, and it seems that if the etiology of femoral hernia be considered in the light of common sense, the saccular theory offers the only satisfactory explanation. The etiology of abdominal herniæ is not merely of academic interest, but has an important bearing upon the question of treatment. A surgeon who believes that the chief factor in the production of the hernia is the presence of a preformed sac, would, in operating for a radical cure of the complaint, adopt less complicated measures than would be adopted by one who believes that the muscular and aponeurotic structures of the abdominal wall are primarily at fault. Direct evidence as to the exact manner in which a hernial sac is formed in the femoral or other regions is not obtainable, "but the conclusion forced upon the mind by an unbroken train of circumstances pointing in the same direction is often more forcible than positive direct testimony, for witnesses may be mistaken, deceived, or deliberately false, while circumstances 'cannot lie.'"

A Simple Operation for Uncomplicated Oblique Inguinal Hernia in Young Adults.—The operation proposed by G. L. Chiene is thus described: An incision is made half an inch above and parallel to the middle third of Poupart's ligament, the center of which corresponds to the position of the internal abdominal ring. This incision exposes the external oblique muscle which is incised in the direction of its fibers and retracted, thus exposing the lower portion of the internal oblique muscles and the upper portion of the cremasteric. The fibers of the latter are divided in the same direction as those of the external oblique muscle. The lower edges of the internal oblique and transversalis muscles are then retracted upwards and outwards and the transversalis fascia exposed. This fascia is dealt with in the same manner as the external oblique and cremasteric muscles. The neck of the sac is thus exposed at the internal ring. It is freed from the cord, opened, and divided. The neck is ligatured and fixed to the under surface of the abdominal wall, above and external to the internal abdominal ring, the rest of the freed portion being cut off. This concludes what is sometimes termed the "first stage" of the operation. The second stage consists in suturing the split fibers of the external oblique by the overlapping method and closing the skin incision. In some cases the fibers of the cremasteric muscle are drawn together with a single stitch, but in the majority they will fall into apposition naturally. It will be noted that the internal oblique and transversalis muscles are left untouched, also that the sac, with the exception of a small portion at the internal ring, is left *in situ*.

Motile Elements Seen in Certain Cerebrospinal Fluids.—F. C. Eve notes that when certain pathological cerebrospinal fluids are examined fresh under an oil immersion lens there may be seen minute filaments with very active lashing movements simulating spirochetes. These may be seen to originate from the degeneration of leucocytes, which extrude finger-like processes, which become long filaments, which in turn run into rows of spherical beads. These three stages are to be regarded (presumably) as surface tension effects, the first two stages being in unstable and the last in stable equilibrium. The motility of the filaments, though very lifelike, may possibly be explained as the resultant of the Brownian movement of a number of beads on a string, each bead trying to oscillate independently. Motile globular bodies consisting of one or more spheres variously linked by filamentous junctions are often seen in cerebrospinal fluids, sometimes in large numbers. These originate in the same way as the filaments. The occurrence of these filaments and motile globular bodies may prove worthy of note clinically when found in quite fresh cerebrospinal fluid, as they may then afford evidence of cell degeneration *intra vitam*, or be an index of degenerative changes in the central nervous system.

Congenital Weakness.—P. Budin says that prematurely born children are not easy to bring up. The internal organs are not well developed and not capable of functioning properly. The lungs inhale air only into the bronchial tubes, not into the alveoli. The gastrointestinal system does not act properly and assimilation is poor. There is marked muscular weakness, a soft transparent skin, of a bright red color, that allows the blood-vessels to be seen through it. Temperature is subnormal, and they are subject to attacks of cyanosis ending in death. The weight is less than normal, and those that weigh less than 2,000 grams are pretty sure to die. At the same time, some infants of small weight are perfectly developed and their organs function properly. Others are undeveloped on account of hereditary conditions such as syphilis and tuberculosis. It is most important that such children should not be allowed to cool even to the normal temperature of the air, since a condition of hardening of the tissues comes on that is generally fatal. To keep them warm they are wrapped in cotton under their clothing, though allowed free movement, and they should be placed in an incubator kept at a temperature of 28° to 30°C. The feeding is most important, and mother's milk is absolutely necessary, and must be given with a spoon, since the weakness of the infant prevents him from drawing the milk from the breast. Every two hours the child should be removed from the incubator to feed and change it. If too much food is given, diarrhea and gastrointestinal troubles will end the patient's life. In case of cyanosis, artificial respiration becomes necessary, gently performed. They must be guarded against contagious diseases, since they easily succumb to them. *Annales de Médecine et Chirurgie Infantiles.*

Book Reviews.

Foods and Their Adulteration. Origin, Manufacture, and Composition of Food Products; Description of Common Adulterations, Food Standards, and National Food Laws and Regulations. By Harvey W. Wiley, M.D., Ph.D. With eleven colored plates and eighty-six other illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

While scientific readers are well provided with technical literature on the subject of food sophistication, the layman has received but little attention at the hands of the writers on this topic. The present era of investigation of the character of the food stuffs presented for sale is likely to arouse more or less curiosity in the minds of all intelligent persons, and Dr. Wiley's experience has fitted him to be an excellent expounder of the sins of omission and commission that have been laid at the doors of the purveyors of what we eat and drink. The present volume represents only half of what is in contemplation, however, for another volume is to be devoted to the beverages and their adulterations. This volume will probably serve well its purpose of instructing the average reader, for it is written in clear language, with avoidance of technical terms and with an interesting manner of presentation. In fact, the author's hope expressed in the preface, that the consumer and the manufacturer, the scientific and the general reader will all find in it something useful is more than realized and the book is one that would form a useful adjunct to every physician's library. No doubt the problem of elimination has been a difficult one, but we fear that at times the author's anxiety to make the work suitable for general perusal has caused him to forget for the moment that it will also be expected to serve as a guide by many special workers in this field. For example, in the section on the identification of the different sorts of meat the precipitin method, which is undoubtedly the most reliable, deserves at least a mention. The chapter on milk, which should certainly, owing to the importance of the subject and to public interest in it, be one of the strongest, is one of the weakest in the book. The subject of milk adulteration is very inadequately dealt with, there is no description of the use of the lactometer, the Babcock fat testing method, the detection of the many widely used preservatives—often containing formaline—that are added to milk, no discussion of the differences in the product yielded by cows of different breeds, etc. For the most part, however, the volume is both interesting and instructive and will no doubt do much toward educating the public in regard to a most important subject.

Einführung in die gerichtliche Medizin für praktische Kriminalisten. Vier Vorträge von Dr. Hugo Marx, I. Assistent der Unterrichtsanstalt für Staatsarzneikunde an der Universität und II. Arzt der Untersuchungsgefängnisses Moabit in Berlin. Mit 14 Textfiguren. Berlin: Verlag von August Hirschwald, 1907.

The titles of the four lectures comprising this little book on criminology are as follows: The place of the deed; methods of violent death; crimes of specifically sexual character; and in the laboratory. The author maintains that medical investigations of crimes should be conducted by competent medical men or under their direction, and not left, for example, to chemists, whose field should be restricted. The methods of investigation to be pursued are carefully and logically described; and the book, used in connection with larger works, will be found both convenient and practical by the criminologist.

A System of Medicine, by Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College, and Humphrey Davy Rolleston, M.A., M.D., F.R.C.P., Physician to St. George's Hospital and to the Victoria Hospital for Children; Sometime Fellow of St. John's College, Cambridge. Volume II., Part II. Tropical Diseases and Animal Parasites. London: Macmillan and Co., Limited: New York: The Macmillan Company, 1907.

This volume, which is the third in the series of the new edition of Allbutt's System, is devoted to tropical diseases, but includes also a consideration of the animal parasites, some of which, especially the helminths, are more or less cosmopolitan, their habitat having a tropical temperature in whatever part of the world their hosts reside.

The volume opens with an introduction by Sir Patrick Manson, following which is a very interesting series of articles on Protozoa and on Mosquitos, Blood-Sucking Flies, and Ticks, which are known or likely to be concerned in the transmission of the pathogenic agents of disease. In the section on tropical diseases and those originating in the tropics and subtropics and prevailing at times in temperate regions during the warm season, are articles on Trypanosomiasis, Sleeping Sickness, Kala Azar, Malaria, Blackwater Fever, Tick Fever, Spotted Fever of the Rocky Mountains, Yellow Fever, Dengue, Japanese River or Flood Fever, Plague, Malta Fever, Cholera, Dysentery, Sprue, Hill Diarrhea, Tropical Liver, Tropical Abscess of the Liver, Ponos, Beriberi, Epidemic Dropsy, Leprosy, Yaws, Verruga, Ulcerating Granuloma of the Pudenda, Oriental Sore, Climatic Bubo, Ainhum, Goundou, Tropical Diseases of the Skin, Latah, Sunstroke, and Snake-poison and Snake-bite.

In the list of names of the authors of these articles are found those of all the best-known British authorities on tropical diseases, including Manson, Sambon, Leishman, Davidson, Cantlie, the late Sir Joseph Fayrer, Sandwith, J. W. W. Stephens, and many others. Two American authors contribute to the volume: W. S. Thayer of Johns Hopkins, and Flexner of the Rockefeller Institute, the first writing on malaria, the second on dysentery. The article on Rocky Mountain Fever is not by an American; it is a good article, but it would have been more authoritative had it been penned by one familiar with the disease from personal observation.

The articles on the animal parasites are: Psorospermosis, by W. Bullock, Worms, by Sir Patrick Manson and A. E. Shipley, Bilharziasis by F. L. Sandwith, and Hydatid Disease by E. C. Stirling and J. C. Verco.

The volume is extremely interesting and contains a vast amount of information, not only of value in a practical sense but stimulating also to the searcher after the curious. For example, it is interesting, and somewhat terrifying, to learn that there are at least 82 genera of mosquitos, with no end of species, though fortunately not all of them are credited with the power of transmitting disease, only eight genera (with their many species) being as yet known to be of medical interest—but nearly all of them bite. The sections on the disease-bearing insects and on the animal parasites are well illustrated. The white man's burden includes not only civilizing the natives of the tropics and introducing among them the vices of the superior race, but also relieving their physical ills and curing their diseases, and as a means to the latter end this volume will be found most serviceable.

Diseases of the Rectum; Their Consequences and Non-surgical Treatment. By W. C. Brinkerhoff, M.D. Chicago: Orban Publishing Co., 1907.

This little volume of two hundred pages represents the author's views on the injection method of treating hemorrhoids and is evidently written for the layman as well as the practitioner. The writer takes occasion to flay the profession at large for their slipshod diagnoses and their too frequent recourse to surgery. He is of the opinion that his method is the best in the vast majority of cases and he cites case histories galore where he has succeeded and others have failed. He tries to prove that the Andrews report on the injection treatment was based on inexpert evidence. A few pages are apportioned to apoendicitis, constipation, polypi, abscess, and fistula, and there are four plates, three of which illustrate the author's instruments.

Diseases of the Intestines and Peritoneum. By Prof. Dr. Hermann Nothnagel, late Professor of Special Pathology and Therapy, University of Vienna. Edited, with Additions, by H. D. Rolleston, M.A., M.D., F.R.C.P., Physician to St. George's Hospital, and to the Victoria Hospital for Children, London; Sometime Fellow of St. John's College, Cambridge. Second Edition, Thoroughly Revised. Authorized Translation from the German, under the Editorial Supervision of Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Philadelphia and London: W. B. Saunders Company, 1907.

It is certainly a compliment to a work which deals with such a limited portion of the human anatomy to have the demand necessary to require a second edition within three years. The changes in this issue do not materially alter the text; in fact, the editor has, quite rightly, respected the author's work and has confined his changes to only such subjects as demanded it. The march of science compels certain additions, while the omissions are limited to dropping a few case histories. The author again has as collaborating editors Mr. D'Arcy Power and Dr. A. Jex-Blake, who have dealt especially with the subject of intussusception and the introductory sections.

The new edition is brought thoroughly up to date and the editor quotes extensively from the English authorities, particularly where they differ from the continental writers. The general attitude on the subject of operative interference in appendicitis is, as in the first edition, more conservative than it is with the leading American surgeons. The work is thorough and exhaustive and makes an excellent reference work, but by virtue of its bulk and many-sidedness loses some of the directness in its teachings.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 21, 1907.

THE PRESIDENT, DR JOHN A. WYETH, IN THE CHAIR.

Six Cases of Malignant Endocarditis.—Dr. ALFRED MEYER read this paper. (See page 925.)

Some Surgical Aspects of Malignant Endocarditis.—Dr. JOSEPH A. BLAKE read this paper. (See page 943.)

Malignant Endocarditis in Children.—Dr. WM. P. NORTHRUP presented this communication. He said he had been asked to report regarding the frequency of malignant endocarditis in children. It had been his privilege to serve as pathologist to the Foundling Hospital for twelve years; this hospital had an annual death rate of 300 or 400, and during that time he had encountered but one case. Dr. J. Lewis Smith saw a mysterious case which was brought to the hospital with the history that the patient had been very sick, but with manifestations that could not be determined. At autopsy the house physician carelessly threw the parts into a bottle of Müller's fluid, but fortunately the heart was in good condition for examination and he found it to be the seat of an ulcerative malignant endocarditis. The condition of the other viscera could not be determined. The heart lesion was typical, with the little nipple hanging from the mitral valve. This was the only case at the Foundling Hospital, and it occurred during his first two years' service there as pathologist; during the following ten years he knew of no case, although he had been constantly on the lookout for one. Dr. Northrup said he had searched the literature for other cases and he had also looked over the records of the Presbyterian Hospital. There he had found records of three cases more or less incomplete. In some blood cultures were obtained with growth, but there had been no autopsy; in others there had been no autopsy and no growth, but the characteristics of the disease were almost typical. These three cases were not worth while dwelling upon. Dr. Northrup wished to emphasize the scarcity of cases of malignant endocarditis in children; they were very rare. In all the cases examined, with one exception, he had failed to find a valvular lesion. The ages of the patients at the Presbyterian Hospital were 9, 11, and 12 years, respectively; those at the Foundling Hospital were four years and under. It might be safely stated that malignant endocarditis was rare under four years of age.

Practical Significance of Our Knowledge of Bacteria in Their Relation to Malignant Endocarditis.—Dr. AUGUSTUS WADSWORTH read this paper. He said the lesions in malignant endocarditis varied greatly, but were usually situated in the left side of the heart. At autopsy the lesions often showed all degrees of infiltration, hyperplasia, and necrosis. The etiology of endocardial inflammations had long been studied and was the seat of vague speculation. The trend of opinion was that acute endocarditis was an infectious disease, symptomatically and anatomically, with wide variations. The results of bacterial examination in malignant endocarditis were well known; there were to be found pneumococci, streptococci, staphylococci, and gonococci. With malignant endocarditis and its bacterial excitants various other diseases were associated. Pneumonia and sepsis of puerperal form were most commonly associated. Practically all the more common infectious diseases of man might complicate an endocardial affection. Whether they extended from the blood stream, or from the endocardial supply, or developed as a secondary bacteriemia or pyemia infection arising in previous infectious disease, was not definitely known. The infectious diseases acted as predisposants in the etiology of malignant endocarditis. It was remarkable the rapid and complete recoveries from injuries that took place when the interior of the heart was injured by passing an instrument into it through the aorta. Definite clinical and experimental evidences had suggested the development of malignant endocarditis in the course of infectious diseases in man and was determined by previous lesions of the endocardium. This might be of recent development or of long standing. Hence the occurrence of infectious processes in the individual with the simplest valvular lesion was of practical interest both to the surgeon and the physician. Fever in malignant endocarditis might be considered as conservative on the course of the disease. The administration of serum from immunized animals had practically failed to be of material value. Such methods now were little used, or only in an experimental way. Recently the administration of vaccines to secure the maximum immunity by the body cells had been revived. As yet, however, they had no reliable specific treatment that was available. In the present state of our knowledge each case was a problem by itself.

DR. DAVID BOVAIRD, JR., said that much objection had been made to the term "malignant endocarditis" as not being properly applicable to the cases they were dealing with. They were dealing with endocarditis as well as an infection of the blood. Therefore, these two elements were concerned in every case of malignant endocarditis, the endocarditis, and the blood infection. So far as their present knowledge went endocarditis was a primary affection. In these cases the more one studied them the more was one convinced that the patients were suffering from chronic endocarditis, and that in some way the already injured cardiac valve had become infected by the lodgment upon it of bacteria; in other words, it was an infective endocarditis. There was an endocarditis that had become secondarily infected. These two conditions formed the so-called malignant endocarditis. With regard to the petechial eruption, he believed that was a reliable sign in the development of malignant endocarditis, especially when found in the conjunctiva. This observation, first brought out by Dr. Janeway, was of great interest and distinctly helpful. As to the chronicity of the disease, at the Presbyterian Hospital three cases lasted six months and one practically covered one year.

DR. N. E. BRILL said that "malignant endocarditis" did not constitute a pathological or clinical entity. It was not a pathological entity, because all of its manifestations might be produced by a number of entirely different microorganisms as the streptococci, pneumococci, gonococci, staphylococci, and others. It was not a clinical entity because its entire symptomatology might be reproduced by a bacteriemia superimposed upon an old cardiac valvular lesion without the diseased valve being affected, and from which bacteriemia it was possible for the patient to recover. It was possible that such cases might represent the "recoveries" from malignant endocarditis. Dr. Libman had reported a patient with post-partum sepsis in whom a blood culture showed a bacteriemia. She had a cardiac murmur, together with the characteristic signs of "malignant endocarditis." After death the heart showed an old valvular lesion, but with not the slightest signs of a recent endocarditis either on the old diseased valve, where it might be expected, owing to the fact that a diseased valve is especially liable to bacterial infection, or elsewhere in the heart. In the light of present opinion one must accept that almost all cases of acute endocarditis are secondary to a bacterial infection. While it was true that the offending organism had not been recovered in all the cases, and that in some cases the primary focus of infection might be concealed, yet their absence did not necessarily invalidate the conclusion, especially where there was such a vast accumulation of presumptive and prima facie evidence to support this view. The difference between the non-fatal and malignant types of acute endo

carditis was one of degree, depending to a large extent on the type and virulence of the organism and its toxins, and on the resistance of the endocardial tissues and their defenses against bacterial invasion. One might say that the grave or so-called malignant type of endocarditis was the result of a greater malignancy of the systemic and local cardiac infection. Clinically it might present itself in relation to the degree of bacterial virulency and tissue resistance in an acute, subacute, or chronic form. There were two distinctly clinical types depending upon the ascendency of the heart lesion, or the predominance of the signs of systemic reaction to the bacteriemia. The one was the type in which the heart symptoms were the prominent clinical features and the septic symptoms not markedly obtrusive. These cases were not infrequently secondary infections superimposed upon an old valvular lesion. The other was the type in which the chief symptoms were those of a violent septicemia, with or without a heart murmur. It was possible to have a marked valvulitis with soft vegetations without a cardiac murmur being demonstrable. A number of such cases with post-mortem proof had been reported. The signs of sepsis might vary, as they did in other forms of systemic infections, so as to present either prominent cerebral symptoms, like a meningitis, or typhoid-like symptoms, or symptoms of pyemia. Embolic processes might occur in all the types and give rise to suppurative or non-suppurative infarcts with their additional regional or focal symptoms. A symptom occasionally present and not touched upon was the painful swelling along the course of some of the smaller arteries which might be due in some cases to mycotic aneurysm formation from an embolic piece of bacterium carrying heart vegetation, in others to embolic aneurysms, and perhaps in the third class to a focal arteritis and periarteritis. As the superficial lymph nodes enlarged in many other forms of systemic bacterial infections, they should be looked for in all cases of suspected grave endocarditis. Not infrequently were the bronchial lymph nodes, especially at the root of the lungs, found to be enlarged and swollen. Leucocytosis might or might not be present in this disease. In fact, a diminished number of leucocytes in the blood might be noted. He asked if one might not infer, as one did in pneumonia, a much more rapidly fatal termination when leukopenia was present. In the light of what had already been said and published in regard to the presence of conjunctival and palmar petechiæ in assisting in a diagnosis, it should be remembered that such petechiæ did occur in other conditions than malignant endocarditis. He had recently seen a case of acute pneumococcus endocarditis which presented painful hemorrhagic infiltrations in the depths of the skin of the feet and hands, a very uncommon symptom of the disease. In conclusion he said he wished to insist upon blood cultures being taken in all cases of acute endocarditis as a routine practice. Bacteriemias with heart murmurs, chills, pyrexia, petechiæ, and other signs of sepsis did not necessarily constitute the malignant form of endocarditis. A bacteriemia might occur as a secondary affection in a chronic case of endocarditis and recovery follow. There existed a form of chronic endocarditis which might be accompanied by an irregularly intermittent fever and other acute symptoms which might last for months without a demonstrable bacteriemia and which might be fatal either on account of the perverted dynamic circulatory disturbance or from the result of the pyrexia.

Dr. E. G. Janeway said he had been interested for many years in this subject of malignant endocarditis, or septic endocarditis, or bacterial endocarditis, or simply "endocardial fever." He had seen cases running eight months and even one and a half years before death. He reported one case, a man who came to his office complaining of chill, fever, and sweating; the temperature was from 105° to 106°. No plasmodium was found in the blood. The man returned and had no fever and no plasmodium. At his third visit he had a temperature of 100° and a pulmonaric systolic murmur added to a pulmonic regurgitant murmur. He was sent to St. Luke's Hospital, where he was treated. He finally recovered. He now had a pulmonic insufficiency. This was an infection from the gonococci. Since then he had had another case and he felt sure would recover from his septic endocarditis because it was of gonorrheal type. He said it was well to bear in mind the type with hemorrhages, because of the difficulties encountered in diagnosis; this type was likely to be mistaken for hemorrhagic types of the infectious diseases, particularly cerebrospinal meningitis, purpura variolosa, and typhus fever. He reported an instance of malignant endocarditis occurring in a young lady who died the day after he saw her. She had been having hemorrhages from the nose and a plug had been inserted; the infection was from this source. He saw in consultation with a fellow of the Academy a gentleman who had an apparent cough, heart murmur, and a temperature of 103°. He lived three months. The blood culture revealed a streptococcic infection. A point of interest was that he had been insured three months before and the doctor found no heart trouble at all. He had taken to violent bicycle riding. The diagnosis from typhus fever was very difficult, but the development of the petechiæ on the conjunctiva was of great service. But at times one met with cases that were not easily diagnosed. He reported one case of malignant endocarditis resulting from an ulcerated tooth; there was a little abscess at the root. Another case was treated for months as one of malarial fever; the chill, fever, and sweat occurred regularly every day. In this case the question of ulcerative endocarditis was never considered. Dr. Janeway emphasized the fact that because a man had an embolism, heart disease, fever, petechiæ, etc., did not necessarily mean that he was going to die. With regard to making blood cultures, this might do very well in hospital practice, but it would not be tolerated in private practice; it hurt somewhat the feelings as well as the sensibilities of friends. He could not report any satisfactory results from the serum treatment, but he hoped for a more sure plan of treatment soon.

Dr. F. P. Kinnicutt said that his conception of acute endocarditis was that it was always of infective origin and nature, was almost always secondary, and provoked under varying circumstances by different microorganisms, the pyogenic bacteria being the most common. This conception of the nature of endocarditis did not admit of a sharp line of division between the so-called malignant endocarditis and the less acute and grave forms. There was, moreover, no essential anatomical difference, as all gradations were met with. The malignancy, the severity, the benignance of the individual case was one of degree rather than of kind and seemed to depend upon the varying virulence of the infective agent and the varying natural body resistance to the different pathogenic microorganisms and their toxins. The clinical history of many cases of chronic endocarditis as seen in the hospital wards was one of apparent recurrent or reinfections of presumably nutritionally weakened and sclerotic valves. Here again, he believed, in proportion to the varying virulence of the infective organism and the varying natural body immunity, they observed the malignant type, presenting all the symptoms and signs of grave septic infection; a less severe type with a temperature curve somewhat resembling that of typhoid fever, commonly, however, exhibiting a slightly lower range. The fever might extend over a period of several months and was often followed by a long interval of fair health. Finally they saw a comparatively mild type in which fever was the only symptom. The curve resembled that associated with slightly active tuberculous processes in the lungs. The morning temperature might

be normal and the diurnal rise not more than one or two degrees. As in the former variety the fever might be of very long duration and be followed by long periods of good health. According to his conception, even the mildest forms represented a toxemia of bacterial origin. In regard to the use of vaccines in the treatment of the gravest types, he said that in four recent cases of malignant endocarditis in the Presbyterian Hospital vaccines prepared according to Wright's method had been used without appreciable benefit. Nevertheless, since they possessed authentic reports of several cases treated by Wright and his colleagues with entire success, when all other methods had failed, it seemed to him proper that further trial should be made of the vaccine treatment in similar cases. As he understood Dr. Wadsworth, he believed that the opsonic index was impracticable and untrustworthy as a guide in the use of vaccines. He was prepared to admit that it was impracticable for general use. As he saw it used a few weeks ago by Wright in his service at Westminster Hospital, he was not prepared to admit that it was an untrustworthy guide. That some guide was necessary for the intelligent and efficient use of vaccines he thought would be generally admitted.

Dr. A. G. Gerster said that there was one heart affection which was apt to lead to confusion, an undetermined general septic endocarditis which was to be diagnosed from pyclophlebitis, or an infection of the renal vein. So far as the practical side of the question was concerned, septic endocarditis as it affected the surgeon, there were certain groups of infections in which the surgeon's opinion might be called for. First, the infarcts. These generally occurred in the lungs or the various glandular organs; sometimes they affected the intestines. Secondly, there were the embolisms which might produce aneurysms, or necroses of extremities. The question arose, was it worth while to do something for such an aneurysm? Was it a true septic or an ordinary form of endocarditis? They should do something if the indications were well made out and if the patient suffered. If the aneurysm was ready to burst, something should be done. Again, if they were dealing with necrosis of an extremity, something should be done. Third, there were the various forms of suppuration, and perhaps these were most frequently encountered by the surgeon. Here the same principles obtained. If the sufferings of the patient demanded it, interfere. One must individualize in these cases in answering the question, whether or not the surgeon should interfere. Dr. Gerster related his personal experience in one case, where he interfered in a case of septic endocarditis. In this patient bacteria were found in the blood. The patient had the characteristic cardiac lesion and an osteomyelitis. The joint was incised and the patient seemed to improve. The fever diminished, the general condition became better, and he was hopeful after all that recovery might ensue. Suddenly symptoms of empyema of the pericardium set in and rupture occurred into the mediastinum. This was a true case of ulcerative malignant endocarditis.

Dr. M. Nicoll, Jr., said that, in the Foundling Hospital, he had never seen a case with valvular involvement, and in many thousand autopsies the only case he knew of was the one reported by Dr. Northrup. At the North Brother's Island hospitals the records were not complete and could not be relied upon. Therefore, septic endocarditis was an extremely rare disease either with or following diphtheria, scarlet fever, or measles in childhood. They met with many heart murmurs, but the children died from sepsis.

Dr. Harlow Brooks said that if routine blood cultures were made in those cases in which heart murmurs were associated with fever, one would be surprised to learn the number of cases in which they would prove positive. The prognosis of bacterial endocarditis was not so terrible as believed. The absence of bacteria in the blood as shown by the ordinary methods must not be taken as negative evidence. He did not believe they could determine the toxicity of the disease by counting the bacteria found. The mildest case he saw was one in which he isolated the streptococcus; because the case was so mild he asked for another count and found the streptococcus. Therefore, because one found the streptococcus in the blood, one should not throw up the hands and expect an autopsy. As to the time for taking the culture, it was best taken when the fever was high. With regard to finding bacteria in the urine, he thought that the urologist could teach them something; in doing ureteral catheterization bacteria were found quite commonly in the urine. It should be borne in mind that death in endocarditis was due to one of two conditions, either a toxemia from the growth of the bacteria or the products of metabolism, or from an embolism.

Dr. James Ewing said that an injury first to the valves of the heart was first necessary before a malignant endocarditis could develop. Prudden had shown that it required but a slight traumatism to develop endocarditis when bacteria were present in the blood. He asked what should they call malignant endocarditis. The term should be limited to those cases in which the heart condition and valvulitis were more or less in the background and septicemia in the foreground.

Dr. Thomas W. Hastings said that, with regard to the possible use of the bacterial vaccines, he was glad to hear Dr. Janeway and Kinnicutt say they would continue using this form of treatment. In Wright's cases he seemed to get good results. The use of the vaccines gave no bad results. But one should give them carefully, after they had been properly prepared, and then no untoward results would follow. This harmlessness was a point that should be more emphasized.

Dr. E. Libman said that the term malignant was one that was applied to a type of disease that led to death, and the disease they were dealing with was endocarditis. To show the relation of bacteria to endocarditis, he said that among 150 cases there were 60 that showed bacteria in the blood and 90 that did not. The results of bacterial invasion of the blood gave rise to different types. A person might have many bacteria in the blood, with symptoms of malignant endocarditis, but at post mortem nothing would be found. There might be a bacteriemia with but a slight effect upon the endocardium. Another type was that in which bacteria might be found in the blood, and an endocarditis, the disease lasting days or weeks. Here the valve was attacked by the bacteria and the clinical picture depended upon what happened. Either they multiplied in the blood or became localized on a heart valve and set up trouble, with the clinical picture of an endocarditis. Very often one found a large number of bacteria in the blood and a lesion of the valve. When there were a great many bacteria in the blood there might be an enlargement of the lymph nodes all over the body. This was an acute type of the disease. One might meet with a chronic endocarditis with fever and no bacteria demonstrable in the blood. There was also a very important set of cases that had not been studied thoroughly in recent years, a chronic endocarditis in which one found the organism covering a period of weeks or months. Here the heart symptoms were the predominant symptoms. The organisms in acute cases were mostly the pneumococcus, staphylococcus, and streptococcus. He had seen one case the result of a diphtheroid bacillus. In those cases that ran weeks or months they found a peculiar attenuated streptococcus or diplococcus. As to the terminology, they called the cases acute, subacute, or chronic endocarditis. They added the word grave if it was a bad case. If they found a certain organism, they called it by name. In this way the name applied gave an insight into the nature of the disease. As to the diagnostic value of

bacterial findings in these cases, in the acute cases he did not think one should make a diagnosis unless bacteria were found in the blood. It never took more than two cultures to make a diagnosis. In the subacute or chronic cases it might be necessary to make more. In an extensive pyelophlebitis no bacteria, as a rule, was found in the blood. In the severe forms of endocarditis one always found bacteria in the blood. This was an important differential point. As to treatment it did not seem to him that the vaccines were indicated in the acute types of the disease, but in the subacute or chronic types; these he believed to be the ideal diseases for treatment by vaccines if the vaccines were ever useful.

Dr. Northrup said there were clinically four diseases which in their beginnings simulated each other, typhoid fever with early hyperpyrexia, typhus fever, cerebrospinal meningitis, and ulcerative malignant endocarditis. As for the production of petechiæ, he asked if the pathologists thought they were due to emboli, to toxin, or to both. It seemed to him that toxins could account for some petechiæ.

Dr. Wadsworth closed the discussion.

SECTION ON SURGERY.

Stated Meeting, Held November 1, 1907.

DR. JOHN F. ERDMANN IN THE CHAIR.

Abscess of the Frontal Lobe.—Dr. FIELDING LEWIS TAYLOR said that the patient whom he had intended to present was operated on nearly fourteen months ago by himself and Dr. A. B. Tucker, for a very large chronic abscess of the right frontal lobe, due to an injury received four months previously. Except for a persistent optic neuritis of some severity, he appeared to have recovered completely. He lived in an inaccessible place about one hundred miles away, so that he had seen him only once during the past year, although he received most satisfactory reports concerning him on several occasions. Yesterday he was disappointed to learn that he had been taken ill suddenly with convulsions and died two days later. He will report the case in full later.

Large Cavity in Skull.—Dr. C. A. MCWILLIAMS presented a woman who, as the result of a fall, had a large cavity in her skull about two inches deep. He brought her before the Section in order to obtain suggestions as to the best method of closing it.

Dr. ROBERT T. MORRIS said that in such head injuries the use of peroxide of hydrogen was invaluable as a preliminary step for sterilizing the field. Curetting should then be done, dissecting up the margin of the skin and filling the cavity with blood clot; there should be no question of filling in the cavity completely without difficulty, provided one used Lister's oiled silk. When Schede first saw this demonstrated, he was skeptical; but after seeing the results in a number of cases, he employed the method in even larger openings than the one presented. Another method might be used, that with decalcified bone and iodoform. It was very essential that the skin should be dissected up so that the epithelium could shoot across.

Dr. CHARLES H. PECK said he would be inclined to cover in the opening with a pedunculated skin flap, and cover the surface left with a skin graft.

Intussusception (Adult) Caused by Papilloma of the Sigmoid. Resection.—Dr. C. A. MCWILLIAMS presented this patient, a woman, forty-five years old, who was admitted to the hospital May 10, 1907. She had been sick off and on for four weeks. At first she had dysentery, passing some blood; she also had pain. This attack lasted one week. One week before admission she began to have pain in the back and left lower abdomen. During this week her bowels moved but once, although she had a discharge of blood. There was much nausea. During the first part of the week she vomited, but not during the last two days. Dr. DeWitt C. Romaine, her attending physician, in a letter to Dr. McWilliams, said that one month ago she had eaten heartily of cream cheese and ice cream, which was followed by an attack of acute indigestion, treatment of which relieved the symptoms. A similar attack followed later after eating freely of hash. The treatment failed to relieve the diarrhea; it continued three or four days, and then stopped suddenly, May 8. That night she had a moderate hemorrhage from the bowels, which was followed by intermittent colicky pains in the abdomen, constipation, tenesmus, and the passage of mucus and blood from the rectum. The abdomen was slightly tympanitic and tender. The digital examination of the rectum was not made until May 10; this disclosed an invaginated bowel in the rectum. The patient was operated on at midnight of May 10. When under the anesthetic one could feel the mass in the left iliac fossa, apparently rising up from the pelvis and extending from just below the left anterior spine to the median line. It was smooth and about the size of an orange. The finger in the rectum felt a rounded projection about three inches from the sphincter ani; it felt like an open cervix uteri; this seemed to be attached to the invaginated bowel. This mass was flat and seemed to be about one-half the circumference of the bowel, and to obstruct it completely outside the invaginated bowel, but its walls and those of the rectum permitted the passage of the finger all about without encountering any adhesions and without reaching the upper limit. At operation the small intestine was found to be almost collapsed. On passing the hand into the pelvis a mass was felt about the size of a fist. The large intestine was seen to go into the lower dilated piece of bowel. It appeared as though the sigmoid had gone into the rectum, the upper end of the lower segment corresponding about to the upper end of the rectum. In their efforts to reduce the intussusception a transverse slit was produced which permitted the finger to enter the lumen of the gut and a growth was felt there. Traction and squeezing reduced it all. It was then found that there was an enlarged growth about three inches long on the circumference of the gut, opposite the mesenteric border; it was hard and puckered up. A resection of the gut was made, Murphy buttons were tried but failed to work, and, therefore, an end-to-end anastomosis was made with silk sutures. After washing the pelvis with salt solution, four cigarette drains were used in the wound and two in the pelvis. The patient had a weak pulse, but otherwise was in good condition. Patient made an uneventful and good recovery. The pathologist reported that the lumen of the gut was entirely taken up by a projecting nonulcerating growth. It was a papilloma, possibly malignant, but with no definite indication of the muscular coat having been invaded.

Dr. JOHN F. ERDMANN said that last summer he saw a patient, sixty-five years old, with a suspicious tumor in the iliac fossa. He suspected malignant disease of the cecum. On the following day he discovered an intussusception of the cecum and ascending colon, which was readily reducible, and the patient made a perfect recovery.

Perforated Gastric and Duodenal Ulcer; A Report of Eight Cases.—Dr. CHARLES H. PECK read this paper and presented three of the cases included in the reports. (See page 930.)

Dr. GEORGE E. BREWER called attention to some introductory remarks of Moynehan, expressing his opinion of the condition found in gastric or duodenal ulcer, that "of all the surgical catastrophies that occurred to the human being, none was equal in suddenness and intensity to gastric or duodenal ulceration." It had been shown in a large series of gastric and duodenal ulcerations that the recoveries were directly in proportion of the time after the accident to the operation. He could recall a number of patients that died, but it was only within the last two years that he could save cases of gastric ulcer. During the last year

two patients were brought in earlier and both were remarkably free from symptoms. One had a perforating gastric ulcer and was operated on ten hours after the onset of symptoms. This patient had but little in his stomach at the time, and, although there was a well-marked irritation and peritonitis, yet there was no great extravasation of the stomach contents. The patient was in such a condition that he hesitated in stating positively that a perforation was present, or that a gastroenterostomy should be done. The duodenum was found to be as large from infiltration as the closed fist, and he did not believe there was much lumen left in the gut. After inverting the edges of the ulcer the question arose whether or not he should shut off all the lumen, and he decided to take a chance and a gastroenterostomy was not done. There was such a variation in the symptoms of gastric ulcer that he was not surprised that an early diagnosis was not more often made. Within the past three weeks he saw a patient at Roosevelt Hospital, brought there one and a half hours after the onset of violent abdominal pain which marked the time of perforation. This was the earliest case he had ever seen. The condition was different from that usually seen. The temperature was 97° in the rectum, pulse 68 and feeble. The abdomen was scaphoid. The only sign present was the board-like rigidity of the abdominal muscles. The last meal had been taken six hours before the perforation. With the exception of a small amount of gastric juice there was practically nothing to wash out. The perforation was closed in the usual way and here also arose the doubtful propriety of doing a gastroenterostomy. As the walls were infiltrated he had to use a great deal of tissue in closing the perforation by inverting it. He said he was inclined to endorse absolutely what Dr. Peck had said regarding secondary operations. Here were two cases in which he felt sure that a decided obstruction would occur from the operative work; but in neither case was there the slightest evidence of pyloric obstruction subsequent to operation.

Dr. Alexis V. Moschcowitz asked what the real objection was to performing a gastroenterostomy operation in these cases; if there arose serious doubt that there might occur a stenosis at the pylorus there might be some great danger. In similar cases he always performed a gastroenterostomy, and this did not prolong the operation by any great length of time. He used Murphy's button. In other respects he said he was in accord with Dr. Peck's remarks except that in cases of diffuse peritonitis he did not wash out the abdomen until there were distinctly present large pieces of foreign matter or food. Personally he always drained by a small counter incision over the pubes and inserted a cigarette drain into the pelvis. In all of the cases presented by Dr. Peck it was universally noted that the lesser peritoneal cavity was not involved. He thought it might interest the members to have reported a case in which the peritonitis was limited to the lesser peritoneal cavity. A young man was admitted to Mt. Sinai Hospital a year and a half ago with a perforated gastric ulcer. He was at once operated on and, much to his surprise, he found the entire peritoneal cavity free. He then made a median incision in the gastric region, elevated the stomach and duodenum, and looked for some other cause for the sudden onset of the pain. But nothing was to be found in the abdomen. He then raised the stomach up and found behind the colon and stomach a large mass of exudate. Upon entering the lesser peritoneal cavity there was quite a gush of seropurulent fluid, and he found a perforation situated near the fundus of the stomach. The patient made a good recovery, and was discharged from the hospital. Three weeks later he was operated on for an intestinal obstruction and made an uneventful recovery.

Dr. A. Ernest Gallant related two cases of gastric perforation. The first he saw four years ago. A man was working in a store lifting boxes, when he felt something give way in his stomach. This was accompanied with vomiting and pain. Dr. Gallant saw him on the day following. The second day after he made the diagnosis of gastric perforation and the man was sent to the hospital. He was kept there for five days and was then operated on for appendicitis. Upon enlarging the incision an opening into the stomach was discovered. The patient died that night. He had had no previous symptoms of indigestion. The second patient was seventy-six years of age, and gave a similar history. He was a farmer, and was lifting bags of potatoes when he felt a sudden pain which was accompanied with vomiting. He said he felt very sick. His temperature ranged from 100° to 102°, and his pulse from 90 to 100. The abdomen was quite distended and board-like. He decided to make an incision in the median line below the umbilicus, which was done under cocaine. When an opening was made gas escaped. He was then given chloroform and made an opening in the upper curvature, when the patient turned black in the face and collapsed. A roll of gauze was inserted and the man did nicely. He was out of bed on the eighth day, and in two weeks was out of doors. The daughter had since told him that he was doing well and in good health. These two cases illustrated the suddenness of onset without previous symptoms. These cases he did not believe were in condition for a gastroenterostomy operation, as a rule. The location of the ulcer had very much to do with the seriousness of the peritonitis; the higher up the perforation the better chance did the patient have.

Dr. C. A. McWilliams asked how many had noticed the characteristic odor of the gastric contents in gastric perforations. In the three cases he had had he could not detect this characteristic odor of the escaped gastric fluid in the abdomen.

Dr. Fielding Lewis Taylor remembered one case at the Hudson Street Hospital in which there was a perforation; there was a distinct odor of root beer.

Dr. Charles H. Peck said that in his first case the perforation was on the anterior aspect of the pylorus itself, and there was a great deal of inflammatory thickening about it, so much so that he expected he would have to do a secondary gastroenterostomy. He was much gratified to find no evidences of retention of gastric contents or pyloric obstruction. The inflammatory thickening must have been absorbed quickly. As regards not doing a gastroenterostomy, this was an added procedure which meant more trauma and the consumption of additional time. Then, too, in his cases it was shown that this was not necessary. In answer to Dr. McWilliams he said in one case there was a pronounced odor of aromatic castor oil.

Lantern-Slide Demonstration of Radiographic Findings in Syphilis of the Long Bones.—Dr. Martin W. Ware gave this demonstration. He presented a series of slides, demonstrating some of the findings in syphilitic bone disease. Attention was directed to the constancy of periosteal involvement and its absence in tuberculosis. The value of the radiograms was emphasized in differentiating tuberculous from syphilitic dactylitis. The aid of the x-ray might be called into requisition when it was necessary to differentiate a traumatic subperiosteal swelling, or a callus formation of a fracture, from a suspected gumma. Sclerotic changes in bones, absorption of bone, and bowing of the bones were clearly reproduced in the shadows of the radiograms; they afforded an index for operative interference, and the extent of the denudation of those shadows marked the progress of favorable treatment.

Dr. George E. Brewer asked Dr. Ware if these syphilitic cases, particularly where the x-ray showed large areas of rarefaction, were accompanied by much pain.

Dr. Ware said that was not universally so. Some such cases were very painful, while others were not.

Dr. Henry W. Frauenthal said that the acquired syphilitic cases suffered considerable pain.

Surgical Suggestions.

Stricture of the Urethra.—The habit of looking for a stricture with a small sound is a pernicious one. Begin with a large one and use smaller calibers until the size is determined. Small sounds are very apt to have their points engaged in the glandular crypts of the urethra.—*American Journal of Dermatology.*

A New Symptom of Basedow's Disease.—Gifford (*Wiener medizinische Wochenschrift*) found that in three patients suffering with Basedow's disease he had some difficulty in everting the upper lid, and after the eversion had been successfully performed it was very difficult to keep the lid in that position. This is one of the earliest symptoms of the disease, and is probably produced by an unusual irritability of Muller's muscle; this symptom might have some connection with Dalrymple's (Stellwag's) symptom. Another early sign is the thickening of the tissues beneath the eyebrows; the skin appears solid and thick; the lids seem to be swollen.—*Ophthalmology.*

Proctoscopy.—Sultan (*Deutsche Zeitschrift für Chirurgie*) brings up two new points: The first is the danger of bursting the rectum by an extreme inflation with air. This is to be feared in persons of reduced vitality, with marked relaxation of all the muscles, in the presence of old inflammatory conditions. The accident has been reported several times. Such cases must be excluded from proctoscopic examination. The second point to which he draws attention is a new instrument for obtaining small pieces of tissue from the rectal mucosa for microscopic study. It consists of a handle bearing a shaft twenty-two inches long, which has at its outer end two small rings like ring curettes, which can be placed at any angle to the handle; after introduction these are brought together, seizing a bit of tissue between them. The instrument differs from similar instruments largely in its length.—*The Therapeutic Gazette.*

The Prophylaxis of Syphilis.—Maisonneuve, after submitting himself to a careful personal examination, in order to preclude definitely any evidences of syphilis, allowed himself to be inoculated in the sulcus coronarius on each side from the virus of two initial lesions from two well-defined cases of primary syphilis. This in the presence of Metchnikoff and four other physicians. The skin was scarified and the virus thoroughly rubbed into the abraded surface. One hour after the inoculation the parts were treated with ten per cent. calomel-lanolin ointment. Apes which were inoculated with the same secretion showed typical lesions of syphilis; others, likewise inoculated, but also treated with calomel ointment, remained free from syphilis. Maisonneuve submitted himself to careful examinations for three months, without showing the slightest evidence of syphilis, and the wounds promptly healed within seven days.—*Southern Medicine and Surgery.*

Treatment of Eclampsia.—On the first occurrence of an attack, or of the restlessness which frequently precedes an attack, chloroform should be administered and an enema containing twenty to thirty grains of chloral hydrate should be administered, the latter to be repeated in an hour's time if required. If possible the patient should be put into a hot bath. A plethoric person showing a good deal of cyanosis may be bled to twenty or thirty ounces. If chloroform and chloral fail, morphine is a drug of great value; some authorities give as much as two to three grains in twelve hours. Morphine must be given very cautiously when the patient is passing only a small quantity of urine. —Blacker.

Closure of the Pyloric Stump in Pylorectomy.—Krogius says that owing to the fact that it is often necessary to cut through the duodenum low down at a point where its posterior surface is devoid of peritoneum, the task of effecting a satisfactory closure of the stump by invagination is very difficult. He recommends beginning by uniting the lateral edge at the line where the peritoneum is reflected so as to effect a longitudinal invagination through which the bare portion of gut, which is very friable and does not hold sutures well, is buried in the lumen of the intestine and the diameter of the resulting cylinder is much reduced. It is now an easy matter to invaginate the end of the stump and to pass the sutures through tough and resistant tissue.—*Zentrallblatt für Chirurgie.*

Counter Irritation to the Spine.—The best method is the actual cautery. A Pacquelin's cautery, or even a good-sized copper wire, made red hot, may be drawn along the skin for three or four inches on each side of the tips of the spinous processes. The application does not cause sufficient pain to demand a general anesthetic, and the use of cocaine is inadvisable, as the benefit of counter irritation is probably obtained through action on the nerves —*The Hospital.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Board of Health of Kentucky.

Louisville, April 23, 1907.

ANATOMY.

1. Describe (*a*) the gracilis, (*b*) gastrocnemius, (*c*) rectus femoris, giving origin and insertion of each.
2. Describe the pancreas.
3. Name the structures to be divided in operating for strangulation of an oblique inguinal hernia.
4. Describe the fourth cervical vertebra and distinguish it from the fourth dorsal vertebra.
5. Bound the axilla and name and give relations of structures in axillary space.
6. Name the muscles, nerves, and arteries severed by a cross section of the thigh at the junction of the middle and lower thirds.
7. Describe (*a*) the superficial and deep palmar arches, (*b*) the brachial artery, branches and relationship.
8. Describe and give contents and relations of parts in Scarpa's triangle.
9. Describe (*a*) the superior longitudinal sinus (*b*) the lateral sinus, (*c*) torcular Herophili.
10. Give the anatomy of the liver.

SURGERY.

1. Give varieties of hernia; describe one operation for inguinal hernia.
2. (*a*) Name different kind of fractures and give differential diagnosis between fracture of the neck of the femur and dislocation of hip. (*b*) Give treatment of the latter.
3. How would you make a diagnosis of gonorrhea? Give a bacteriological examination.
4. What is empyema? Give diagnosis, prognosis, and treatment.
5. Give symptoms, diagnosis, and treatment of intestinal obstruction.
6. How would you diagnose retention of urine? What would you do for it?
7. How would you determine that a limb is injured beyond hope in a crushing accident?
8. What are the indications for appendectomy?
9. Give the treatment of shock resulting from hemorrhage.
10. Give contraindications to the employment of ether and chloroform?

MEDICAL JURISPRUDENCE.

1. What constitutes expert testimony?
2. How would you determine that a full term dead baby was born alive?
3. How would you determine (*a*) that a wound was inflicted by a blunt instrument? (*b*) or that it was done before or after death?
4. Differentiate between idiocy and lunacy.
5. What is paresis? Give symptoms, prognosis, and treatment.

OPHTHALMOLOGY.

1. Differentiate iritis and glaucoma, giving symptoms of each.
2. Describe and give etiology of (*a*) phlyctennlar keratitis, and (*b*) interstitial keratitis.
3. What is ophthalmia neonatorum? Give etiology and the probable results of a badly managed case.
4. Give symptoms and etiology of ciliary blepharitis.
5. Differentiate myopia and hyperopia and hypermetropia; give the anatomical reasons for their existence, and tell what you would recommend for the relief of each.

PHYSIOLOGY.

1. (*a*) Give several varieties of food. (*b*) Which enzymes act on each variety?
2. (*a*) Describe absorption, and give the function of the lymphatics. (*b*) Describe the thoracic duct.
3. Give chemistry and uses of bile.
4. Describe the circulation of the blood. What forces govern it?
5. Give histology of the kidney and function of the various structures.
6. Name and give the function of each of the cranial nerves.
7. Describe and give functions of sympathetic nervous system.
8. What are the functions of the skin?
9. Describe the blood.
10. Describe the cardiac cycle.

OBSTETRICS AND GYNECOLOGY.

1. Define presentation and position.
2. Tell exactly how you would manage a shoulder presentation.
3. What is mensuration? (*b*) How is it conducted in obstetrical cases? (*c*) How is it of value?
4. How would you diagnose and conduct the delivery of a hydrocephalic fetus?
5. (*a*) What would you suspect in antepartum hemorrhage? (*b*) How confirm your diagnosis? (*c*) How manage the case?
6. (*a*) When is ventrofixation indicated? (*b*) What is ballottement, (*c*) when is it valuable and how is it performed?
7. Give diagnosis of extrauterine gestation.
8. Give symptoms and pathology of carcinoma uteri.
9. Describe ovary and uterus during stages of menstruation.
10. (*a*) Give two indications for hysterectomy (*b*) Reasons for preferring abdominal or vaginal method.

CHEMISTRY.

1. What is (*a*) an atom? (*b*) a molecule? (*c*) What are isomeric compounds?
2. (*a*) What are the symptoms of acute arsenic poisoning? (*b*) What is the chemical combination of its antidote and how does it act? (*c*) Tell in detail how to detect arsenic in the stomach of a case of suspected poisoning.
3. Describe in detail a method for the quantitative estimation of sugar in the urine.
4. Tell in detail how to detect bile in the urine.
5. (*a*) Contrast dairy milk with human milk, and (*b*) give a brief description of the essentials for the production of pure dairy milk.
6. What is (*a*) H_2SO_4, (*b*) BaO_2, (*c*) HCl, (*d*) HNO_3? (*e*) What is the formula for methyl alcohol?
7. (*a*) What is acetphenetidin? (*b*) hexamethylene- tetramine? (*c*) From what are they prepared?
8. (*a*) Describe oxygen. (*b*) Give its formula, (*c*) valency, (*d*) atomic weight. (*e*) Tell how to prepare it, and give formula of your method.
9. (*a*) What is specific gravity? (*b*) How obtained for solids, (*c*) liquids, (*d*) gases?
10. Describe the chemical changes in starch during digestion in detail, giving formulas.

NERVOUS DISEASES.

1. Give etiology of migraine.
2. Give etiology and symptoms of sciatica.
3. Describe (*a*) epilepsy, (*b*) catalepsy.
4. Describe a case of progressive bulbar paralysis.
5. Differentiate between (*a*) illusions, (*b*) delusions, (*c*) hallucinations.

PREVENTIVE MEDICINE.

1. How long after recovery would you keep in quarantine a case of (*a*) diphtheria, (*b*) scarlet fever, (*c*) smallpox?
2. Name the portals of entry of tubercular infection in the order of their importance.
3. Describe in detail just how you would manage cases of typhoid fever for the protection of the community.
4. How would you disinfect a room after a communicable disease?
5. What is the difference between contagion and infection?

PRACTICE.

1. Define constipation; give etiology, diagnosis, and prognosis.
2. Define vertigo; give varieties and diagnosis.
3. Define myxedema; give etiology, diagnosis, and prognosis.
4. Define hydrothorax; give etiology, diagnosis and prognosis.
5. Define angina pectoris; give etiology, diagnosis, and prognosis.
6. Define asthma; give etiology, diagnosis, and prognosis.
7. Define adenoids; give etiology, symptoms, and dangers.
8. Define enterocolitis in a child; give etiology, diagnosis, and prognosis.
9. Give essentials for the production and preservation of pure dairy milk.
10. Give etiology, diagnosis, and prognosis of meningitis in a child.

OTOLOGY.

1. What is Politzer's method of inflating the tympanum, and how is it accomplished?
2. Define tinnitus aurium, and give the cause of it.
3. Give etiology, symptoms, and diagnosis of acute otitis media.
4. What is the pyramid of light, and where would you expect to find it?
5. Give symptoms, etiology, and probable serious results of mastoiditis.

BACTERIOLOGY.

1. Tell in detail (*a*) how you would detect malarial organisms in blood, (*b*) how distinguish between the quartan and estivoautumnal parasite.
2. Describe (*a*) Widal's test for typhoid fever; (*b*) what is its diagnostic value?
3. Differentiate between the culture of *Bacillus typhosus* and that of the *Bacillus coli communis*.
4. How would you examine a suspected specimen of sputum for tubercle bacilli? Give details.
5. Define (*a*) toxins, (*b*) antitoxins, (*c*) amboceptors, (*d*) bacterioproteins, (*e*) lysins.
6. Give the morphology of the tetanus bacillus; what are its toxins?
7. Tell in detail how to examine a suspected urethral discharge for gonococci.
8. Discuss Ehrlich's side-chain theory of immunity.
9. Differentiate between the pneumococcus and Pfeiffer's bacillus of influenza.
10. What is phagocytosis? What is accomplished by it?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF HEALTH OF KENTUCKY.

Louisville, April 23, 1907.

ANATOMY.

3. The structures to be divided in operating for strangulation of an oblique inguinal hernia are: Skin, superficial fascia, intercolumnar fascia, Cremaster muscle and fascia, infundibuliform fascia, subserous areolar tissue, and peritoneum.

4. Differences between the fourth cervical vertebra and the fourth dorsal vertebra: *The fourth cervical vertebra* has a small, transversely elongated body, with no facets for ribs; the laminæ are long and slender; the spinous process is short, nearly horizontal, and bifid; the transverse processes are short and contain a foramen for the vertebral artery; the superior articular process is directed upward and slightly backward; the inferior articular process is directed downward and slightly forward; the spinal foramen is large and triangular.

The fourth dorsal vertebra has a heart-shaped body with a facet on each side for articulation with a rib; the laminæ are broad and deep; the spinous process is long and points downward; the transverse processes are long, articulate with the tubercle of a rib, and do not contain a foramen; the superior articular process is directed backward and slightly outward; the inferior articular process is directed forward and slightly inward; the spinal foramen is smaller and circular.

5. The axilla is *bounded*: *Anteriorly*, by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly*, by the Subscapularis, Teres major, and Latissimus dorsi; *internally*, by the first four ribs, first three Intercostal muscles, Serratus magnus; *externally*, by the humerus, Coracobrachialis, and Biceps.

"*Contents*: The axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue. *Their position*: The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axillary space, in contact with the pectoral muscles, are the thoracic branches of the axillary artery, and along the anterior margin of the axilla the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the subscapularis muscle, are the subscapular vessels and nerves; winding around the lower border of this muscle is the dorsalis scapulæ artery and veins; and toward the outer extremity of the muscle the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

"Along the inner or thoracic side . . . are some important nerves, viz., the posterior thoracic or external respiratory nerve, descending on the surface of the serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercostohumeral nerve or

nerves, passing across the axilla to the inner side of the arm." (Gray's *Anatomy.*)

6. In a cross section of the thigh, at the junction of the middle and lower thirds there are severed: *Muscles*, Vastus internus, Rectus femoris, Crureus, Vastus externus, Biceps, Semitendinosus, Semimembranosus, Gracitis, Sartorius, Adductor magnus; *Nerves*, sciatic, long saphenous; *Arteries*, superficial femoral, anastomotic, deep femoral, perforating.

8. Scarpa's triangle is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents*: The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

SURGERY.

1. Varieties of Hernia: Hernia may be classified:

I. *Anatomically*:

1. Inguinal
   - Oblique
     - Acquired
     - Congenital
     - Infantile or encysted
   - Direct
     - External
     - Internal
   - Interstitial
     - Intraparietal
     - Interparietal
     - Extraparietal

   [Incomplete, or Bubonocele.]
2. Femoral
3. Umbilical
   - Congenital
   - Of infants
   - Of adults
4. Ventral. 5. Lumbar. 6. Obturator. 7. Diaphragmatic, 8. Pudendal, etc.

II. *Clinically*: Reducible irreducible, obstructed or incarcerated, inflamed, and strangulated.

2. (a) Fractures are variously classified:

I. Simple, compound, and complicated.

II. Complete (transverse, oblique, spiral, longitudinal) and incomplete (fissured, greenstick).

III. Single, and multiple.

IV. Comminuted, impacted, etc.

V. Intra- and extra-articular; intra- and extracapsular.

In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture.

3. The diagnosis of gonorrhea is made by finding gonococci within the leucocytes in a urethral discharge. For details, see below—Bacteriology, Number 7.

7. A limb may be said to be injured beyond hope in a crushing accident: (1) When it is pulpefied; (2) when the main artery or vein or both are severed and the collateral circulation is also interfered with; (3) when very extensive cellulitis or gangrene appear within a short time of the accident; (4) when there is extensive laceration of tissues and extensive comminution of the bone.

8. *The indications for appendectomy* vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so, or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack.

10. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics*: "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

MEDICAL JURISPRUDENCE.

1. In expert testimony the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

3. (a) A wound inflicted by a blunt instrument will have somewhat of the appearance of a contused wound; the edges will not be so clean cut, and the surrounding tissues will be more or less bruised.

(b) A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

4. "Idiocy differs from other states of insanity in the fact that it is marked by a congenital deficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it." (Taylor's *Medical Jurisprudence.*)

OPHTHALMOLOGY.

1.—

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Secretion	None, or watery.	None, or watery.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy and steamy surface.	Cloudy.
Anterior chamber	Shallow.	Unchanged.
Iris	Discolored.	Discolored.
Pupil	Dilated, oval.	Contracted, synechiæ.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.
Treatment	Eserine, pilocarpine, iridectomy.	Atropine.

(From Alling and Griffin's *Diseases of the Eye and Ear.*)

3. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc. The probable results of a badly managed case are: Ulceration and sloughing of the cornea, perforation of the anterior chamber, and blindness.

PHYSIOLOGY.

1. (a) Foods are classified as follows:

I. Inorganic
   - Water.
   - Salts.

II. Organic
   - Non-nitrogenous
     - Carbohydrates.
     - Fats.
   - Nitrogenous—Proteids.

(b) Carbohydrates are acted on by ptyalin and amylopsin, fats by steapsin, and proteids by pepsin and trypsin.

The constituents of the bile may be shown in the following table, which presents the averages of three analyses given by Hammarsten; the results are given in parts per thousand:

Water	971.380
Solids	28.620
Mucin and pigments	4.910
Bile salts	12.197
Taurocholate	2.431
Glycocholate	9.766
Fatty acids from soaps	1.200
Cholesterin	1.243

Lecithin and fats	0.970
Soluble salts	7.360
Insoluble salts	0.317

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis; and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

4. The circulation of the blood is regulated in (a) *the arteries* by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

7. "The sympathetic nervous system consists of (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers." (Gray's *Anatomy.*)

Its *functions*: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence.*" (*Reference Handbook of the Medical Sciences.*)

8. The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

OBSTETRICS AND GYNECOLOGY.

1. By *presentation* is meant the part of the fetus which presents at the pelvic brim; examples—vertex, breech, face.

By *position* is meant the relation between a point on the fetus and a point on the maternal pelvis; examples—in a vertex presentation the position may be (1) left occipito-anterior, (2) right occipito-posterior, (3) right occipito-anterior, (4) left occipito-posterior.

5. (a) Placenta prævia, or premature separation of a normally situated placenta.

7. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

10. (a) Two indications for hysterectomy: Carcinoma and fibroids.

(b) As to preference between the vaginal and abdominal routes, the following is taken from Garrigues' *Gynecology*: "If the vaginal route is available, it should be preferred, because it entails much less shock, requires a simple after-treatment, does not leave any visible cicatrix, predisposes less to hernia, and allows the patient to resume work in shorter time. On the other hand, the vaginal route is more difficult on account of the limited space. Hemorrhage is more troublesome to check, adhesions are harder to separate, and the bladder and intestine more exposed to injury and less accessible for repair. The pelvic cavity cannot be seen so well and the abdominal not at all. If tissue is left to mortify, it emits an offensive odor."

CHEMISTRY.

1. (a) An *atom* is the smallest portion of an element that can enter into a chemical reaction, or that can enter into the composition of a molecule.

(b) A *molecule* is the smallest quantity of any substance that can exist in a free state.

(c) *Isomeric compounds* are compounds which, while differing in properties, possess the same percentage composition.

2. (a) The *symptoms of acute arsenical poisoning*: "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities." (Witthaus' *Essentials of Chemistry.*)

(b) The chemical antidote is freshly prepared ferric hydroxide. The ferric hydroxide changes the arsenic into ferrous arsenate, which is nonpoisonous. The reaction is represented by the following equation:

$$As_2O_3+2Fe_2(OH)_6=Fe(OH)_3+5H_2O+Fe_3(AsO_4)_2.$$

(c) *Test for arsenic*: Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

3. Method for the *quantitative estimation of sugar in urine*: *"Fehling's method.*—The solution is made as follows:

I. Dissolve cupric sulphate	51.98 gm.
in water to	500.00 c.c.
II. Dissolve Rochelle salt	259.9 gm.
in sodium hydroxide soln. sp. gr. 1.12 to	1,000 c.c.
(Piffard).	

When required for use, one volume of I. is to be mixed with two volumes of II. The copper contained in 10 c.c. of this mixture is precipitated completely, as cuprous oxid, by 0.05 gm. of glucose.

"To determine the quantity of sugar, place 10 c.c. of the mixed soln. in a flask of about 250 c.c. capacity, dilute with H_2O to about 30 c.c., and heat to boiling. On the other hand, the urine to be tested is diluted and thoroughly mixed with four volumes of H_2O if it be poor in sugar, or with nine volumes of H_2O if highly saccharine, and a burette filled with the mixture. When the Fehling soln. boils, add a few gtt. NH_4HO and then 5 c.c. of the urine from the burette, boil again, and continue the alternate addition of diluted urine and boiling of the mixture until the blue color is quite faint. Now add the diluted urine in quantities of 1 c.c. at a time, boiling after each addition until the blue color just disappears. Have ready a small filter, and, having filtered through it a few gtt. of the hot mixture, acidulate the filtrate with acetic acid, and add to it 1 gtt. soln. of potassium ferrocyanide. If a brownish tinge be produced, add another ½ c.c. of dil. urine to the flask, boil, and test with ferrocyanide as before. Continue this proceeding until no brown tinge is produced. The burette reading, taken at this point, gives the number of c.c. of dilute urine containing 0.05 gm. glucose, and this divided by 5 or 10, according as the urine was diluted with 4 or 9 volumes of H_2O, gives the number of c.c. of urine containing 0.05 gm. sugar. The number of c.c. urine passed in twenty-four hours divided by 20 times the number of c.c. containing 0.05 gm. glucose, gives the elimination of glucose in twenty four hours in grams.

Example.	Urine in 24 hours	= 2,436 c.c.
	Fehling's soln. used	= 10 c.c.
	Urine diluted with 4 vols. H_2O	
	Burette reading	= 18.5 c.c.

$$\frac{18.5}{5} = 3.7 = \text{c.c. urine containing 0.05 gm. glucose.}$$

$$\frac{2{,}436}{3.7 \times 20} = 32.92 = \text{grams glucose eliminated in 24 hours."}$$

(Witthaus' *Urinalysis.*)

4. Test for *bile*: Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

5. (a) Dairy milk (assuming it to be pure) contains (approximately) 4 per cent. each of proteids, fat, and sugar; whereas in human milk the proteids are about 1 to 2 per cent., the fat about 3 to 4 per cent., and the sugar about 6 to 7 per cent. Dairy milk may be acid in reaction and contains numerous bacteria, whereas human milk is amphoteric or slightly alkaline and generally contains no bacteria.

6. (a) H_2SO_4 is the formula for a molecule of sulphuric acid; (b) BaO_2 for one of barium dioxide; (c) HCl for one of hydrochloric acid; (d) HNO_3 for one of nitric acid. (e) The formula for methyl alcohol is $H.CH_2OH$.

7. (a) Acetphenetidin (or phenacetin) is ethylparaacetamidophenate.

(b) Hexamethylene-tetramine is urotropin.

(c) The former is prepared by the action of glacial acetic acid upon paraphenetidin; the latter by the action of ammonia upon formaldehyde.

8. (a) Oxygen is a colorless, odorless, tasteless gas, slightly soluble in water, heavier than air. It has a strong tendency to combine with other elements, and forms binary compounds with all elements except fluorine and bromine. Oxygen is necessary to the processes of life and combustion.

(b) Its symbol is O; (c) valence, two; (d) atomic weight, 16.

(e) Oxygen may be prepared by heating a mixture of equal parts of potassium chlorate and manganese dioxide. The latter remains unchanged, while the former gives up all of its oxygen, according to equation:

$$2KClO_3 = 2KCl + 3O_2.$$

9. (a) *Specific gravity* is the weight of any substance as compared with the weight of an equal volume of another substance taken as a standard under like conditions of temperature and pressure.

10. The ptyalin of the saliva and the amylopsin of the pancreatic juice act upon boiled starch, and by hydrolysis convert it into soluble starch. By further hydrolytic cleavage, maltose, erythrodextrin, and achroodextrin are formed.

"According to Brown and Heron the reactions may be represented thus:

One molecule of gelatinous starch is converted by the action of an amylolytic ferment into *n* molecules of soluble starch.

One molecule of soluble starch $= 10(C_{12}H_{20}O_{10}) + 8(H_2O)$, which is further converted by the ferment into

1. Erythrodextrin + Maltose.
   $9(C_{12}H_{20}O_{10})$ $(C_{12}H_{22}O_{11})$

then into

2. Erythrodextrin + Maltose.
   $8(C_{12}H_{20}O_{10})$ $2(C_{12}H_{22}O_{11})$

next into

3. Achroodextrin + Maltose.
   $7(C_{12}H_{20}O_{10})$ $3(C_{12}H_{22}O_{11})$

And so on; the resultant being:

$10(C_{12}H_{20}O_{10}) + 8(H_2O) = 8(C_{12}H_{22}O_{11}) + 2(C_{12}H_{20}O_{10})$."

Soluble starch Water Maltose Achroodextrin.

(From Kirkes' *Physiology.*)

NERVOUS DISEASES.

1. *Etiology of migraine*: Heredity, female sex, and age (about the time of puberty) are all predisposing factors; neurotic family history, epilepsy, and hysteria also predispose; overwork at school in conjunction with lowered physical health, eyestrain, injury, shock, fatigue, gout, rheumatism, indigestion, and autotoxemia may all cause migraine.

5. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

PRACTICE.

2. *Vertigo* is a disturbance of the sense of equilibrium, a condition in which the patient or objects surrounding him appear to be in a state of rotation or oscillation. It is not a disease; but is a symptom of many pathological conditions.

The chief *varieties* are: (1) Auditory, or labyrinthine, also called Menière's disease; (2) cerebral; (3) gastric; (4) toxic; (5) senile; (6) hysterical; (7) essential.

The *diagnosis* is based on the history of the case, the etiology and the absence of unconsciousness and of convulsive movements. It is to be differentiated from epilepsy, in which the patient is unconscious and also has convulsive movements.

7. *Adenoids* are hypertrophied adenoid tissue in the nasopharynx.

Causes: The real cause is unknown, but the condition is generally observed in childhood; heredity is also supposed to be a factor; males are more frequently affected than females; malnutrition and scrofula seem to be causative factors; the condition is often associated with enlarged tonsils, enlarged cervical glands, hypertrophy of the nasal mucous membrane, deviations of the septum, spurs; it often follows some of the acute infectious diseases.

Symptoms: Mouth-breathing; snoring; open-mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters.

Effects: Earache and other ear affections; mental deficiency; frequent attacks of coryza; nose-bleed; stunted growth; convulsions, laryngismus stridulus, and various other neuroses may also be noticed.

OTOLOGY.

2. Tinnitus aurium is the name given to any subjective sounds heard in the ear. The chief causes are: Neurasthenia, impacted cerumen, otitis, and other ear diseases; Menière's disease, obstruction of the Eustachian tube, anemia, leukemia, cerebral hyperemia and anemia, arteriosclerosis, gout, digestive disorders, excessive use of alcohol or tobacco, and the use of certain drugs such as quinine or salicylic acid.

4. The pyramid of light is a reflection of light from the anterior inferior quadrant of the membrana tympani. It is roughly triangular in shape, and its apex touches the tip of the manubrium of the malleus, while its base lies on or near the periphery of the membrana tympani.

BACTERIOLOGY.

2. (a) The Widal test for typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology.*)

(b) Its diagnostic value is believed by some to be great; others place little reliance on it. It may be absent in cases of typhoid fever; it may be present for several months after an attack of typhoid; the reaction may not be obtained till the third week of the disease; it may be present in other diseases or in perfectly healthy persons. The above have all been urged as objections; certainly only positive results have any value at all.

3. The cultural and microscopic points of difference between the *Bacillus coli communis* and the *Bacillus typhosus* (of Eberth) are:

"(1) The motility of the colon bacillus is, as a rule, not very pronounced, sometimes absent; that of the typhoid bacillus is usually very active.

"(2) On gelatine plates the colon bacillus develops more rapidly and luxuriantly than the typhoid bacillus, and on potato it grows more abundantly, being almost always visible.

"(3) The colon bacillus coagulates milk with acid reaction within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.

"(4) The colon bacillus causes fermentation with pro-

duction of gas in media containing sugar; the typhoid bacillus does not.

"(5) In nutrient agar or gelatine containing lactose and litmus tincture and of a slightly alkaline reaction, the color of the colonies of colon bacillus is pink and the surrounding medium red; while the colonies of typhoid bacillus are blue and there is little or no reddening of the medium.

"(6) The colon bacillus produces indol in cultures of bouillon or peptone; the typhoid bacillus does not.

"(7) When a twenty-four-hour-old bouillon culture of the colon bacillus is mixed with the blood or serum of a patient suffering from genuine typhoid fever, in a dilution of one to ten or more, after the first week of the disease, the Widal reaction is negative; cultures of the typhoid bacillus treated in the same manner and examined in the hanging drop give the characteristic agglutination and clumping of the bacilli." (*Reference Handbook of the Medical Sciences.*)

4. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

5. (a) *Toxins* are the poisonous products of pathogenic bacteria.

(b) *Antitoxins* are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

(c) *Amboceptors* are antibodies having a double combining affinity; one linking on to the cell to be destroyed, and the other linking on to the alexin or complement.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery...Jan.	7
Arizona*	Ancil Martin, Phoenix	Phoenix...Jan.	6
Arkansas*	F. T. Murphy, Brinkley	Little Rock...Jan.	14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco April	7

THE HEART REFLEX AND THE MECHANISM OF ANGINA PECTORIS.

BY ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO.

BEFORE discussing the mechanism of angina pectoris it will be necessary to refer to certain preliminary facts concerning the heart reflex.

Attention was first directed[1] in 1898 to the phenomenon now known as the heart reflex. The reflex in question is a contraction of the myocardium of varying duration, which results when the skin of the precordial region is irritated. The cutaneous irritant may be a spray of ether directed over the region of the heart or the skin may be rubbed with a blunt instrument or by means of an ordinary pencil eraser or by a series of percussion blows. The nearer the irritant is applied to the precordial region and the more vigorous the cutaneous friction, other things being equal, the more pronounced is the heart reflex. The reflex is best observed with the Roentgen rays with the fluorescent screen approximating the anterior chest wall. The reflex is, as a rule, more manifest in the left than in the right ventricle, and the contraction of the myocardium is not always sudden and of momentary duration: on the contrary, its duration in children on whom most of the original observations were made is not less, as a rule, than

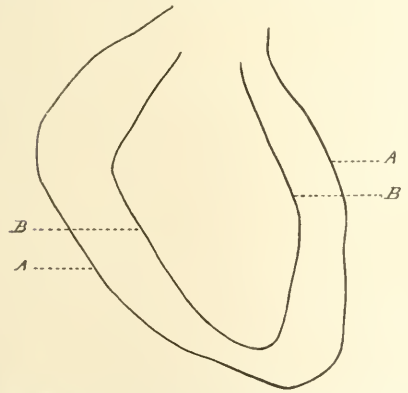

FIG. 1.—Heart reflex in a boy, aged 8 years. Duration of reflex, 2½ minutes. The normal outline of the heart drawn on the fluoroscope is represented by A, whereas B represents the outline of the heart after cutaneous irritation and shows the degree of myocardial recession or the heart reflex.

two minutes, and, furthermore, the myocardial recession continues even after the source of cutaneous irritation is removed. The degree of myocardial recession (heart reflex) varies greatly. In some persons it is scarcely perceptible, while in other individuals the heart may recede more than two centimeters on either side upon the first application of the cutaneous irritant. (See Fig. 1.)

In other instances, although the reflex is rarely absent in the norm, it is strictly confined to the left ventricle, as shown in Fig. 2.

In individuals with dilated hearts the reflex is very evident and is of very much longer duration than in healthy hearts. This latter observation, as we shall learn presently, has been confirmed by the careful observations of Merklen and Heitz.

FIG. 2.—Heart reflex in a boy aged 14 years. Duration of reflex, 55 seconds. A represents the cardiac outline before, and B after, cutaneous irritation, while C represents the upper border of the liver.

In the original communications concerning the heart reflex, the latter was observed only in the transverse cardiac diameter, but with the *x*-rays it can also be seen in the sagittal diameter. Subsequent observations demonstrated that the heart reflex could be elicited by irritation of more remote regions, viz., (1) by irritation of the nasal mucosa; (2) by irritation of the gastric mucous membrane; (3) by irritation of the rectal mucosa; (4) by irritation of the esophageal mucosa in the act of swallowing; (5) by percussion of the muscles; (6) by psychic irritations; (7) by vertebral concussion.

Irritation of the Mucous Membranes.—Here investigations were conducted during the time the *x*-rays were traversing the chest, and by means of the fluoroscope the heart was directly observed. It was noted that when irritating vapors were inhaled there was a decided recession of the cardiac ventricles (heart reflex), especially the left, and that this heart reflex was more pronounced than when excited through the skin of the precordium. Ether and chloroform inhalations also excited the reflex and in a few instances these vapors produced a veritable cardiac inhibition. It was noted that the reflex in question was excited by irritation in succession of the nasal, pharyngeal, and laryngeal mucous membranes, and when the latter were made anesthetic by cocaine no heart reflex could be elicited.

The accompanying sphygmogram (Fig. 3) shows a decided difference in the output of blood into the general circulation before and after the inhalation of ammonia:

The heart reflex may also be elicited by irritation of the gastric mucosa when the sponge of the gyromele is made to revolve against the membrane in question. One may also excite the reflex by irritation of the rectal mucosa by means of the finger in the rectum.

Percussion of the Muscles.—If one percusses the muscles (*tapotement*) of the extremities one can elicit cardic reflex. The latter is essentially a reflex of muscular origin exclusively, as such a reaction does not follow irritation of the skin of the extremities or percussion of the bones. Percussion of the muscles of one arm only suffices to elicit this reflex. Another curious feature of this myopathic heart reflex is that it causes retraction of the right heart ventricle only, the left being uninfluenced. Placing the subject before the *x*-rays this reflex is at once evident. After the heart borders are defined, request an assistant to percuss the muscles of one arm by means of a percussion hammer. Following the maneuver the right ventricle shows considerable retraction. The effect on the systemic blood pressure by percussion of the muscles is very slight, and this is obvious, considering that the left heart ventricle is uninfluenced by the maneuver.

Psychic Irritation.—We have always recognized the effects of emotions in the heart, but no tangible evidence of such effects has been demonstrated. The epigram of Peter is worth repetition: "The physical heart is the counterpart of a moral heart." The conventional expression of the frightened individual, "my heart was in my mouth," finds justification by an *x*-ray study of the heart. Inform the patient standing before the rays that you are going to burn him with a hot iron or frighten him in some other way, and the effect on the heart is at once manifest. It is a veritable psychic heart reflex implicating the entire organ. The heart becomes very much reduced in size, and appears as if it were retreating towards the neck. I know of no irritation, cutaneous or otherwise, that is so pronounced as is this psychic factor of fright in inducing the heart reflex. The foregoing fact is of the utmost importance in eliminating emotional influences in the treatment of cardiac diseases. Even in an ordinary *x*-ray examination of the heart one may observe in nervous patients a reduction of the heart mass. Mr. Bezley Thorne[2] observed that the heart shrank after exposure to the Roentgen rays. It is evident that the shrinkage thus observed was naught else but a cardiac reaction (heart reflex) to emotional influences, for an *x*-ray examination to the average patient is a momentous procedure. I have frequently witnessed the pulmonary reaction of fright: the lungs become hyperresonant on percussion, and the superficial areas of cardiac, hepatic, and splenic dullness become diminished, a condition which was called the *psychic lung reflex of dilatation.*[3]

The latter psychic reflex may be easily demonstrated if the areas of the organs in question are first outlined, and later, if the patient is frightened, percussion will demonstrate that the areas of the organs are reduced in proportion to the psychic reaction which provokes a dilatation of the lungs.

Vertebral Concussion.—Heretofore only one heart reflex was recognized, viz., the heart reflex of contraction, but when the spinal processes of the eighth, ninth, tenth, eleventh, and twelfth dorsal vertebræ are rapidly concussed in succession there is a decided increase in the area of cardiac dullness as obtained by percussion. This increase in the area of cardiac dullness is not associated, as the *x*-rays show, with any increase in the diameters of the heart. The latter fact corresponds with the investigations of Kornfeld,[4] who demonstrated that the heart muscle possesses the property of increasing the size of its cavities without any corresponding augmentation of tension of its walls, a condition which he calls *Ausweitungsfähigkeit.* By concussion of the spinous process of the seventh cervical vertebra, one may also provoke the ordinary heart reflex of contraction.*

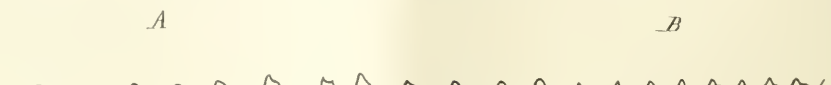

Fig. 3.—Sphygmogram of the radial artery A before, and B after the inhalation of ammonia.

Practical Value of the Heart Reflex.—Percussion of the heart, or, for that matter, any other organ adjacent to the lung, is associated with many errors, unless one takes into consideration the lung reflex. Percussion of the heart, as executed ordinarily, yields an absolute or superficial, and a deep or relative dullness. Practically little or no value can be attached to the superficial dullness in estimating the size of the heart, as it varies with the position of the overlapping lung borders. Even the lightest percussion blow will provoke sufficient cutaneous irritation to induce the lung reflex of dilatation, *i.e.* an acute dilatation of the lungs which may diminish the area of superficial cardiac dullness, even to obliteration. Cabot,[5] in his classical book, makes the following observation: "Anyone who has demonstrated an area of percussion dullness to many students in succession must have noticed occasionally that the more we percuss the dull area the more resonant it becomes, so that those who last listen to the demonstration, the difference which we wish to bring out is much less obvious than to those who heard the earliest percussion strokes. Abrams has referred to this fact under the name of the '*lung reflex.*'" Sahli, in his "Diagnostic Methods," refers to the same fact. The mere influence of room temperature materially changes the results of percussion. Let any one, after percussing the areas of superficial dullness, direct a current of cold air, *e.g.* from an atomizer, over the regions percussed, and

*The writer has reported other vertebral reflexes, but as yet the profession has given to them only inconsiderate attention. Such reflexes are of undoubted value in diagnosis and treatment and are unconsciously evoked by the manipulations of the osteopath who seems to have monopolized this field of vertebral therapy. Anyone who has reason to doubt the value of manual manipulation of the spine may attempt a maneuver which I have only recently observed. While palpating, say the radial pulse, make firm pressure at the vertebral exit of the spinal nerves (preferably at the side of the upper dorsal vertebræ) and one will note a decided alteration in the character of the pulse, which often amounts to inhibition of the latter.

the result will be diminution or obliteration of the areas in question. It is evident from what has preceded that, while the heart reflex can always be determined by the *x*-rays, after cutaneous irritation of the precordium, mere percussion of the superficial area of cardiac dullness cannot determine its exist-

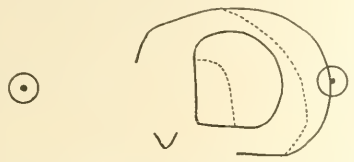

Fig. 4.—Cardiac reflex in a neurasthenic with functional troubles of the heart, reduction of the absolute and relative dullness. (After Merklen & Heitz.)

ence because the irritation necessary to evoke the heart reflex will also induce the lung reflex, which must necessarily mask the heart reflex.

Thus the observations of Schott and others, who seek to demonstrate the effects of carbonated baths on the heart by percussion of the latter organ are evidently erroneous unless such percussion takes into consideration only the deep or relative cardiac dullness. Heitler[6] perpetrates the same error by failing to take into consideration the coincident lung reflex when making cutaneous irritation. Heitler seeks to determine the sufficiency of the heart muscle by a series of percussion blows over the heart region. If, thereafter, the cardiac dullness is much diminished, it is an evidence, he argues, that the cardiac musculature is sufficient, for the tendency of the normal muscle tonus of the heart is to maintain a limited patch of dullness. As before remarked, the heart reflex can be observed directly with the rays, but if strong percussion is employed so that reliance is alone placed on the deep or relative cardiac dullness, the reflex in question may be determined by percussion. Heitz,[7] in discussing "Le Reflexe Cardiaque d'Abrams," observes that, while in the nor-

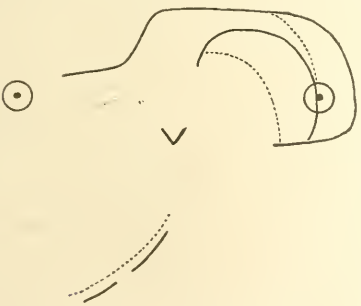

Fig. 5.—Hyposystole in an arteriosclerotic; reduction of the absolute and relative cardiac dullness and ascension of the inferior border of the liver under the influence of precardial massage. (After Merklen and Heitz.)

mal subject the heart reflex is of short duration, in cardiectasis it may persist for several hours. In the third edition of their valuable book ("Examen et Séméiotique du Cœur"), Merklen and Heitz show graphically the effects of friction of the skin in the region of the heart of a cardiac neurasthenic (Fig. 4), and in a cardiopath with hyposystolie (Fig. 5).

In Fig. 5 the reduction of the hepatic dullness is shown following the friction of the skin; the continuous lines show the superficial and the deep dullness of the heart before, and the interrupted lines the reduction of the areas after friction of the skin.

All physicians do not possess equal skill in determining the relative cardiac dullness, and I have devised a simple apparatus called the "Vibrosuppressor,"[8] which serves to simplify topographical percussion. If one percusses the normal chest, say

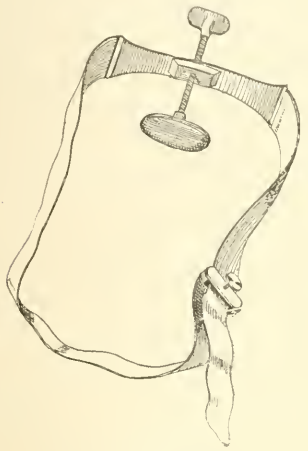

Fig. 6.—The vibrosuppressor.

beneath the clavicle, a sound is produced which is the product of the vibration of the lung tissue and

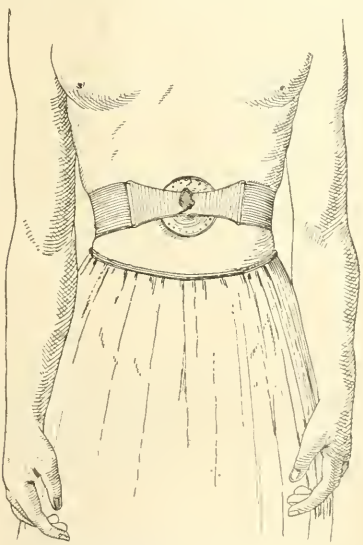

Fig. 7.—Application of the vibrosuppressor to the chest.

the thoracic walls. It is the summation of this vibration which interferes with the elicitation of the dullness of the airless organs in juxtaposition to the lungs. If the vibration in question can be eliminated, the definition of the viscera will prove easy of attainment. Briefly, lung resonance is made up of two chief factors, viz., vibration of the air in the lungs and vibration of the sternum. The latter is essentially a sounding-board. Thoracic vibration can be eliminated as far as possible by percussion of the organs at the end of a forced expiration, when

there is comparatively little air in the lungs to vibrate and by suppressing the vibrations of the sternum by means of the vibrosuppressor (Figs. 6 and 7).

The apparatus is modeled after a tourniquet, consisting of a pelote, screw, band (6 cm. wide) and clamp for fixing the latter. It is so applied that the pelote rests on the xiphoid cartilage of the sternum. The pelote is made to compress the cartilage by aid of the screw with all the pressure the patient can tolerate. Percussion is then executed during the time the apparatus is employed and preferably during suspended respiration, after forced expiration. In the absence of the apparatus, firm pressure made on the lower end of the sternum by the hand of an assistant will aid topographic percussion during the time the patient has suspended respiration after forced expiration.

The Heart Reflex of Nasal Genesis.—Reference has already been made to the fact that the heart reflex can be provoked by irritation of the nasal, pharyngeal, and laryngeal mucous membranes, and that if the irritation is sufficiently prolonged and violent the movements of the heart may be inhibited. If the membranes in question have been previously cocainized the heart reflex cannot be elicited. It is evident, then, that previous cocainization of the nasal and pharyngeal mucous membranes should precede the employment of an anesthetic. On theoretical grounds, the laryngeal mucosa should not be cocainized, as it is necessary to preserve the laryngeal reflex to prevent the entrance of foreign substances into the larynx.

The Heart Reflex of Gastric Genesis.—Knowing that irritation of the gastric mucosa will provoke the heart reflex, it is not improbable that sudden death of gastric origin may be caused by reflex inhibition of the heart. In instances of this kind the fact of a dilated stomach directly compressing the heart cannot be ignored. I have studied, by aid of the *x*-rays and the fluoroscope, the action of a dilated stomach on the heart by artificial distention of the stomach. The healthy heart can tolerate considerable compression and dislocation without modifying the intensity of the heart tones, but when the organ is diseased, the slightest compression and dislocation is followed by evil consequences. Artificial insufflation of the colon will also compress and dislocate the heart, but never in the same degree as will insufflation of the stomach.

The Heart Reflex of Rectal Origin.—Irritation of the rectal mucosa will also induce the heart reflex. Straining at stool in elderly people by increasing intraabdominal pressure, and thus putting a strain on the cerebral vessels, predisposes to rupture of the latter. Straining, however, is not wholly a question of pressure. Some patients, particularly those with weak hearts, suffer from collapse symptoms while straining at stool. In investigating the cause of such symptoms, I found that contraction of the abdominal musculature will cause even in the norm a veritable heart reflex with diminished output of blood from the left ventricle. For the latter reason the amount of blood is decreased in the arterial system and increased in the veins. The accompanying sphygmogram (Fig. 8) illustrates the effects of contraction of the abdominal musculature on the heart.

It is evident that if the heart is enfeebled the effects of such cardiac inhibition may be attended with serious results. It is well known that different nerves from the abdomen and intestine are in close communication with the cardioinhibitory center in the medulla and that reflex inhibition of the heart can be easily produced in the frog by tapping a loop of the intestine with the handle of a scalpel. Severe abdominal affections, like peritonitis and appendicitis, are frequently attended with symptoms of heart collapse, owing, no doubt, to reflex inhibition of the heart.

Anyone can appreciate the inhibitory influence on the heart by contraction of the abdominal muscles, by palpating the radial pulse while straining at stool.

Relative Valvular Insufficiency.—The normal heart can easily adapt itself to the average grades of dilatation such as occur during exertion; in fact, the size of the cavities of the heart varies even in health, and a dilatation is physiological as long as the heart cavity is capable of emptying its contents during systole. What is called "getting wind" in climbing a mountain or in athletic training is practically a moderate dilatation of the cavities of the right heart. In relative valvular insufficiency the valves are normal, but they are no longer capable of completely closing the orifices of the heart. This condition is frequent after heart strain and involves particularly the tricuspid valves. A murmur which is heard in such instances may be made to disappear

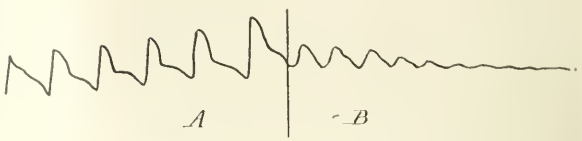

FIG. 8.—Sphygmogram (A) before and (B) while straining at stool.

temporarily by inducing the heart reflex, which, by causing myocardial contraction, reduces the size of the cardiac orifices, thus enabling the valves to close the openings. Here the excitant of the heart reflex must be vigorous and for this purpose the sinusoidal current, with both electrodes to the precordial region, is most efficacious. Percussion of the precordial region with a percussion hammer will often suffice.

Pericardial Effusion.—The differential diagnosis between a dilated heart and a pericardial effusion is often conceded to be a difficult clinical problem. From what has preceded we see the heart reflex can be employed in diagnosis. The reflex in question is absent in pericardial effusions and present in cardiectasis. In other words, after the heart reflex is provoked the area of deep cardiac dullness will be uninfluenced in effusions but modified in cardiectasis.

It may be difficult to say whether a pulsating intrathoracic mass examined with the *x*-rays is the heart or an aneurysm. A retraction of the mass after provoking the heart reflex would indicate that it is the heart and not an aneurysm. Cooper utilized the foregoing fact in differential diagnosis. I will not attempt to discuss the therapeutic value of the heart reflex, but it is my personal opinion that the carbonated baths in the Schott treatment possess no special effect beyond their action in provoking the heart reflex by cutaneous irritation and that cutaneous friction by any other method is equally efficacious. The foregoing conclusion is formulated only as a result of many years of observation. Massage of the precordial region or the

employment of the sinusoidal current, especially in cardiopaths, will reduce the area of the heart and the pulse-rate and augment blood-pressure. The now prevailing fetish in cardiotherapeutics is Nauheim. I subscribe equally to the efficiency and deficiency of this famous resort, but it is puerile to endow its waters with marvelous attributes.

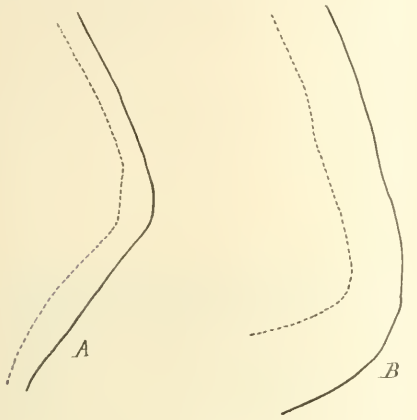

Fig. 9.—The heart reflex. A before, and B after, the use of digitalis.

Angina Pectoris.—Among the theories of angina, that of Allan Burns appeals most cogently to reason. The latter assumes that, in consequence of a transient ischemia of the heart-muscle caused by disease or spasm of the coronary arteries, a condition analogous to intermittent claudication ensues. It is known that the coronary arteries are practically always diseased in fatal cases of angina, but if we accept the observation of Schäfer that the coronary vessels are unprovided with vasomotor nerves, the theory of intermittent claudication of the coronaries must necessarily suffer a serious setback unless supported by other evidence. The coronary arteries supply the heart with blood only during diastole, for during systole the ventricular wall is so strongly contracted that the muscular tension becomes greater than the coronary pressure and so the coronary artery and branches are compressed and the blood is driven back into the aorta. It is our contention that the theory of Burns is correct, but that the ischemia is quite independent of the coronary arteries, which are merely passive structures. We assume that any factor operating to augment the tonicity of the cardiac musculature compresses the arteries in question and thus induces ischemia. The heart reflex is essentially a myocardial contraction and when the reflex is in evidence the coronary arteries are subjected to varying degrees of pressure. If in an attack of angina, the pulse shows augmented tension and is small and perhaps diminished in rate, or if syncope is observed, such symptoms are explainable by the heart reflex.

We know that when the reflex is in evidence, the heart is practically inhibited; there is a diminished output of blood into the general circulation and, if the pulse shows increased tension, it is only an expression of vasomotor activity which assumes the burden of maintaining the circulation.

If one studies the etiology of angina, one notes that the factors which precipitate a paroxysm are also equally operative in inducing the heart reflex. Muscular effort is a potent factor which also provokes the myopathic heart reflex. Emotion is another prominent factor and led John Hunter to observe that "his life was in the hands of any rascal who chose to annoy and tease him." Emotion as a cause corresponds with the psychic heart reflex. A gust of wind striking the chest is equally involved in inducing either an attack of angina or the heart reflex.

Oliver demonstrated that patients who have suffered from precordial pain obtain permanent relief on the supervention of cardiac dilatation and failure, and Broadbent has shown that the supervention of mitral insufficiency may diminish the tendency to anginoid attacks.

Now, in cardiectasis, while the heart reflex can be provoked, the cardiac musculature is enfeebled and the resulting pressure on the coronary arteries is correspondingly diminished. Reference has been made to the heart reflex of dilatation and in several instances, during my office hours, I have inhibited anginoid pains by concussion of the vertebræ which induces cardiac dilatation, and I have employed the same method with fairly good results in the treatment of angina pectoris. In other instances, I have unintentionally provoked attacks of angina in studying the heart reflex and the methods for its elicitation.

By means of the heart reflex, one can easily comprehend the attacks of false angina. In functional angina, the heart reflex is always accentuated as I have assured myself by repeated *x*-ray examinations. In cardiodynia (*Herzangst*) observed in neurotics, one is dealing essentially with a psychic heart reflex.

There are etiological factors concerned in angina which on first view could find no explanation by my heart reflex ischemic theory, yet on reflection, the theory is applicable. Thus, one of my friends, a physician in Paris, suffers like several other members of his family from pronounced attacks of angina pectoris several hours after the use of coffee, tea, or tobacco. One knows, for instance, that the effect of caffeine in small doses on the cardiac muscle is to increase its activity; in larger doses, it produces phenomena analogous to fatigue, and in very large doses, the muscle is thrown into rigor. In the latter instance, the strong contraction of the myocardium (which is essentially a heart reflex) mechanically compresses the coronary vessels.

The toxic factor here involved in eliciting the heart reflex is necessarily delayed and cannot be

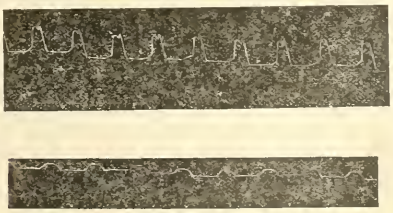

Fig. 10.—A, Tracing a normal anterior tibial artery; B, tracing of same artery in claudication.

immediate like the other factors concerned in the elicitation of the reflex in question. Digitalis and other circulatory stimulants may provoke an attack of angina for the reason that they augment the tonicity of the cardiac musculature. Digitalis increases the amplitude of the heart reflex as shown in Fig. 9.

Recently I have observed the following singular

phenomenon: After placing the ankle of one lower extremity on the knee of the other extremity, the pulse of the anterior tibial artery is easily palpated. Next, direct the patient forcibly to extend and flex his foot (the leg occupying the same position) a number of times in succession. If the tibial pulse is again sought, it will be either very feeble or absent. In the norm fully 30 seconds may elapse before the pulse has attained its former volume. The blood-pressure also falls. In a patient with claudication, five minutes elapsed before the tibial pulse resumed its former volume. This test may prove of value in the diagnosis of the latter affection. I assume that the tibial artery, immersed as it is in a muscular atmosphere, responds reflexly to the muscular contractions, and in arteriosclerosis the longer duration of the arterial contraction accounts for the phenomena of claudication. Here, as in my heart reflex theory of angina, the ischemia is dissociated with vasomotor action, insomuch as when amyl nitrite is inhaled, obliteration of the tibial artery is effected by the muscular maneuver suggested.

The treatment of angina pectoris includes the elimination of all factors concerned in the elicitation of the heart reflex. The value of amyl nitrite inhalation in the treatment of a paroxysm is universally conceded. When the latter drug fails, and it often does, the failure may be attributed to irritation of the nasal mucosa which induces the heart reflex, which would still further accentuate the paroxysm. In such instances and, in fact, in nearly all instances, the action of the drug in question is aided by previous cocainization of the nasal mucosa, which eliminates the irritant factor in amyl nitrite inhalations. Concussion of the lower dorsal vertebræ (daily treatment) should be given a trial in the treatment of angina pectoris to induce the counter-reflex of dilatation.

THE REACTIVE POWER OF THE WHITE RAT TO TISSUE IMPLANTATION.

A PRELIMINARY COMMUNICATION.*

By ISAAC LEVIN, M.D.,

NEW YORK.

The question, with what measure of success can we implant tissue or even whole organs of a highly organized animal into another part of the same individual or into another individual of the same species, is of greatest interest and importance in biology and medicine.

The tissues and organs of an adult organism perform the different functions allotted to them, take part generally in the metabolic processes of nutrition; but, with few exceptions, they do not grow any further; the cells of the tissues do not proliferate. The same difference in the life energy of the cell takes place apparently when it is severed and implanted in a new place. The transplanted cells may remain alive and are able to perform their normal functions for a certain time; but they do not proliferate. The whole thyroid and pancreas have been successfully transplanted, and lately Carrel[1] performed the wonderful experiment of transplanting the whole urinary system—kidney, ureter, and part of the bladder—from one cat into another, whose own kidneys were removed, and the second cat lived for some weeks. On the other hand, we meet with far less success when we are implanting only pieces of an organ with the aim of causing the further proliferation of cells of the severed tissue.

Of all the pathological processes in which proliferation of cells takes place, the hardest to comprehend as well as the most important, is the formation of a malignant new growth, and practically all the experiments with implantation of tissue have been done in order to elucidate the genesis of malignant tumors.

The implantation of normal tissue, embryonic or adult, has usually been done in order to prove a certain preconceived theory as to the factor inciting the cell proliferation in a new growth, the genesis of tumors. Cohnheim's theory that the excitants of tumors always act upon embryonic cells, which remain in a certain part of the organs without developing into mature tissues, was followed by a series of experimental works dealing with implantation of embryonic tissue by Zahn,[2] Fischer,[3] Birch-Hirschfeld and Garten.[4] Weigert and Ribbert maintained that no outside irritant acting on a cell could induce a bioplastic process, but only a katabiotic, *i.e.* that cells under the influence of some irritating agent acting from without may disintegrate, undergo regressive metamorphosis, but not proliferate. They have consequently advanced the following hypothesis to explain the genesis of tumors. Every cell of the organism is able to proliferate. That it does not do so under ordinary circumstances is due to the fact that it forms a part of the organic whole, and is

Fig. 1.—Appearance of a piece of liver tissue ten days after implantation.

*Read before the New York Pathological Society, November 13, 1907.

therefore restrained by the "tissue tension." If these influences are removed through the severing of the connection of the cells with the rest of the organism, the proliferating power hitherto suppressed manifests itself until the tissue tension is restored. If the severance of such cells from their organic connection is complete, and the disconnected cells are not so numerous as to contain a certain "tension" in themselves, malign tumors will develop. On the other hand, if such cells are but incompletely severed, and comprise a kind of organic union, benign tumors will develop.

This hypothesis explains in a very satisfactory manner the formation of tumors, and also presents a uniform conception of all the factors of growth and development of an organism, but it certainly requires some experimental proof. Some tissue implantation, with the aim in view to prove this theory, was done by Ribbert[5] himself and Lubarsch.[6] In 1901 I published the report of a series of experi-

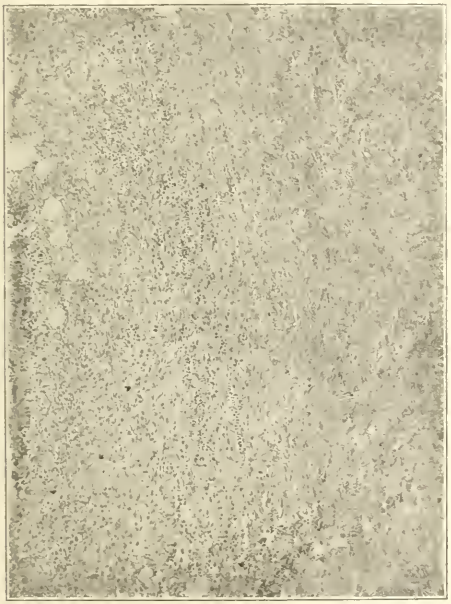

Fig. 2.—Appearance of a piece of skin after double implantation—seven days in the peritoneal cavity of one animal, thirteen days in that of another.

ments which I had undertaken on rabbits and dogs with implantation of different tissues.[7] In these experiments I tried in a variety of ways to free cells from the restraining influence of the rest of the organism under conditions most favorable for their subsequent proliferation, and thus to ascertain whether they could be made to proliferate indefinitely and consequently produce a tumor. Nichols[8] reported, in 1905, a very similar set of experiments. In the great majority of these experiments the results were negative. The implanted tissue usually becomes necrotic and is subsequently absorbed. The only exception is implanted epidermis, which proliferates to some extent.

A priori one would expect more success with the implantation of pieces of tumor than with normal tissue. Whatever the cause, tumor cells are certainly in a state of increased proliferation. But the implantation of tumor tissue in animals gave the same negative results. The successful transplantation of the sarcoma of the genital organs of the dog cannot be considered here, as the question whether this is a real tumor or an infectious growth similar to lues is not yet settled.

In complete contrast with all these negative results stands the great success of the transplantation of sarcoma and carcinoma in white mice and rats. Since the first reports of positive grafting by Hanau,[9] in 1889, an immense number of successful transplantations were done by Morau,[10] Velich,[11] Loeb,[12] Jensen,[13] Michaelis,[14] Bashford,[15] Ehrlich,[16] Flexner and Jobling,[17] and others. This great difference between tissue implanted into any other animal which had so far been experimented upon, and pieces of a tumor of a white rat or mouse implanted into another animal of the same species, could be due only to one of two causes: Either the intrinsic power of limitless proliferation of a carcinoma or a sarcoma cell of a white rat or mouse is greater than that of a cell of any other animal, or else these animals react differently to tissue implantation than do other laboratory animals. The majority of the workers in this field seem to lean to the first explanation, and think even that the experiments on these animals have proven that the genesis of tumors generally must be explained by the intrinsic power of a tumor cell to limitless proliferation. Nevertheless, there are facts in the results of these transplantations which seem to indicate that a great deal may be due to the reaction of the organism to the implantation.

In the first place, while a cell may act quantitatively differently in a different animal, it is hard to suppose that tumor cells so completely identical morphologically will be absorbed completely when implanted in any other animal, and will continue their growth and proliferation in a rat, and that still the difference will lie only in the cell itself. It has been shown that if we take pieces of a tumor from a rat or mouse, and implant them into one hundred other rats, the pieces will grow in only ten or twenty rats, and will disappear in the other ninety or eighty rats. But if pieces from an implanted tumor are reimplanted into other rats or mice they will take in a greater percentage, and this increase will continue in the following generations of transplantation. On the other hand, through certain agencies the animals can be made refractory to tumor implantations. This difference in the capacity for growth of the same tumor in different animals of the same species must certainly be due either to something the tumor cell has acquired in the previous host, or else to the different reactive powers of the different animals. The same holds true for the fact that the same tumor, while growing well in a rat taken from Copenhagen, does not grow at all in a rat from Berlin.

It may be interesting to note in this connection the following facts: A great deal of work was done with transplantation of human tumors on an animal and, as was to be expected *a priori*, with negative results. But Dagonet succeeded by implanting human carcinoma on a white rat in producing a real epithelial growth; and, what is very important from the standpoint of the influence of the host on implantations, the cells in the rat differed in size from the implanted human cells.

The hardest phenomenon to explain by the intrinsic power of the implanted tissue is the change of an implanted carcinoma into a sarcoma. Ehrlich thinks that in these cases the connective tissue stroma of the implanted tumor changes into sar-

coma; but it would certainly be impossible to prove that this stroma is the implanted one and not the one formed by the host.

In view of all this it seems *a priori* possible that the white rat reacts differently to implantation, not only of tumor, but also of normal tissue, and to test this question experimentally this research was undertaken. I am implanting tissues of different organs into another place of the same rat or into other rats. While the work is not yet finished, and the detailed report of the experiments will be published later, some impressions have already been gained which seem of considerable interest.

Pieces of tissue of a size that would be absorbed in another animal very rapidly remain unabsorbed in the rat for a longer time, even when, as in the peritoneum, they do not become attached anywhere, but float like a foreign body. Much more frequently the pieces are either surrounded by a capsule consisting of an outer fibrous layer, and an inner one made up chiefly of round cells, or else the round cells invade and eat away, as it were, the implanted tissue. One is impressed with the great amount of organization going on around the implanted pieces. On the other hand, the pieces themselves seem to retain the cell structure much longer than is usual in other animals. Figure 1 presents a specimen that was prepared from a piece of liver which was implanted ten days before the animal was killed; the nuclei and the general structure of the liver are still apparent. The same specimen shows the great quantity of round cells around the implanted piece.

Figure 2 presents a specimen from a very interesting growth. A piece of skin, which had previously been for a week in the peritoneum of a rat was implanted into the peritoneum of another rat. The animal was killed thirteen days later. At the autopsy there was found a tumor the size and shape of a nut, which was adherent to the anterior wall of the stomach and the lower surface of the liver, and moving freely with the liver. On incision it appeared to be a cyst containing a cheesy mass and pus; the wall was about one-eighth of an inch in thickness. As is seen under the microscope, the wall of the cyst consists of an external fibrous part and an internal one richer in cells.

Such an extensive reactive cellular organization, whether against an implantation of foreign tissue, or even against infection, one does not meet in other laboratory animals. We know, then, that the implanted tumor tissue of a rat proliferates and grows. It was further proven experimentally that extracts or filtrates of tumors without cells do not produce any growth in another animal.

The aim of my work is to see whether the normal tissue of a rat implanted into another rat will itself grow or only incite the cells of the host to proliferation, and, if so, whether it can incite to proliferation only the connective tissue cells, or the epithelium also. Should the cells of a normal implanted tissue not proliferate, then I shall combine normal tissue with cell-free extract of a tumor, and shall note whether in this combination a normal cell can be caused to proliferate in the host. All this will be the subject of my future communication.

In conclusion, I wish to express my gratitude to Prof. T. M. Prudden for the privilege of the laboratory. Prof. J. H. Larkin has aided me greatly in the microscopical part of the work, and I take pleasure in extending to him my thanks.

NOTES ON EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

By HERBERT MAXON KING, M.D.,
Liberty, Sullivan County, N. Y.
Physician-in-chief, Loomis Sanatorium.

As it is obviously impossible in the time which has been allowed me to elaborate upon all of the refinements of diagnosis of phthisis, I propose to confine my discussion of the subject to such features only as are more or less limited to the earliest stages of the disease and to such methods as are at the command of every practising physician.

At the meeting of the National Association for the Study and Prevention of Tuberculosis in 1905, the Committee on Nomenclature presented a scheme of classification of the various stages of phthisis which was adopted by the Association. In this scheme the incipient stage of the disease was described as follows: "Slight initial lesion in the form of infiltration limited to the apex or a small part of one lobe. No tuberculous complications. Slight or no constitutional symptoms, etc. Slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest. Expectoration usually small in amount or absent. Tubercle bacilli may be present or absent."

None realize more keenly the inadequacy of such a definition than did the members of that Committee, of which I was one. On the other hand, some plan of classification upon which all could agree seemed necessary and—without going into a lengthy, intricate and confusing description—no better definition was brought before the Committee, which finally agreed upon the foregoing, unsatisfactory though it be.

The difficulty is this—that no description, based upon physical signs alone, is sufficient to determine the incipiency of a tuberculous lesion and as a consequence a diagnosis, which would classify a case as incipient according to this definition, might and not infrequently does convey a very erroneous idea of the situation. For instance, a patient presenting such a clinical picture as would thus classify him might very well have had tuberculosis for ten years and thus, in a true sense, his disease would naturally be anything but incipient, and the diagnosis could not on the broadest acceptation of the term be called an early one.

It follows, therefore, that the first and most important procedure in arriving at an early diagnosis is a thorough and painstaking inquiry into the personal and family history of the patient. Such an investi-

*Read by invitation at a meeting of the Third District Branch of the Medical Society of the State of New York, October 22, 1907.

gation when intelligently conducted is, I venture to say, of even greater value than the physical examination itself, for in the true incipiency of a tuberculous lesion, especially if deeply located, physical examination of the chest is often negative or at best uncertain. History taking is very apt to become a perfunctory, and in so far valueless, inquiry into the first symptoms of the present illness, while a negative answer to the question: "Has any member of your family died of consumption?" is too often accepted as sufficient to cover the ground of family history.

To arrive at a correct diagnosis of an early pulmonary tuberculosis, before consolidation and bacilli are demonstrable, is by no means an easy matter, yet its importance every one may realize who will familiarize himself with the statistics of treatment. Any procedure, therefore, however tedious and time-consuming, which will aid in diagnosis at this stage of the disease cannot be considered gratuitous. In taking a history one should not be satisfied to begin with the present and trace back to the earliest manifestations of ill health which the patient presents, but should start with an inquiry whenever possible into the family conditions at the beginning of pregnancy and make a sequential investigation from that time to the present. It is surprising how frequently such an investigation will throw light upon a case and justify conclusions as to its tuberculous nature, when without such a history with its circumstantial evidence one would be unwilling to assume the responsibility of pronouncing a positive diagnosis with all that the latter involves to the patient and his family. I need only mention, to make evident their important significance, such points as the history of a persistent, however slight, afternoon elevation of temperature, of loss of weight, undue lassitude following slight exertion, of occasional night sweats, of great susceptibility to "colds," of attacks of supposed "grippe," etc., to say nothing of such almost pathognomonic phenomena as hemoptyses and pleurisies.

Again with regard to family history, while it may be found that no member has died of the disease, a careful inquiry may develop the fact that at some time during the previous life of the patient some one of the household was invalided for a greater or lesser period with symptoms which justify the assumption that tuberculosis was the cause, and while such an individual may have recovered, it may very well not have been until infection was propagated. I regard, therefore, a searching investigation into the personal and family history as of first importance in arriving at an early diagnosis and of value, compared to which the physical examination itself is secondary.

Physical Examination.—In the refinements of physical examination of the chest we have not to-day progressed much beyond the teachings of Laennec. Indeed, to read Laennec's marvelously accurate descriptions of the adventitious signs elicited by auscultation one can but regard him with wondering admiration and acknowledge that he left little to be developed by future generations along the lines of his peculiar researches. It is not, however, with classical signs of phthisis that he has to deal who would diagnosticate incipient tuberculosis—here the departures from normal in the sounds elicited are so slight as often to be confounded with perfectly physiological phenomena, and only repeated and most painstaking search under the best conditions will give definite results, while it must be remembered that absolutely negative results from a physical examination may not be incompatible with a tuberculous lesion which has advanced beyond a true incipient stage. Nevertheless, in the vast majority of cases a thorough examination of the whole surface of the chest under suitable conditions will reveal enough to justify a diagnosis especially when, as most frequently is the case, corroborative evidence from the history is at hand.

For accurate results the physical examination should be conducted in a well lighted apartment where quiet prevails—first, with the patient standing and afterwards, if necessary, reclining on a suitable table. It goes without saying that the patient should be stripped to the waist and that a proper stethoscope be used, for the finer signs of the earliest changes cannot be detected by the unaided ear nor with the intermediation of a handkerchief or towel, opinions to the contrary notwithstanding. Adventitious sounds produced by recent development of tubercle and during the stage of incipiency are necessarily confined to very limited areas, hence it follows that to detect them the stethoscope must be applied to every available part of the surface of the chest in order to locate the lesion and to eliminate multiple deposits. This certainly takes time and is tedious, but it is essential to early diagnosis.

Before beginning the examination a few minutes may profitably be spent in instructing a patient how to breathe and to cough, for much depends upon the intelligent cooperation of the patient in such an examination. The patient should be told to take full, rather deep, but not forced, respiration except when asked to do otherwise. If there is any nasal obstruction better results are obtained by mouth breathing. When asked to cough the patient should be instructed to do so without violence, and at the end of expiration a single easy cough to be followed immediately by a rather full inspiration.

Proceeding now with the examination and limiting the discussion to those signs which are associated with the earliest demonstrable changes in the lungs. Inspection may be of aid provided the lesion involves or is just under the pleura when a slightly delayed and possibly restricted mobility may be demonstrated upon the affected side. If this is marked, or if Litten's sign be present, the lesion is not incipient, but a slight difference in rhythm or extent of mobility between the two sides is often a very early sign.

Inspection should moreover be carried beyond the chest. For instance, a pupillary dilatation should be recorded if present. A pallor of the lips and mucous membrane, of the pharynx and larynx is very significant and often an early sign—always appearing at a later stage. Slight or even pronounced vasomotor disturbances, particularly a disproportionate emotional flushing of the face associated with dilatation of the pupils, are not infrequently observed in the earliest stages of the disease. Palpation and percussion phenomena may properly be left out of present consideration, as any lesion which is capable of producing a percussion dullness, however slight, or a perceptible increase in vocal fremitus can no longer be classed as early or incipient. The changes which we have to look for it must be remembered are yet interstitial and confined perhaps to a small field of peribronchial lymphatics; there is no consolidation or softening, and the infiltration is not sufficiently widespread or intense to cause change in percussion resonance.

Auscultation, however, if thoroughly practised with a good stethoscope will commonly reveal even the earliest changes in the lung, unless very deep seated. In practising auscultation one should have in mind the physiological differences in breath sounds and voice conduction between the two apices and the peculiar wavy harshness in an area near the lower angle of the left scapula which is also physio-

logical and probably produced by the cardiac relations in this region.

J. S. Billings, Jr., has shown that the normal relative intensity of the breath sounds between the apices and bases of the upper lobes may be expressed in the ratio of 4 to 3 or 5 to 3, respectively, and that any considerable departure from this ratio may be considered abnormal. To demonstrate this ratio Billings advocates the employment of the graduated tube of Oertel's stethoscope, but admits that it is applicable only in the hands of an expert. From my own experience I am inclined to believe that the method has merit, but is not practicable with instruments at present available. A small tuberculous mass entirely too minute to cause percussion dullness may, and usually does, cause changes in the character of the breath sounds, which careful auscultation will bring out. All are familiar with these signs—prolonged expiration, slightly raised in pitch and an occasional inspiration click especially after coughing. It is unnecessary to discuss them in detail at this time. What I desire to emphasize is the undeniable fact that when râles, percussion dullness, increased fremitus, increased vocal resonance, or even a marked intensification of the signs, which I have enumerated as being characteristic of a very early lesion, are any or all of them present the disease is no longer incipient, and therefore the diagnosis cannot be termed an early one. Moreover, sputum and x-ray diagnoses need not here be considered since neither are of benefit in discerning the early changes, which alone we have at present under discussion.

It is indeed a comparatively rare experience for a physician to have the opportunity of examining a really incipient case of pulmonary tuberculosis, notwithstanding the energetic propaganda of the last ten years or more. It is seldom that the physician is consulted at all before the disease has advanced to a stage where bacilli are easily demonstrable in the sputa and consequently where softening has occurred. This is evidenced by the difficulty which all sanatoria encounter in their efforts to secure early cases even for their charity divisions. Of the refinements in methods of diagnosis applicable to tuberculosis, refinements which have by their reliability won their way into a more or less general recognition and favor, the application hypodermatically of tuberculin is perhaps the oldest and most tried. In early, or for other reasons, obscure cases a positive reaction undoubtedly clears up the diagnosis. In the hands of experts the method is probably free from danger, but I confess I cannot overcome a prejudice against its general employment, and am convinced that in the hands of those who have not had a large experience in its use, it may not only fail to aid in diagnosis, but be fraught with no little danger to the patient.

The agglutination test, similar in theory to the Widal reaction in typhoid fever, has never become popular because of the necessary limitations in its field of application, the difficulty in commanding the necessary laboratory facilities, and still more because it has so often proved an unsatisfactory aid to diagnosis. Interest has more recently been aroused by the discovery by von Pirquet of Vienna, of a phenomenon which follows the application of a solution of tuberculin to a scarified area on the skin of a tuberculous individual. This has been called the "cuti-reaction" and consists in the formation of a small vesicle with a surrounding areola of hyperemia and mild induration disappearing after eight to fifteen days. The reaction when positive is very characteristic. Von Pirquet and his colleagues have employed it chiefly in children and have claimed remarkable accuracy of results. Others, however, have not found it so reliable, especially when applied to adults.

Von Pirquet's communication was made early in the present year and somewhat later Calmette suggested a modification of von. Pirquet's method, known as the "ophthalmo-reaction." This reaction depends upon the sensitization of the conjunctival mucosa by the presence and development of tubercle in the system just as the "cuti-reaction" depends upon the sensitization of the skin. It is, however, apparently a more delicate and consequently more sensitive test of the presence of tuberculosis in the system. It seems to correspond in point of accuracy with the subcutaneous method and it is difficult to imagine how it can be in any way harmful when ordinary aseptic precautions are taken. Dr. Baldwin and his colleagues in Saranac Lake, who have doubtless had the largest experience of any in this country in the application of this test, up to the early part of September had applied the "ophthalmo-reaction" to 136 persons. A summary of their results was presented by Dr. Baldwin at the First Annual Meeting of the Fourth District Branch of the Medical Society of the State of New York, September 18, and will doubtless be published presently. Briefly described, the technique of its application is as follows:

Koch's old tuberculin is precipitated by 95 per cent. alcohol, and a 1 per cent. solution in physiological salt solution is then made of the precipitate. About one drop of this solution is instilled into the conjunctival sac of one eye. (Baldwin advocates using ½ per cent. solution first to avoid severe reaction.) At the expiration of from three to forty-eight hours afterwards the reaction appears in the form of a well-marked congestion of the palpebral conjunctiva, while the lacrymal caruncle becomes swollen and red. In severe reactions the whole conjunctiva is congested and there may be a fibrinous secretion. There is no pain nor much discomfort, although a mild photophobia and burning sensation are experienced. The reaction has practically disappeared within twenty-four or sixty-six hours after its commencement. It is, of course, contraindicated when there exists disease of the eyes or lids.

Through the kindness of Dr. Baldwin I recently obtained some suitable solutions of tuberculin thus prepared and up to the present time have applied the test in twenty-three cases as follows:

The twenty-three cases were divided into four classes:

(*a*) Five normals. These were taken from apparently perfectly healthy nurses and members of my staff, giving no suggestion either past or present of ever having had a tuberculous infection.

(*b*) Ten doubtful cases in which their present condition or past history was suggestive of a latent or incipient tuberculosis.

(*c*) Five cases of unquestionable pulmonary tuberculosis, moderately advanced, and with one exception with positive sputum at the time of the test.

Finally, (*d*) Three cases of unquestionable tuberculosis with positive sputum, but who were under inoculation treatment with "bacillen-emulsion," having reached a dosage of two milligrams of the solid substance.

On October 15, .025 c.c. (about one drop) of a ½ per cent. solution was instilled into the conjunctival sac of the left eye of each individual. The normals, comprising Class (*a*) gave an unquestionably negative reaction. Of the ten doubtful cases in Class (*b*), only six were tested with the

½ per cent. solution, all responding negatively with one exception and that giving but a faintly positive reaction. Of the five undoubted cases of tuberculosis, comprising Class (*c*), three gave a positive reaction, one a questionable reaction, and one a negative reaction. Of the three cases under inoculation treatment, comprising Class (*d*), all were clearly negative.

Fifty-eight hours later, .025 c.c. of the 1 per cent. solution was instilled into the conjunctival sac of the right eye in all cases which had given a negative response to the first test. This test resulted as follows:

The five normals again gave a clearly negative reaction. Of the five cases in Class (*b*) giving a negative response to the first test, only one gave a positive reaction and this a rather questionable one. Of the remaining four cases in this class two were negative and two positive. Of the latter one was a young man giving a very suspicious history, but quite negative to physical examination of the chest. Of the two undoubtedly tuberculous cases in Class (*c*) giving a negative and doubtful reaction respectively to the first test, the first gave a faintly positive reaction and the second a negative reaction to the last test. Of the three patients under inoculation treatment responding negatively to the first test, two responded negatively to the second test and one gave a very slightly positive reaction.

These results, it seems to me, are extremely interesting, especially when considered with the results of the much larger number of individuals tested by Dr. Baldwin and his associates. Of course, it is too early to draw conclusions or very broad inferences, but it would seem as though we had in the ophthalmo-reaction an aid to early diagnosis every bit as reliable as the subcutaneous injection test, much easier of application since the presence or absence of elevated temperature is immaterial and a close observation of the temperature curve following the application of the test is unnecessary. Furthermore, there appears to be absolutely no constitutional reaction, and apparently no possible danger from the application of this test. For private or dispensary practice its advantages over the subcutaneous tests are obvious. Its most promising field of application seems to lie with just this class of individuals for whom a reliable test is most important, viz., the class of truly incipient tuberculous individuals in whom other methods of diagnosis are either doubtful or fail altogether. Experience up to the present time would indicate that the ophthalmo-reaction is likely to be negative in certain cases of long-standing tuberculosis where a long-continued autoinoculation has conferred a certain immunity, in acute general miliary tuberculosis, and among those individuals who have been immunized by inoculation treatment. It would further seem that the delicate sensitization of the tissues, which appears to obtain during the very earliest developmental period of tuberculosis favors the most characteristic reactions, and for this reason particularly the test is most promising.

In conclusion a word must be said regarding the value of the opsonic curve in relation to early diagnosis. I am aware that the opsonic index as applied for the purpose of diagnosis in pulmonary tuberculosis and its application to the treatment of the disease has of late been to a considerable extent discredited by many. I am not prepared at present nor am I allowed the necessary time to discuss this subject at any length. Nevertheless, from a study of considerable accumulated data in our laboratory, extending over a period of more than a year, there is much to lead me to believe that in early initial pulmonary tuberculosis, and during the period when the disease is, correctly speaking, localized and before constitutional symptoms are manifest, the opsonic index is universally low, sometimes so markedly depressed as to justify a diagnosis even in the absence of all other evidence of the disease; and even where such marked depressions are not present a continued though slight subnormal opsonic content, when taken in connection with a suspicious history, should, in my opinion, be sufficient to justify the assumption of the presence of incipient tuberculosis.

ON COMA AND THE VALUE OF THE OCULAR SIGNS OBSERVED THEREIN.*

By BURTON CHANCE, M.D.,

PHILADELPHIA.

THERE is, I suppose, no condition in the daily rounds of the busy physician requiring more clear-headed understanding, and more prompt and efficient handling, than that confronting him when called to attend a person who has suddenly become unconscious, or one who has lapsed into coma, without having displayed any premonitory signs.

When we speak of coma we mean the complete loss of consciousness. The individual appears to be in the profoundest sleep; his perceptions and the exercise of his will are suspended. The face wears a confused look; his mouth is open and the tongue is dry. All conscious and unconscious response to sensory irritation is lost. Shouting and shaking will not arouse him. The extremities are relaxed. The breathing may be rhythmic, but it is frequently irregular; at times it is retarded and full, at others it has the Cheyne-Stokes character; while towards the close it becomes stertorous and stridulous. The reflexes are abolished. Swallowing is impossible. The sphincters are no longer resistant, and incontinence of urine and feces develops. The eyes may deviate from their normal axes; the pupils are dilated, or unequal and sluggish, or sharply contracted and immobile.

Coma always betokens a serious disturbance of the functions of the brain presiding over the vital activities of the body. It is brought about either through a blotting out of the cerebral centers, as in edema, or when an effusion presses upon them, or when the centers have been inhibited through inanition which may have been caused by defective circulation in the brain, or by the effects of poisons circulating in the blood in the course of a general toxemia. The brain may suffer from a deficient supply of arterial blood, or from an excess of venous blood, or from both these conditions variously combined.

This state of unconsciousness may come on in the course of a great variety of diseases; it may be at the end of a prolonged illness of definite character and be marked by distinct preliminary manifestations; or it may seize a man suddenly while he is in the midst of his daily business. It may be recovered from and the individual may have repeated attacks, or it may shortly end in death without manifesting a single sign to give one a clew as to its cause. The question paramount is obviously an immediate and exact diagnosis, particularly if the person is in a deep coma when seen for the first time. The value of a leading sign which may be reasonably depended

*Read before the Germantown branch of the Philadelphia County Medical Society, Thursday, November 7, 1907.

upon is evident. Such a sign may be found, as I shall show in this paper, from the examination of the eyes. For, from the examinations of many cases, I am led to believe that coma arises from cardiovascular disturbances and that the characteristics elicited from the careful examination of the intraocular vessels are indicative of and entirely comparable to those found in the brain of such subjects. Let us consider then the conditions under which coma may arise.

The most complete coma is seen in gross disturbances of the cerebral circulation when it may come on quickly without premonitory signs. Embolism and thrombosis of the cerebral vessels will produce symptoms similar to those occasioned by their rupture. In a typical apoplectic stroke the patient falls into deep unconsciousness from which he cannot be aroused. The face is injected, sometimes cyanotic, or of an ashen hue. The respiration is noisy and the pulse is slow. We must therefore ask ourselves the question when called to a case of suspected apoplexy whether the coma has been caused by an obstruction of the vessels or by their rupture.

The age of the patient may guide us in determining the probable cause and help us in our hope for his recovery. We may suspect arterial obstruction if the patient is young or is in early middle life, if there is fibrosis of the arteries, or if within a brief period several incomplete attacks have occurred before the completely comatose condition has set in.

The diagnosis at times may be cleared by a study of the ocular symptoms. In a typical seizure ptosis of the upper eyelid is a not very uncommon symptom, and the eyes may be fixed in the position of "conjugate deviation" which has been brought about as the result of the suspension, for the time, of all the functions of the affected hemisphere, so that no stimuli can be transmitted to the visual center—which may be paralyzed itself also. The pupils vary; usually they are dilated, and sometimes unequal. In deep coma they are always inactive. If there be a loss of reflex on one side and the pupil is rigid, doubtless the coma is due to a hemiplegic lesion. When a hemorrhage has flooded the ventricles, or is in the pons, however, there may be marked contraction of the pupils from irritation of the oculomotor nerve nucleus. An opthalmoscopic examination will reveal in what an analogous condition the walls of the cerebral vessels must be. The retinal vessels are seen to be stiffened and more tortuous, and where they cross one another they show strangulations or constrictions with a diminution of their lumen. Above and below the points of constriction are found dense whitish streakings; and where the vessels cross, the blood columns are narrow and the vessel wall is either invisible or it presents a fusiform thickening. When a stiffened artery presses upon a softer vein, the vein is seen to curve under and around the artery. Here and there along the lines of the vessels and at the points of constriction, there may be small hemorrhages without apparent inflammatory changes. In extreme cases, the veins also may show analogous strangulations and sacciform dilatations. These symptoms should be studied together with the results of the examination of the patient's cardiovascular system. By this time it may have been learned from other sources that the individual is the subject of renal disease. A large proportion of the cases of apoplexy occur in those with affected kidneys, especially those with granular contracted kidneys. Hemorrhage therefore is likely, if the heart is found to be hypertrophied and if the disease of the kidneys co-exists.

Consciousness may be lost in an attack of angina pectoris, and syncope may follow the epileptiform convulsive seizures attending profound disturbance of the heart's action which have been seen notably in instances of heart-block. The unconsciousness is doubtless due to cerebral anemia. In the case of the Adams-Stokes syndrome, the abnormally slow and disordered pulse; the stiffened arteries or signs of cardiac disease; the age of the patient; the unwounded tongue; and the unrelaxed sphincters, are points to be regarded to confirm us in our hypothesis that it is not true epilepsy with which we have to deal.

Drink and narcotic poisons may produce coma which may be most difficult to distinguish from the coma of apoplexy, and, to make it still more difficult, sometimes a person who has been drinking may be stricken with apoplexy. In a simple drunken stupor there may be complete unconsciousness, yet the person may not be bereft of all power of motion; he certainly is not paralyzed. The pulse is not slow; it is usually frequent. The pupils are generally dilated. The eyes are injected and show no lateral deviation. When apoplexy comes on in a drunkard, the coma is deeper, stertor is present usually, and there may be evidences of hemiplegia in the greater flaccidity of the limbs on one side.

In narcotic poisoning, especially from opium, we are likely to encounter a gradual intensification of the coma. The coma is scarcely less complete, but as a rule it does not appear so suddenly as that of apoplexy. The pupils are much contracted; yet a hemorrhage into the pons may cause comatose symptoms with marked contraction of the pupils. In each of these conditions convulsive seizures may have preceded the coma; and because of the quiet respiration, and because paralytic symptoms may not be present early in apoplexy and pontine effusions, the diagnosis may be exceedingly difficult.

The coma attending uremia is as a rule less sudden in its onset than that of apoplexy, or that from narcotic poisoning, and it is only in the rarest instances that it has not been preceded by convulsions. The convulsions are always general and not localized as in cerebral apoplexy; and the coma is not always profound; it may come on and pass off suddenly. The stertor is peculiar. It appears to come from the mouth, the loud sound of the expirations is not like the low guttural tones of apoplexy, but is pitched in a much higher key. Cheyne-Stokes respirations may be present. The ankles are swollen and the eyelids are puffy.

The pupils are as a rule widely dilated, though they may be normal and the reactions to light preserved. The preservation of the light reflex proves that the blindness is not caused by disease of the eyes or of the optic nerves, but is due to the disturbance of the cerebral centers—excretory matters retained in the blood circulating about them have poisoned them. If the pupillary light-reflex is absent, the action of these poisons may be upon both the central and peripheral parts of the visual paths, or only on the peripheral parts, the optic tracts, and the nerves.

The ophthalmoscopic examination may be negative, that is to say, there may be none of the signs of that form of retinitis commonly seen accompanying disease of the kidneys. The association of nephritic retinitis and uremic amaurosis is not common. The retinal inflammation noticed in Bright's disease is generally persistent and the recovery of vision seldom takes place, whereas, the blindness in uremia has been caused by toxemia, and the sight is re-

stored rapidly and completely on the elimination of the poison.

In the coma of Bright's disease the cause is made manifest by the finding of albumin and casts in the urine and by there having been more or less definite attacks of uremia. Of course, the preceding history may aid us greatly and the examination of the urine may conduce to certainty in the diagnosis, yet for obvious reasons they cannot always do so at once. Albumin may be present after apoplectic strokes and after convulsions not associated with uremia, for a slight amount of albumin may be found following violent epileptic seizures.

It is well to remember, however, that coma may develop without convulsive seizures. Twitchings of the muscles of the face and hands may occur, yet there may be cases in which these muscles are not involved. In such cases there may be no indications of previous renal disease and their nature may be overlooked unless the urine has been examined. In this connection it must be remembered that the absence of albumin must not be taken as proof that no renal disease exists.

Are we not coming more and more to believe that the presence of albumin in the urine does not always specifically indicate the health of the kidneys? Albumin and other compounds may be absent in the urine in definite lesions of the kidneys and they may be found present in cases of apparently healthy kidneys which have been examined after death from other causes. So we may be confident that the presence of albumin is not a criterion of the localization in the kidneys of a process which of itself alone is sapping the vitality of the individual in whom it is present. On the other hand the urine may be taken as only one of the indexes of the state of the general bodily health and we may infer from it that the organs from which it has been received are diseased in company with many others in the branches of the vascular tree.

In all cases of albuminuria we must consider carefully the condition of the cardiovascular system. The heart must be examined for evidences of hypertrophy or dilatation; the arteries must be examined to ascertain whether their coats present evidences of thickening or other disease. The coexistence of such signs indicates a general arteriosclerosis while their absence renders it probable that the albumin is derived from the kidneys, or has been produced by some functional disturbance.

Except in the cases of coma following acute poisoning, in which those from alcohol and from opium are included, arterial degeneration is associated with all of them. Miliary aneurysms are often associated with sclerosis of the large arteries of the brain, though it was once difficult to explain the reason for such an association. From the study of the eyegrounds of a large number of arteriosclerotics, I have been led to believe the characteristics elicited from careful examination of the retinal vessels are indicative of, and entirely comparable to those found in the brain of such subjects; and the frequent association of these changes with manifest disease of the cerebral vessels only proves the contention. It must be remembered that in these examinations we have been dealing with visible pulsating blood-vessels and not with one only palpated with the fingers.

For years I have been skeptical of the accepted dictum that the causal relation is direct between visual disturbance and disease of the kidneys in the so-called "uremic amaurosis." As pointed out above, blindness in Bright's disease does not appear until late, and the visual disturbance is permanent, because portions of the retina and choroid have been blotted out by distinct hemorrhagic and inflammatory processes which we denominate "albuminuric retinitis."

On the other hand, the eye-grounds of the uremic present no such changes, as a rule. The authorities state that "the fundus is here negative." Alas! the conditions are *not* negative. I have noticed distinct alterations in the appearance of the retinal vessels, and the chief importance of these retinal changes lies in their association with disease of practically a similar nature in the kidneys and the brain, as well as in the liver, and accompanying a more or less general arterial sclerosis. Many cases of supposed uremia are not specifically renal in origin at all, although albumin has been found in the urine. Such cases, I believe, are dependent upon a form of toxemia brought about by the retention of compounds in the vascular currents which would have been eliminated had not the coats of the vessels become impervious; and, further, I believe that to treat such affections upon the supposition that they are based solely upon deficient renal activity is to jeopardize the life of the patient.

Coma occurs sometimes in connection with diabetes also, and when that disease ends suddenly it is likely to do so by the so-called "diabetic coma." The comatose condition is preceded by vomiting usually, and by abdominal pains. The respiration is labored and the breath has a sweetish chloroform odor.

Diabetes develops in neurotic individuals, particularly in those who have lived a sedentary life and are the subjects of mental emotion from worrying or from excessive devotion to business. It is therefore a disease chiefly of the upper classes of society. It appears to be caused by the presence of acetone in the blood. Acetone is derived from acetic acid or from beta butyric acid, and the coma is doubtless due to an excess of these compounds. Certain it is that the disease is due to some extremely acid toxic agent in the blood, for examination of the urine will reveal the presence of sugar, acetone, and perhaps diacetic acid also.

The difficulties attending the diagnosis of diabetic coma are not many. It rarely happens that an individual affected with diabetes becomes unconscious without some warning; or that we are called to minister to one about whom we are unable to obtain some knowledge of the previous conditions. The ocular features are not of especial concern. The state of the pupils varies, they may be dilated, or they may be unequal. The retina usually presents evidences of chronic alterations of structure; and for our purposes in this discussion, diabetes and Bright's disease may be considered together.

Akin to diabetes is that state of bodily ill health brought about by the disordering of the gastrointestinal digestion which we now call "intestinal autointoxication." Here, from defective chemistry, there has been developed a general toxemia, the elimination of organic compounds has become perverted in quality and quantity, and there have been thrown into the system elements which have proved noxious to it.

Persons thus afflicted often have periods of hebetude, lapses of memory, and in some instances complete loss of consciousness. The difficulty in the last case arises in deciding whether or not we have to deal with uremia; indeed, in considering these cases I have been led to place them in very close analogy with the sudden "uremic" ones.

In this group no systematic classification has been

made of the ocular symptoms present at the time of coma. They may be such as we find in simple "uremia," or there may be distinct evidences of congestion and stasis in the choroid with degeneration of the vitreous. I have noticed in chronic melancholics, who have become stuporous, unequal and irregular pupils, cloudiness of the aqueous and vitreous, and congestion of the internal tunics. I would expect to find similar conditions in the autotoxic cases, for melancholics are invariably the victims of a depraved metabolism dependent upon gastrointestinal derangement.

Occasionally we are called to attend a person of advancing years, of sedentary habits, who has suddenly lost consciousness while at table after a hearty meal. This, too, is from a form of intestinal autointoxication, though it has been a common inference that uremia of renal origin is at the bottom of these attacks. A careful examination of such individuals will disclose signs of arteriosclerotic changes in the retinal vessels as well as disturbances in the vitreous and choroid, as outlined above. The urinous odor emanating from these prostrate persons is not due to uremic exhalations, but rather to vesical incontinence.

Ptomain poisoning belongs here, as it, too, may give rise to profound unconsciousness. Sometimes cerebral symptoms may be present in hepatic cirrhosis, when they manifest themselves in convulsive seizures, and a delirium which ends in coma. They, too, resemble similar attacks in uremia; yet a careful study will show that they have been caused by a toxemia comparable to that observed in the common form of intestinal intoxication.

A subject in the secondary stage of the general paralysis of the insane may sometimes be seized with syncopal attacks in which he falls, and, for a variable period, may lie unconscious. And such attacks with vertigo have been noticed in multiple sclerosis. In the early periods of these diseases, these lapses of consciousness may be mistaken for hysterical fits. The eyes of the hysteric are healthy, however, and the visual paths to the brain are open, though luminous impressions are not perceived; the pupils, therefore, react to light. The paretic, on the other hand, commonly presents manifest pupillary changes, and during the syncopal attacks the optic nerves and retinas remain pallid; while in the case of the multiple sclerotic there may be distinct nystagmus and the nerve heads atrophic.

The coma following convulsive seizures in epilepsy may be due to a general toxemia, perhaps, as well as from the exhaustion of cerebral centers. The generation of muscle acids may be so excessive and enter the circulation in such quantities as to be profoundly poisonous. There may be no ocular changes whatever, but, occasionally, hemorrhages from the conjunctival vessels have been noticed, with congestion, as well as hemorrhages, in the choroids and retinas.

Only two more conditions remain to be touched upon: the coma following the convulsions of pregnancy, and the coma induced by inhalation of poisonous gases. Except in the case of an epileptic who has become pregnant, the convulsions and coma are without doubt due to a general toxic state dependent upon profound disturbance in the fluids of the abdominal circulation. I am excluding cases in which the women are the subjects of distinct Bright's disease.

In the matter of diagnosis we are inclined to place more dependence in the circumstantial evidence attending a case of gas poisoning than in the actual physical conditions present. There may be profound coma with deep, loud, snoring respirations, free from the odor of alcohol. The face is bright red and there may be deeper colored patches in the skin. The mucous membranes are dark purplish and the scleral vessels are injected. I have examined the eyes of only one patient suffering from gas poisoning. The fundus in each eye of this patient was of an intense lake color. The pupils were widely dilated.

In studying this group of nervous phenomena, attention has been given to the prominence of the ocular symptoms in certain of the diseases marked by coma; and, as these symptoms are easily observable, their importance in diagnosticating the probable causative factors becomes manifest. As we view the suddenly prostrated individual who lies apparently lifeless before us, the necessity for a distinct and signal symptom becomes urgent, in order that we may be led out of the confusion, as well as to provide for the patient's recovery without entailing further damage to his already embarrassed vitality. For, assuredly, the management of an apoplectic seizure must not be the same as that for the coma attending opium or other narcoses. Thus, the deviation of the axis of the eyes, or the condition of the pupils, may designate whether there is a suppression of the cerebral centers or only their irritation from disturbed nutrition.

The finding of albumin in the urine of an unconscious person, or the detection of an urinous odor emanating from his body, is not sufficient proof to guarantee the presumption that we have before us a case of uremia of distinctly renal origin. We have seen how albumin can occur in cases without renal insufficiency, that it may be present in obstruction of the cerebral vessels, and we know that it is frequently found in the comatose condition following epileptic convulsions.

Uremic amaurosis is still an obscure subject, but I have no hesitation in saying that, when all the cases are analyzed, we shall find the large number of them dependent upon a general toxemia generated by a disturbance in the chemic and metabolic processes in the gastrointestinal tract. Remedies and other measures designed to eliminate the festering products in the intestinal tube, very commonly are effectual in relieving the blindness too; and, except in the case of late Bright's disease, in which ocular disturbances have existed long before coma has set in, there are no markedly visible changes in the intraocular tunics. It is my belief, however, that careful examination of the retinal blood-vessels, from the disks out to their finest extremities, will disclose periarterial and endoarterial changes. These vascular changes are comparative indexes of the state of the cerebral circulation.

In studying cases of coma it is our duty to attend to the careful examination of the ocular fundus. Except in the case of acute narcosis following the ingestion of well-known poisons, there are distinct arterial changes to be seen; and as transient visual disturbances may arise from an interference in the nutrition of the cells of the retina, so in like manner, cerebration, psychic and physical, may be interrupted through nutritional changes. Again, as the extremity of arterial changes in the eye may culminate in the rupture of the vessels, whereby areas of the retina are blotted out, so may there be rupture of the cerebral vessels whereby not only may regions of the brain be affected but life itself may be blotted out.

EXPERIMENTAL ARTERIAL DEGENERATION.*

By PHILIP FRANK, M.D.,
NEW YORK.

When Josué[1] in 1903 announced the production of arteriosclerotic lesions in rabbits by the intravenous injections of adrenalin, the subject was taken up zealously throughout the world, and a host of experimenters proceeded to repeat his experiments, to refute or to corroborate his work. Very soon reports were published from v. Rzentkowski,[2] Erb,[3] Fischer,[4] Lissauer,[5] Pearce and Stanton,[6] and others. Most met with success, and in general the results were identical with those obtained by Josué. Explanations as to the modus operandi of adrenalin were next sought, and several theories were propounded. Whether the lesions produced were due to a cachexia resulting from the frequent injections continued over long periods, or to an interference with the nutrition of the vascular wall through a constriction of the vasa vasorum, or to the direct toxic action of the drug itself, or to an increase in blood pressure resulting from it, has been answered differently. Each theory has its advocates and its objections, and all of them are still in dispute.

Not only was this research undertaken with adrenalin, but the field was extended to experiments with barium chloride and with nicotine. Regarding the former, Dr. L. J. Miller[7] reported that by intravenous injections of the drug he succeeded in causing swelling of the elastic fibers. S. Orgielbrand[8] stated that he produced atheroma of the aorta by means of injections of this drug intravenously. As to the work with nicotine, Adler and Hensel[9] produced arterial changes by intravenous injections of pure nicotine, almost identical with those caused by adrenalin.

In line with this work, I myself experimented with ergot. Five rabbits, weighing respectively 1,470, 1,600, 1,430, 1,575, and 1,530 grams, were injected daily with a solution made by dissolving one gram of ergotin in 100 c.c. of a physiological salt solution. The purpose of selecting ergotin was to avoid the impurities contained in ergot itself. The dosage, by intravenous injections, at first was three drops, which I gradually increased to ten drops. After eleven injections one rabbit was killed. The remaining four rabbits received eight more injections each, after which I ceased the injections. It was noticeable very shortly that the rabbits were failing in health. They refused to eat, became emaciated, and appeared to be decidedly sick. Of these four rabbits, one died two days after I stopped the injections, a second three days later, a third six days later, and the fourth fully three weeks later. This last one seemed to be the most sickly. On autopsy, none of the rabbits showed any gross lesions, except the one which died two days after the cessation of the injections. The liver and the gall-bladder were studded with hard, white, little nodules. On crushing some of them between two glass slides, they proved to be very gritty, and, as gas was evolved on the addition of nitric acid, calcium carbonate was evidently present. Microscopical examination revealed no coccidia. But after decalcification of the liver and staining of the section with hematoxylin and eosin, these nodules were found to be calcified coccidial cysts. The organs of the rabbits were fixed in Zenker's fluid and in alcohol, and pieces were also preserved in formalin. The sections were stained with hematoxylin and eosin.

Two of the five rabbits, on microscopical examination of the stained sections, showed areas of necrosis in the liver, with proliferation of connective tissue cells, not only in the portal spaces but also in the liver lobules. The rest merely showed evidences of congestion.

Four out of the five showed a hyperplasia of the lymphatic elements of the spleen, and the malpighian corpuscles were three or four times the normal size. Three out of the five showed organizing thrombi in the arteries of the lungs with a proliferation of the lining endothelial cells and thickening of the arterial wall.

One (killed after eleven injections) showed an eosinophilia (due to ergot?), and one (the first to succumb after cessation of injections) showed a nodule projecting into the lumen of the aorta about half an inch from the aortic valves. It was not an artefact, and I am just as positive that it was not due to oblique cutting with the microtome. It was a decided thickening of the media in which the elastic fibers were somewhat broken and the nuclei of the muscle fibers ran longitudinally instead of transversely. The thickening was not general throughout the media, but was localized to the site where this nodule projected into the lumen of the aorta. Since this occurred in this rabbit only, I cannot justly ascribe it as due to the ergot. I consider the results so far as concerns arteriosclerosis negative. Controls were employed, and these did not show any of the changes mentioned.

My thanks are due to Prof. C. J. Bartlett for the use of his laboratory and for his valuable aid in studying the various sections. Also to Prof. O. T. Osborne for many suggestions.

I believe that formerly many slight arterial changes were reported as arteriosclerotic lesions with too much certainty. Recently the pendulum has begun to swing in an opposite direction. A reactionary skepticism as to the significance of the results obtained from the experiments on rabbits with adrenalin is taking place. And justly so. In the first place it is very peculiar that it is only in rabbits that adrenalin produces arterial changes to any great extent, which conveys the idea of a special susceptibility; and, moreover, right here there is so considerable a variation in the dosage required and the difference in degree of the lesions produced. Large doses frequently repeated may in one case give no results, while in another a single injection may show decided lesions. Cases of spontaneous arteriosclerosis are being discovered and reported. And again, the controversy as to the important factor in the causation of arteriosclerosis is adding its quota of doubt. No one can deny that any substance, no matter how innocuous, when introduced directly into the circulation, is bound to exert a direct toxic influence, and it is easy to see how such toxicity may cause a degeneration of the arteries. The theory of high blood pressure, accepted by the majority of authorities, finds this element of toxicity its chief stumbling block. If high blood pressure is the fundamental important factor, then why the disagreement in the results obtained by injecting potassium iodide simultaneously with adrenalin? Potassium iodide is of benefit in arteriosclerosis in man; then, why not of equal benefit experimentally? Cummins and Stout[10] go so far as to report that potassium iodide will counteract the action of adrenalin, whereas it is asserted by Loeb and Fleischner[11] that the iodide of potassium is of no benefit, and in large amounts will prove distinctly injurious. Even in human arteriosclerosis resulting from high blood pressure due to renal disease, alcohol, hepatic, pancreatic, or gastrointestinal insufficiency, metallic poi-

*From the pathological laboratory of Yale University.

sons, bacterial toxins, syphilis, etc., it may be conceived, which is a reality, that there are present in the circulation toxins exerting a direct toxic influence; so that the question of the element of toxicity again comes up as an almost insurmountable objection. Consequently, for this question to be settled, the subject must be studied by a different method than by intravenous injection of drugs.

While Josué was the first one to work with adrenalin, he was not the first to work on the subject of experimental arteriosclerosis. The work of Gilbert and Lion[12] and of Boinet and Romary,[13] with bacteria and their toxins, and of Croftan,[14] with xanthin and hypoxanthin, antedate Josué's work, and have been referred to in many papers by many writers.

In a search of the literature I have come across certain work which is overlooked by almost every writer on this subject—work that avoids the chief objection to the intravenous method of experimentation and to the question of high blood pressure, *i.e.* it avoids the element of toxicity. As far back as 1877, Di Giovanni,[15] by cutting the cervical sympathetic nerve of dogs, first on one side and a few days later on the other, produced atheromatous incrustations on the aortic valves and in the descending aorta. In 1886 Schnell[16] repeated the experiments of Di Giovanni, with some but not equal success, and recently Pic and Bonnamour[17] have still further repeated these experiments, reporting good results. Their work was done on rabbits. Manometers inserted into the carotids of the rabbits to test the blood pressure indicated a rise on section of the sympathetic nerve.

Still another method has been evolved recently. Carrel and Guthrie[18] have produced arteriosclerosis in the dog by causing a hypertension in an artery (renal) by transplanting it and directing its blood into a venous plexus of a smaller total capacity than the artery itself. It is the maintenance of the resulting hypertension which is responsible for the resulting arterial changes.

These two sets of experiments, after they have been repeated and corroborated and extended more fully, in eliminating the main objection to the inoculation experiments—the toxicity of the substances injected—incline further than any other towards high blood pressure as being the fundamental causative factor in arteriosclerosis. It is along such lines that the obscurities of the problems of arteriosclerosis will ultimately find their solution.

THE ART OF GARGLING.

By GEORGE RICHTER, M.D.,

ST. LOUIS, MO.

FORMERLY PROFESSOR OF PHYSIOLOGY, BEAUMONT HOSPITAL MEDICAL COLLEGE.

THAT the mouth and nose, as principal inlets for everything which serves to build up and sustain our organism, must also be the gates through which most of the harmful substances enter, is quite evident. The mouth is very often, the nose always, an open door.

As a guard against threatening dangers the nose serves with a surface much increased by a large system of folds of mucous membrane and normally coated with a tenacious mucus while the surface of the mouth with its complicated arrangement of teeth, tongue, palate, arch, and tonsils is somewhat less protected by its thinner mucous secretion, which in both cases attacks the microbes, envelops and destroys them either by digestion (saliva) or by disinfection (potassium rhodanate) or by entangling them, as with a liquid glue, in an indigestible slime which carries microbes and pigments through the entire intestinal canal until they are evacuated.

The harmful substances inhaled through the nostrils or introduced into the mouth are apt to appear in such masses or so frequently that the natural guards become overworked and finally fail to do their duty; this is especially the case when the atmosphere is laden with dust and soot, as in the larger cities.

In breathing, the air-current strikes the rear pharyngeal wall and is there deflected toward the larynx at a right angle. Particles which had not been caught in the folds of the nose will be arrested by the inner guard, the slime covering the pharyngeal surface. Just so in mouth breathing the soft palate, the uvula, the arch, and the tonsils stand guard to defend the system from intrusion of harmful material, the secretion from the tonsils apparently exercising a most important function. Incessantly repeated attacks upon this inner gate overtire the watch, the tonsils become inflamed and are themselves converted into foci of infection, harboring germs which they cannot destroy any more, but retain up to a time when the prisoners may overpower the guard.

Again the coating of the pharynx acts as a last resource of the organism to render intruders harmless. But finally the pharynx will also be overpowered; it becomes congested, atrophies, and fails in its functions. At such a stage we will discover a chronic inflammatory condition of the inner nasal surface, the palate, the tonsils, and the pharynx.

The territory being freely accessible, local treatment is indicated. The method employed most frequently is the gargling, by taking a swallow of pure water or of a mixture, allowing it to run into the posterior part of the mouth, and then, with a slow expiration through the mouth while the soft palate occludes the pharynx, to agitate it so that the bubbling fluid washes the surface.

In gargling after this manner the arches of the palate together with the uvula close so far that only the expired air passes through a small opening of the fauces, but none of the gargle itself can flow back into the pharynx. Only the oral cavity is washed.

To reach the pharynx proper and the nose a favorite method with many is the use of the nasal douche. With this, however, usually only the floor of the nose and the median region of the pharynx are rinsed. The laws of hydrostatics will prevent a more extended action of the fluids employed, excepting where the nose is being flushed with the head hanging down backwards until the roof of the mouth is parallel to the floor. That is a difficult and disagreeable procedure. Some of the fluid loaded with poisonous secretion may also penetrate the Eustachian tube and infect the internal ear. Besides, the space between epiglottis, root of tongue, and soft palate remains untouched.

The universally used spray exhibits the following drawbacks: Only very mild substances must be used in order to spare the extremely sensitive larynx; there is a danger that toxic substances may be forced from the nose and pharynx into the lungs; the spray will necessarily travel in a straight line following the air current, and only traces of the spray will reach the recesses situated around the shortest route.

The comparative failure of the three methods finally calls for surgical methods which require much practice and skill and have created a specialty for the treatment of diseases of the nose and throat.

But not every patient can consult a specialist. The "general practitioner" should be in a position to treat the cases in question before they require special methods, before they become too severe for his resources. Undoubtedly proper care in time would prevent the majority of the cases from reaching a stage where he cannot control them. This he can do by teaching the patient to gargle properly. It is done in the following manner:

The patient (at first under the guidance of the physician) should sit well back in a chair, take a swallow of water in the mouth, and bend the head as far back as possible. In this posture the larynx presses upon the vertebræ and occludes the esophagus. Now he must protrude the tongue from the mouth (the tip of the tongue may be grasped with a handkerchief) and in this posture with protruding tongue he must try to swallow the water. The physician should control the patient's vain efforts—for it is impossible to swallow under such circumstances. He will observe how the water flows back into the pharyngeal space, apparently disappearing entirely. The patient has the sensation as if he actually had swallowed the water. Now he must start to gargle, to exhale air slowly. One can see plainly the bubbling of the fluid in the wide-open pharynx. After gargling thus for a while, the patient is ordered to close the mouth and quickly throw head and body forward. Thereby all the fluid is forced through the choanæ and nostrils, washing the throat and nose from behind and expelling all the accumulations, that had been present, with great force.

This should be repeated several times, as the first trial is not always successful and satisfactory. It is an art that must be learned. When properly executed the sensation, as the patient will assure you is that of great relief, not had by any other method. It will be wise for the practitioner to try the method first on himself. Even small children who are at all clever learn the method readily and rather enjoy it.

Medicated gargles used with this method should be of a tepid temperature, but not exactly isotonic with the moisture of the surfaces. The specific gravity of the gargle is entirely irrelevant; with the same specific gravity a gargle may be highly irritating, while a great difference in specific gravity may cause no symptoms whatsoever. Part of the gargle must be expected to remain on the surfaces and exert a more lasting effect. An anisotonic solution will assist greatly towards this end by causing an exchange of substances.

As a rule the aperture of the nostrils is smaller than that of the choanæ, so that the nasal cavity may be compared to a cone the basis of which is formed by the choanæ. This accounts for the welcome force with which gargling after this method is effected.

The method is not by any means a new one, but, as it seems, quite forgotten. Some thirty years ago Prof. Hagen of Leipsic taught it his students. It is well worth reviving.

407 North Broadway.

GRADUAL ANAL DILATATION BY A NEW METHOD.

By DUDLEY ROBERTS, M.D.,

BROOKLYN, N. Y.

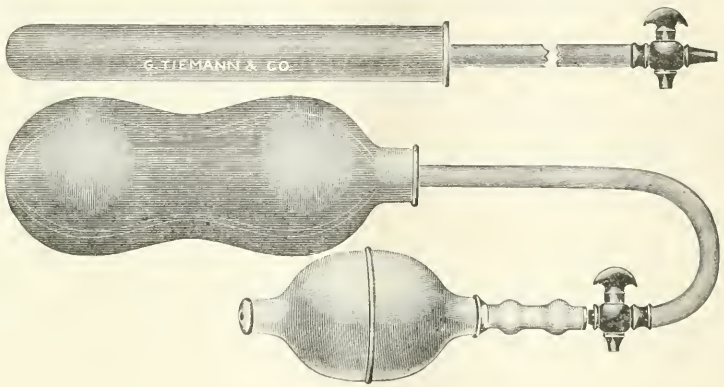
Rapid digital divulsion of the anal sphincter is now recognized as a valuable procedure in the treatment of certain cases of chronic constipation, hemorrhoidal conditions, and fissure of the anus. The objections to this plan of treatment are the necessity for a general anesthetic, the pain of some degree following the operation, the enforced retirement of the patient for one or more days following the treatment, and the tendency of the spasm to recur after a single although complete divulsion.

The slow painless dilatation of the anus recommends itself as the ideal plan when other procedures of an operative sort are not immediately contemplated and a speedy result is not demanded. To be effective, however, such dilatation must actually relax the muscle, and such relaxation must be repeated at frequent intervals over a time sufficiently long to establish a permanent dilatation of the necessary degree.

Gradual dilatation has found only a limited degree of popularity up to the present time, very possibly owing to the large proportion of failures with the instruments designed for the purpose. The expanding metal dilators cause entirely too much pain to allow of their being used in the majority of cases needing the treatment. The different forms of conical metal, hard and soft rubber dilating bougies or sounds, all acting on the wedge principle, cause severe pain even when the size is actually insufficient to accomplish the necessary amount of stretching. On introduction, the pressure of all of these is too much upward against the internal sphincter and levator ani. Their shape is such that dilatation is necessarily sudden, never painlessly gradual. Only a limited length can be allowed from the tip to the greatest diameter, for the long rubber bougies very frequently come into painful contact with sensitive parts in and about the rectum in spite of the greatest skill and care. In my opinion the largest sizes of these instruments are entirely too small to cause sufficient dilatation in the majority of cases. The work of one day must be repeated on the next, as spasm is not actually overcome and stretching is not accomplished.

The advantages of a dilatable bag for overcoming the contraction of the uterine cervix are well known. Such dilatation is under the entire control of the operator; it may be as gradual as demanded and to the necessary degree. The force is exerted in the proper direction, not pushing the tissues ahead of a dilating instrument.

The instrument shown in the accompanying illustration, one-half actual size, has been under trial for many months and in this time has proven to me that failures of gradual dilatation have been due to intrinsic faults of former instrumental methods. Patients whom I had formerly subjected to treatment with the largest sizes of rubber bougies having a circumference of nine centimeters have been better able to stand dilatation with this expanding bag to the full size, a circumference of fourteen centimeters at the constricted portion. It seems to be perfectly feasible to accomplish gradual dilatation of the anus to the necessary degree with comparatively little discomfort. The induced anemia of the tissues pressed upon must contribute to this analgesia. The muscle is gradually tired out and relaxes just as must the fingers if an effort is made to hold the bag against expansion. The smoothness of the instrument obviates any tendency to spasm during introduction. Withdrawal causes no dragging on the mucous membrane.



The apparatus consists of an inner bag of rubberized cloth, the ends made bulbous to prevent slipping inward or outward when distended. To this bag is attached a tube of like material on the end of which is fastened a small stopcock; a hand bulb, valved to prevent the backward passage of air, is attached to the stopcock. Within the bag and extending through a portion of the tube is a slender metal rod with bulbous ends; this is a simple means of giving the collapsed bag sufficient rigidity during introduction. Outside the strong dilating bag is a thin elastic cover free from seams, which gives a perfect smoothness to the bag at all stages of dilatation. The seams and wrinkles of the inner bag are not perceptible through this cover.

The method of use is exceedingly simple and few directions are necessary. The condition of the valves in the hand bulb must be determined, as back leaks make dilatation impossible. The number of slight "squeezings" necessary to fill the bag is a matter of individual experimentation. The "feel" when the bag is full and further distention impossible, is likewise to be determined. The bag is well dusted with talcum powder or covered with an emollient, the elastic cover is then slipped on and turned around to completely lubricate apposed surfaces. Two-thirds of the length of the bag is introduced, the bulbous portion protruding from the anus, and slow dilatation is started. As soon as discomfort is felt the stopcock is turned and a few minutes allowed to elapse in order that voluntary and involuntary spasm may be relaxed. Gradually the dilatation is continued and when as much as possible has been done the bag is left in place for ten to fifteen minutes. The patient is instructed to lie flat on the back and relax completely. Successive treatments follow and each time dilatation is found to be easier, until a normal condition is established.

The advantage of this form of instrument in the treatment of the stricutres of the rectum above the anus is well seen. Through a speculum the bag is introduced and placed in the desired position, when stretching to the necessary degree is readily accomplished.

A larger size than that shown in the cut is necessary in some instances and to meet this demand I have had one constructed without the central constriction; this bag has a circumference of 18 centimeters throughout, the smaller one measuring 14 cm. in the central portion and 16 cm. at the bulbous ends. The same sized cover answers for both bags.

84 Remsen Street.

The De Novo Origin of Bacteria, Torulæ, and Moulds.—H. Charlton Bastian gives the results of a recent series of experiments before the Royal Medical and Chirurgical Society. He began his experiments with various saline solutions containing ammoniacal salts, but after a time had found the best results were to be obtained with one or other of two solutions, one of which contained small quantities of sodium silicate, ammonium phosphate, and dilute phosphoric acid in distilled water, and the other a simple solution of sodium silicate with liquor ferri pernitratis in distilled water. The solutions were placed in previously superheated tubes, which, after being hermetically sealed, were heated again in a calcium chloride bath to 230° F. (115° C.), 248°, 257°, or 266° F. (130° C.), for ten to twenty minutes. The tubes were subsequently exposed, either to diffuse daylight or else in the incubator, and mostly for periods varying from five weeks to four months. No carbon was ostensibly contained in the solutions. On examination of the contents of the tubes organisms were found always on or within the substance of the flakes of silica, while the fluid above remained perfectly clear. The fluid would remain in this condition, and quite free from microorganisms, even for months after organisms were known to be swarming in the silica itself. It was contended that there was good *prima facie* evidence tending to show that silicon was capable of entering into the composition of protoplasm itself—that was, wholly or in part taking the place of carbon. It was concluded that the bacteria, bacilli, vibriones, micrococci, torulæ, and moulds which had been taken from hermetically sealed tubes previously heated to 115°, 120°, 125°, and 130° C. for ten to twenty minutes must have been engendered *de novo* within these vessels.—*British Medical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 14, 1907.

WILLIAM H. S. WOOD, senior member of the firm of William Wood and Company, died on Thursday of this week. The story of his active and useful life will be told later. Here there is opportunity only for faint expression of the deep sorrow which the writer shares with all who have had the privilege of a personal acquaintance with Mr. Wood or who have enjoyed his friendship. A man of strong character has died, one who played valiantly his part in the battle of life, but who was in times of others' grief as tender of heart as a woman; an entertaining companion, a firm and loyal friend, a liberal but unostentatious dispenser of charity, a man of lovable character and full of warm human sympathy.

OPSONIC TREATMENT OF TUBERCULOUS JOINT DISEASE.

HOLLISTER has said that if a patient's tuberculo-opsonic index is considerably below that of a normal individual, he has tuberculosis; if much higher, or very variable, he also probably has tuberculosis. He furthermore claims that a patient's tuberculo-opsonic index can be raised and maintained, if he is infected, by the proper dose of the proper vaccine, and when it is raised and maintained his tendency is toward recovery. These claims and the results reported by Hollister led Ridlon of Chicago to study the effects of Koch's new tuberculin injected in chronic joint diseases after Wright's opsonic method. He selected ten patients, all of whom had been under his observation for a sufficiently long time for him to have a very positive opinion as to how they would be likely to go on under routine treatment. Two were patients who he expected would die within a year; five had sinuses which had been discharging from six months to several years, and he wished to see if the new treatment might be expected to hasten their healing; three had unopened abscesses of moderate size, and he wished to determine if the treatment would cause their disappearance. In two cases the diagnosis was doubtful; in one of these the tuberculo-opsonic index was from normal to 0.7 below normal. After the injection of one-thousandth of a milligram of Koch's new tuberculin the index ran from 0.8 to 1.3, and on the strength of this Hollister made the diagnosis of tuberculosis, and the findings at operation confirmed the diagnosis.

Ridlon reports the results of three months' treatment in the November number of the Chicago *Medical Recorder*. All of the patients were feeling better, eating better, of better color, and had fuller cheeks; all but one had gained in weight and the sinuses had healed more rapidly. On the other hand the abscesses developed more rapidly than he would have expected under routine treatment. He concludes from his observations that a low tuberculo-opsonic index with local joint symptoms may be accepted as evidence of joint tuberculosis, but believes that it is still a matter of opinion how much below normal a patient's index must be, to warrant the positive diagnosis of tuberculosis. A practically normal tuberculo-opsonic index, together with local joint symptoms, neither proves nor disproves joint tuberculosis, in his opinion. He furthermore holds that when the diagnosis of joint tuberculosis has been made, a high index should be maintained, as an operation may be undertaken with a high index, but not with a low one. If use of the diseased joint causes a lowering of the opsonic index, the joint must be immobilized and protected; if the use of the joint does not lower the index it may be permitted; if it raises the index it should be insisted upon.

The time has been too short and the patients too few to furnish any satisfactory basis for the prediction of ultimate results, but the tuberculin injection treatment, guided by determinations of the tuberculo-opsonic index, seems to be a most promising step forward in the treatment of tuberculous joint disease.

FOOTBALL IN ENGLAND.

THE players of football in Great Britain and their very numerous followers have always congratulated themselves that the game in force in their country differed from American football, in that it was really a game, and not especially dangerous. However, this optimistic view has been considerably shaken during the past few years. Accidents have been extremely plentiful; there has been a fair crop of serious ones, and fatal results have occurred with unpleasant frequency. In the course of the present season, according to an article which appeared in the *Lancet* of November 16, football has been responsible for six deaths and for the disablement of sixty persons at Association football alone. This list did not include those injured at Rugby football. When it is considered that at the time of writing the *Lancet* article the season had begun only a few weeks previously, and that it does not end until the end of March, the outlook is decidedly gloomy.

It would appear, then, that the game of football as now played in Great Britain is almost as dangerous as that in America. The writer in the *Lancet* attempts to gloss over the matter somewhat, probably not wishing to offend the susceptibilities of British footballers and their innumerable and influential entourage. Some of the British lay journals, however, are far more outspoken, and state emphatically that steps should be taken at least to regulate the game. The Association game in Great Britain is, according to these papers, entirely in the hands of professional players, who, like our own

baseball players, are "all the time out for the money. If a club cannot uphold its reputation, it loses its grip upon the public and ceases to be a money-making concern. Thus the premium placed upon winning is very great and the temptation becomes proportionately urgent among the players to resort to measures which do not come within the range of legitimate sport."

Thus the *Lancet*. Other papers, especially the lay journals, unhesitatingly state that British football is now too frequently brutal. These dangers have not been adverted to in an effort to condone the asperities of the American game, but rather as an object lesson. There is no reason why an originally healthy game should be brought within the category of dangerous pursuits. "Moderation in all things" is a motto that will apply to foothall in America and in Great Britain as appositely as to all other games and pursuits.

PERMANENT RECTAL INFUSION IN DIFFUSE PERITONITIS.

Diffuse peritonitis is a disease whose outcome cannot be prognosticated with certainty. As regards its treatment, all are agreed as to how to relieve some symptoms and maintain the strength of the patient, but treatment on these lines is of no value in overcoming the inflammation of the peritoneum. The progress of abdominal surgery and the results obtained by the operative treatment of circumscribed peritonitis, have led surgeons to hope that diffuse peritonitis might also be treated surgically. The surgical treatment removes purulent exudate, affords easy escape for future secretion, the patient thus being spared the resorption of much infectious material, and permits suturing or removal of the affected organ from which the peritonitis spread, but it does not affect any general infection which has already taken place at the time of operation. With the idea of influencing the latter, Murphy, Michaux, Lenhartz, and others have advised rectal infusions of physiological salt solution. These have the further advantage of allaying thirst, increasing the blood pressure, stimulating the heart, causing diuresis, and permitting the ingestion of nourishment. The infusions are easily given. An ordinary irrigator is suspended about one half a yard above the level of the patient, and the flow from the irrigator is so regulated by an artery clamp attached to the tube that only two drams per second flow from the irrigator through an ordinary rectal tube inserted into the anus. The patient thus absorbs two quarts in several hours, when the infusion is stopped, but it is repeated after ten hours. In order to keep the fluid warm, hot water bags are hung on either side of the irrigator. After several such infusions have been given, the feces become softened and peristalsis is brought about; a colon irrigation will then usually clean out the bowels, after which a dose of opium may be given to quiet the intestine.

These infusions have been used at Mt. Sinai Hospital in this city for the past year with good result and also in Germany. In the October number of *Die Therapie der Gegenwart*, R. Kothe reports the results obtained in Sonnenberg's clinic in Berlin. Grape sugar and albuminous preparations are frequently added to the salt solution as used in Berlin. Out of twelve patients, eight recovered, some of the latter having been considered hopeless. At Sonnenberg's clinic the infusions are now given in all cases of diffuse peritonitis, whether a laparotomy was performed or not, and as a prophylactic measure in cases of extensive intestinal resections and pyosalpinx operations in which a strict asepsis cannot always be maintained.

Lumbar Puncture in Cerebrospinal Meningitis.

Although the status of lumbar puncture as a curative measure in cerebrospinal meningitis is not yet altogether decided a considerable number of observers express themselves most emphatically in speaking of its virtues. For example, Baginsky has recently termed it the most effective remedial measure, and advises that it should be repeated as often as the recurrence of symptoms of severe cerebral pressure demands. Bokay, in the *Deutsche medizinische Wochenschrift*, November 21, 1907, is equally positive of the effectiveness of the procedure, and describes seventeen cases with ten recoveries. Eight of these patients are stated to have recovered completely, in one the hearing is somewhat impaired, and the other is a deaf mute. Bokey believes that lumbar puncture has a definitely curative effect in cerebrospinal meningitis, and that this is due not only to the mechanical relief of intracranial pressure, but also to the removal of large numbers of pathogenic bacteria and their products. In severe cases it is necessary to repeat the puncture at intervals of from one to three days, the indication for this being the persistence of the symptoms or a renewed increase in their intensity. In infants less than a year old the protrusion of the fontanelle indicates the advisability of repeating the operation. It is wise not to remove more than 30 c.c. at a time in children. In the author's cured cases the total amount of fluid abstracted varied between 165 and 350 c.c. If very little fluid can be obtained, or it is thick and decidedly purulent, it is doubtful whether a repetition of the measure will be of service. While Bokay's results and conclusions are in accordance with those of numerous other writers, it must be remembered that the question is still *sub judice* and that some observers are inclined to attribute little or no therapeutic value to the measure.

The Relation of the Mosquito and the Bedbug to Leprosy.

Since the annexation of Hawaii scientific work with regard to leprosy has again been stimulated and the government has established a Leprosy Investigation Station at Molokai. In Hawaii as long as lepers are segregated the people are not troubled by their existence or worried about their cure. Yet after all, their maintenance is a public expense and the prevalence of the disease in the islands keeps the Hawaiins from earning money through tourists who are in great fear of the leper whom the islanders themselves rarely see or bother about. It would be a good business stroke to remove this fear by abolishing the cause of leprosy. With this in view the resident physician of the settlement, Dr. W. J. Goodhue, has studied the modes of infection, his conclusions being published in the October number of *American Medicine*. He caught mosquitos and bedbugs in leper houses and examined them under the dissecting microscope. Beginning with the anal orifice, the abdominal contents were teased out with

steriie needles. The structures were then crushed between sterile slides, stained, mounted in Canada balsam, and examined. After repeated failures success came finally in demonstrating the *Bacillus leprae* in the female *Culex pungens* and in the bedbug. The high percentage of washerwomen among lepers and also certain other facts have long been considered evidence that the disease spreads through leper clothing. This experience is substantiated by Goodhue's findings, for the mosquito and bedbug infest clothing.

The Scientific Temper.

An article in the *British Medical Journal* for October 5 discusses the peculiar irritable state of mind in which scientific workers seem at times to live. The temper sometimes shown between scientific workers leads our British contemporary to thankfulness that there is no likelihood that a scientific Inquisition will ever be established. Should any such catastrophe befall mankind, it fears that scientific heretics would fare very ill. The irritability of the scientist, like that of the poet, arises, observes our contemporary, "not from vulgar conceit so much as from a keen source of the dignity of his vocation and the loftiness of his work. Hence he feels even more deeply the lack of appreciation by common clay. This feeling is too often justified by the neglect which has been the lot of so many men who have given themselves without stint and without hope of material reward to labor for the lightening of the darkness in which we live and move and have our being. Many have been allowed to starve or spend their lives in hidden grooves, their poverty and obscurity being sometimes in strong contrast with the fame and wealth of others who have reaped where they have not sown. The hardest thing for a scientific man to bear is the attribution of his discoveries to men who have come into the vineyard at the eleventh hour and received the reward of his labors. The history of science is full of examples of such injustice; they all point the moral that it is the inevitable fate of the man who has not the gift of self-advertisement to be overlooked."

A Rapid Test for Tuberculous Pus.

The tubercle bacillus is often difficult or impossible to find in tuberculous pus, it frequently being necessary to inject the pus into guinea-pigs before the clinical diagnosis of tuberculosis is confirmed. The opportunity to experiment with guinea-pigs is, however, not within reach of all practitioners, so that the following test described by Müller in the *Centralblatt für innere Medizin*, 1907, No. 12, may occasionally be of value. A white porcelain dish is filled with Millon's reagent (which turns red in the presence of proteids) and a few drops of the pus to be tested are added. If the pus was caused by some coccus the entire reagent will turn red in fifteen minutes or less, if caused by the tubercle bacillus it will retain its natural color. This difference in reaction depends upon the presence or absence of proteolytic ferments, which if present change the pus into diffusible bodies; these then dissolve in the reagent and color it red. In tuberculous pus they are absent, and hence the coagulable proteid corpuscles are not dissolved, but form a thin membrane on top of the reagent which, while it itself turns red, leaves the reagent beneath it clear. When the tuberculous process from which the pus originated had been previously treated with iodoform, or when a mixed infection was present, the reaction was similar to the one caused by coccus pus. Tuberculosis can, therefore, not be excluded when no membrane forms and Millon's reagent turns red, while, according to Müller it can be positively diagnosed when a membrane forms and the reagent does not change color.

Flat Foot and Bone Tuberculosis.

Flat foot is so common an affection, and its treatment ordinarily yields such gratifying results, that the temptation is very great to make this diagnosis in cases presenting one or more of the characteristic features of the condition, without resorting in every instance to exhaustive examination. Usually the resort to proper footwear, suitably molded plates, strapping, massage, etc., proves the correctness of the diagnosis by bringing about a satisfactory amelioration of the symptoms, but it must be borne in mind that another and much more serious lesion, namely, tuberculosis of the bones of the foot, may at first simulate very closely the subjective and objective manifestations of a relaxed plantar arch. Ewald (*Münchener medizinische Wochenschrift*, November 19, 1907) emphasizes the possibility of diagnostic errors in this regard, and gives the history of four cases in which what was supposed to be flat foot was unsuccessfully treated for long periods of time by measures appropriate for this condition, but which *x*-ray examination finally revealed as being instances of tuberculous disease of one or more of the small bones of the foot. While it is hardly to be expected that radiographs should be made in every case of supposed flat foot it evidently is the part of wisdom always to keep the possibility of tuberculous disease in mind, particularly if the symptoms affect only the one foot, have appeared apparently as the result of traumatism, or have proved obdurate to the measures usually relieving the purely mechanical condition.

Working Toward a Quiet City.

In a few days, it is promised, signs will be placed at each corner of the block surrounding every hospital in the city, warning the passerby that the street is a "hospital street," and that quiet is enjoined in the neighborhood. This is putting into execution the ordinance which the Board of Aldermen passed some time ago, at the instance of Mrs. Rice, President of the Society for the Suppression of Unnecessary Noise, establishing the "quiet zones" around the hospitals. That the enforcement of this ordinance will help in the treatment as well as conduce to the comfort of hospital patients cannot be doubted. It is proposed also to enlist the children in the cause of establishing a children's Hospital Branch of the Society, the members of which will wear badges to promote an esprit de corps and will engage not to play on the street in a hospital block or in front of any house where one of the inmates is known to be ill. Still another evidence of praiseworthy activity on the part of the Society is found in the fact that there have been two convictions recently of tugboat captains for violation of the whistling law. It was proper and natural that the movement for reasonable quiet should have begun in this noise-ridden city, but its influence has spread even further than the founder of the Society had dared to hope. Chicago has recently established hospital quiet zones, similar to those in New York, and there are other signs that a wave of protest against unrestrained noise is sweeping over the country; and even in Europe the authorities of many of the larger cities are instituting anti-noise measures.

News of the Week.

Public Health and Marine-Hospital Service Examinations.—A board of commissioned medical officers will be convened in Washington, D. C., on January 20, 1908, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service. Candidates must be between 22 and 30 years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination in the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. Officers are entitled to furnished quarters for themselves and their families, or, at stations where quarters can not be provided, they receive commutation at the rate of thirty, forty, and fifty dollars a month, according to grade. All grades above that of assistant surgeon receive longevity pay, 10 per cent. in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners application should be made to the Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

Mosquito Fever.—The Third International Sanitary Congress, at its session held last week in Mexico City, adopted a resolution that malaria should hereafter be called "mosquito fever," and that the delegates from the various countries represented should use their influence to popularize the change. It is hoped that in this way efforts to exterminate the mosquito will be facilitated.

Cocaine Peddlers Arrested.—Three men accused of making a business of selling cocaine in saloons have been arrested and held for examination. In the one case there is an additional charge of forging a physician's name to a prescription in order to secure a supply of the drug.

Centenarians.—John Spavin died in the village of Vernon, N. Y., on December 5, at the age of 105 years. He is said to have retained his faculties almost unimpaired until the last, and to have found it necessary to use spectacles for reading only two years ago. George Olley died in Great Bend, N. Y., on December 7, aged 110 years.

The City's Death Rate.—During the week ending November 30 the number of deaths reported as due to cardiac disease was 164, whereas for the corresponding week of last year it was only 95. The total for the week in question was 1,346 and for the corresponding week of 1906 it was 1,244. The deaths per thousand for the two weeks are respectively 16.39 and 15.63.

A New East Side Medical Association.—A number of East Side physicians and druggists have formed an organization called the Physicians' and Pharmacists' Mutual Aid and Protective Association of New York County. Among the objects of the society is to discourage lodge practice, restrict the sale of patent medicines, and prevent abuse of free dispensary treatment.

Typhoid-Contaminated Milk in Orange County.—An epidemic of typhoid fever has broken out in Walden, Orange County, a village of 5,000 inhabitants, and in the past few days forty-one cases have developed and six deaths have occurred. The State health officials attribute the dissemination of the disease to the milk supply.

Professor Koch Honored.—Professor Robert Koch, who has just returned to Germany after a year and a half of work in East Africa on the etiology and treatment of sleeping sickness, has been made a "Wirklicher Geheimer Rat" with the title Excellency.

Dr. Frank Woodbury of Philadelphia has been elected Secretary of the Lunacy Committee of the Pennsylvania State Board of Charities, in succession to Dr. I. Nicholas Mitchell, resigned.

Endowment of Free Beds in Philadelphia Hospitals.—The Sixth Pennsylvania Cavalry, known during the war as Rush's Lancers, has decided that the sum of $10,000 given to the organization by the heirs of the late Charles J. Coxe, who served as major in the corps during the war, should be devoted to the endowment of two free beds in the Episcopal Hospital of Philadelphia to be called the Sixth Pennsylvania Cavalry beds. By the will of the late David Scull of Philadelphia, the sum of $5,000 is bequeathed to the Philadelphia Lying-in Charity, for the endowment of a free bed, to be called the Hannah E. Scull bed, in memory of the wife of the decedent, who was at one time a member of the Board of Managers of the institution. An additional conditional bequest of the same amount is made for the endowment of a second free bed.

Long Sentence for Abortionist.—The Committee on Criminal Abortion of the Chicago Medical Society has secured the conviction of a woman abortionist, and she has been sentenced to imprisonment for twenty years in the State penitentiary.

Quarantine Against Cuba.—An effort is being made by the Cuban government to have the yellow fever quarantine against the island raised, as it is stated that the disease has practically disappeared from Cuba.

Killed by Insane Patient.—Dr. Samuel Goldberg of the staff of the North Texas Asylum for the Insane died on December 8 as the result of injuries received at the hands of a patient who suddenly became violent.

Officers of the Alumni Association of Cook County Hospital (Illinois).—At the annual meeting and banquet of this association, held November 26, Dr. Samuel C. Plummer was elected President, and Dr. Frederic A. Besley, Secretary and Treasurer.

"The American Journal of Urology."—Beginning with the January issue, this journal will be edited by Dr. William J. Robinson of this city. The

journal will be enlarged in scope so as to include venereal and skin diseases, and there will be added an abstract department which will review the genito-urinary and dermatological literature in every civilized language. The address will be changed to 12 Mt. Morris Park, West, New York City.

The Late Dr. Derby.—At a meeting of the New York Ophthalmological Society, held December 9, 1907, the following resolutions were passed: The members of the New York Ophthalmological Society record with deep regret the death of their associate, Dr. Richard H. Derby. Dr. Derby was born in Boston in 1844. He was a graduate of the college and of the medical school of Harvard University, and was house surgean in the Massachusetts General Hospital. While abroad he was a pupil of Von Graefe, and acted as his assistant. He settled in New York in 1870. He had been for many years an active member of the administrative and surgical staff of the New York Eye and Ear Infirmary, and was the Executive Surgeon of that institution at the time of his death. Dr. Derby was a member of our society since 1870. He was a member of the New York Academy of Medicine, of the American Ophthalmological Society, was officially attached to many public institutions, and was prominent and influential in all political reforms and movements for public betterment that have engaged the attention of public-spirited citizens. He was remarkable for his loyalty to his personal friends and for the earnestness with which he devoted himself to the welfare of the societies and institutions with which he was connected. Your committee recommend that this very inadequate expression of esteem and regret be incorporated into the minutes of the society and sent to the surviving members of Dr. Derby's family. W. E. Lambert, *Chairman*, John E. Weeks, W. S. Dennett, John R. Shannon, *Secretary*.

Obituary Notes.—Dr. Arthur E. Green of Los Angeles died on November 21 at the age of fifty-seven years. He received his medical degree from the University of Iowa in 1880 and had practised in Los Angeles for twelve years.

Dr. Charles A. Dorman of New Haven, Conn., died suddenly of heart disease on December 5, at the age of sixty-three years. Dr. Dorman was a native of New Haven and during the Civil War served as hospital steward. He later was graduated in medicine from the Hahnemann Medical College of New York.

Dr. Joseph Catlin of Chestertown, Md., died suddenly at Monmouth Junction, N. J., while on his way from New York to Philadelphia. Dr. Catlin was fifty-nine years of age and was graduated from the University of Pennsylvania in 1872.

Dr. Richard Morris of Vassar, Mich., died of pneumonia on November 27 at the age of sixty years. Dr. Morris was born in Limerick, Ireland, but was brought to this country while an infant and spent his boyhood in London, Can. He received his medical education in the Toronto School of Medicine and the University of Buffalo. He had held many positions of trust and for years had been City Health Officer.

Dr. H. W. Brown of Waco, Tex., died on November 29 at the age of eighty years. He had been a resident of Texas since 1868 and was at one time President of the Texas Medical Society and Vice-President of the American Medical Association.

Dr. A. W. Sims of Ketona, Ala., died of apoplexy on November 26. Dr. Sims had been a resident of Birmington until a year ago, when he removed to Ketona.

THE THIRD HARVEY SOCIETY LECTURE.

The third lecture of the present series given under the auspices of the Harvey Society was delivered on Saturday, November 30, in the large hall of the Academy of Medicine. The speaker was Prof. D. L. Edsall of the University of Pennsylvania, and the subject of his address was "The Bearing of Metabolism Studies on Clinical Medicine."

The speaker began by saying that at the present time there was a marked tendency for the scientist and the practical man in medicine to grow apart. This was due, perhaps largely, to the growing extent of the fields of both, of the large amount of knowledge required. The strictly scientific man was apt to look down on the practical man because the latter had often so little grasp of the former's subject, and attempts made to bring scientific knowledge in acceptable form to the practical man, or to make it of practical applicability was often frowned upon as undignified to science. No doubt it was often dangerous to turn over to the practical man certain scientific data which had only a limited applicability, for very frequently this limitation was disregarded and too general conclusions drawn.

The results of metabolism studies were of the highest value to the clinician. They possessed one great advantage over many other data in this respect, and this consisted in the fact that they could often be presented in the shape of figures. In fact very often the results could be obtained by comparing one column of figures with another, and results which depended on figures as opposed to mere clinical impressions were on the whole far preferable. In the application of metabolism studies in diagnosis, it might well be said that their value had mainly been iconoclastic. Thus, if one glanced at the studies which had been made on the urine constituents, one could not but be struck by the fact that a little knowledge of metabolism would have saved an enormous amount of labor—labor which, because of a lack of this knowledge, had been almost entirely wasted. Extensive clinical studies had been made in which the percentage composition of the urine had been regarded as a definite factor, and yet we all knew that only the total daily excretion afforded any reliable basis for study. But even more than this was necessary in order to make the data of any value; namely, the nature and quantity of the substances ingested. Some time ago the obstetricians read long papers and held animated discussions on the significance of the percentages of urea in the urine of their patients. It was not realized that it is possible, by mere changes in diet, to change the daily excretion from a few grams per day to from 20 to 30 grams. More recently much attention had been devoted to a study of the NaCl factor of the urine and to the results obtained by cryoscopy. In all of these, unless the diet were reckoned with, the figures were useless.

Formerly the presence of oxalate of lime crystals in the urine was made the basis of a definite clinical (?) disease. It was even held that these crystals indicated an excess of oxalic acid in the blood. And the same held true of the phosphates; they had been interpreted as indicating an excess of phosphates in the blood. As a matter of fact, these sediments indicated merely some changes in the reaction of the urine, causing the substances to be less soluble. Perhaps most labor had thus been wasted on studies connected with the presence of uric acid crystals in the urine. Metabolism studies showed that in this case even very refined scientific measurements

of the uric acid excretion taught us little. We now knew that there were several sources of the uric acid, but we did not know the proportion derived from each source.

The application of metabolism studies had thus righted false diagnostic and false therapeutic procedures, and so had been of great value. But this had not been their only function. They had, for example, exerted an important influence in dietetics, although here a great deal had still to be done. Dietetics was still largely unscientific. Perhaps this was due to the fact that there were still so many differences among the physiologists themselves. It was absolutely necessary, however, for the physician to take greater interest in dietetics than he had heretofore taken. Foods should be regarded more like drugs, and one should measure the food value more in proportion to the patient. To be sure, the matter was one of considerable complexity. We might trust to figures in the simpler diets; in the more complex it would be necessary to judge largely by the appetite of the patient and by his general condition. The number of physicians who made any considerable use of their knowledge of food values was still very small. These same physicians, however, would bring the utmost of their scientific knowledge to bear in questions of drugs, or other remedial treatment.

The speaker said it was an error to exclude an entire class of food stuffs because some member of the class was contraindicated. In such a case one should be able to choose another member of the group and seek for a means to prepare it properly. In the case of infants, experiments had shown that they use and need considerable quantities of proteid. He believed that, as a rule, pediatrists gave too little proteid. It was not enough, however, to study merely the intake and the outgo. The intermediate changes were of the greatest importance. This phase of metabolism had recently undergone a considerable change in the point of view through the studies which had been made by Emil Fischer and his pupils on the constitution of the proteid molecule, and by recent studies on the rôle of ferments. The ferments, we now knew, were present in all cells, and were closely bound to them. It was exceedingly difficult to get them out. But, so far as a therapy by means of these ferments was concerned, it was doubtful whether one could do anything with them, anyway. It seemed to have been conclusively shown that the same ferment could act both constructively and destructively, and that the difference in the action depended on the medium. The involution of the uterus after pregnancy was a ferment action, and there was reason to believe that only one ferment was involved, both in the enormous building-up process of pregnancy and in the breaking down during the puerperium. Perhaps some day we should be able to influence these cell ferments. In the case of pneumonia the speaker had tried to affect the ferment action by the use of the *x*-rays, but the results were not yet clear.

Dr. Edsall alluded to the fact that acute yellow atrophy of the liver was now well understood, thanks to studies in metabolism. It was possible that recurrent vomiting might also be thus cleared up. The metabolism of the inorganic substances had not been sufficiently studied. Yet this would probably prove a fruitful field. He referred to the work already done in this line, and spoke of the experiments of Jacques Loeb on artificial fertilization, and of those of Meltzer on the effects of calcium and magnesium salts.

Correspondence.

MILK PURIFICATION.

To the Editor of the Medical Record:

Sir:—A Paris physician has figured out exactly the number of tons of manure Parisians yearly consume with their milk. Another Paris physician points out that 99 per cent. of the milk consumed by the people of Paris is tuberculous. One thousand corn-fed hogs were slaughtered and no traces of tuberculosis were found in their bodies. One thousand hogs, fed on milk such as is served to Parisians, from dairies adjacent to Paris, were slaughtered and 99 per cent. of their carcasses showed lesions of tuberculosis. And a hog's intestines are pretty strong. What is the solution of this problem?

Establish purifying and sterilizing stations either at the initial point of delivery or at the receiving station or stations in the city. Fifty strainings will *not* remove manure, blood, pus, seeds, hair, and microscopic dirt from milk; *centrifugal separation* will. Visit a creamery where De Lavae milk separators are used and verify this. See a batch of milk strained through twenty strainers (usually it is strained once) and then see it separated and note the filth cleaned from the machine. You never will drink milk again. Sterilization is good, is necessary; Mr. Strauss has proven that. But let us first *purify* the milk, and centrifugal separation is the only known method, and then let us sterilize it afterwards.

It is only a question of time when this must and will be done. Why can not the progressive medical men hurry it along?

Charles Cristadoro.

Point Loma, Cal.

A USEFUL MANOMETRIC TABLE.

To the Editor of the Medical Record:

Sir:—I am sending herewith a brief scale showing the equivalent of the mercury and water columns in ordinary manometric work, which I trust you will publish for the benefit of your readers. So many are now using blood pressure apparatus that a question sometimes arises as to the height of a column of water that would correspond to the height of the mercury column. It is not always easy to turn to a scale, as none is given in the ordinary reference books. The meaning of the figures is clear, as, for instance, at the top of the column eighty millimeters of mercury equals one hundred and eight millimeters of water. Further down, two hundred and fifty millimeters of water equals one hundred and eighty-five of mercury.

Mercury.		Water.	Mercury.		Water.
80	=	108	150	=	203
90	=	122	160	=	217
100	=	136	170	=	230
110	=	149	180	=	244
120	=	163	185	=	250
130	=	176	190	=	257
140	=	190	200	=	271

EARLY BELIEF IN THE MICROPARASITIC NATURE OF MALARIA.

To the Editor of the Medical Record:

Sir:—In a treatise on the "Geology and Mineralogy of Georgia," published at Atlanta in 1871, Dr. M. F. Stephenson, referring to the cause of malaria in that State, says: "These fevers evidently are caused by animalcular irritability and are cured at once by using any remedy which is readily taken into the circulation, and destructive to the animals." Is not this, dated 1871, of interest in view of the fact that not until 1880 did Laveran isolate the organism?

Newington, Fairfax County, Va.

Tuberculosis and Weather.—Twenty years' observation of phthisis over a district in Dartmoor and North Devon, England, has convinced investigators that populations exposed to strong prevalent rainy winds have a higher death rate from consumption than populations sheltered from them. The contrasts in the phthisis death rate in the sheltered and exposed parishes are very marked.—*The Therapeutic Record.*

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEETING AT COLLEGE OF SURGEONS—REPRESENTATION OF MEMBERS, ADMISSION OF WOMEN, CERTIFICATE OF TROPICAL MEDICINE, ETC.—ROYAL SOCIETY OF MEDICINE—OPERATIVE TREATMENT OF GOITER—RECURRENT DISLOCATION OF SHOULDERS—CONGENITAL HEART DISEASE IN ADULTS—PNEUMOTHORAX—DUCHESS OF ALBANY AT HOSPITALS—UNION OF PUBLIC HEALTH AUTHORITIES—OBITUARY.

LONDON, November 22, 1907.

YESTERDAY afternoon there was the annual gathering at the Royal College of Surgeons, which the Council persists in calling the annual meeting of the Fellows and Members. It is true that a report of the Council to the Fellows and Members who may care to attend is presented and on this they are permitted to comment. Resolutions may even be passed, but they have no effect, the Council holding that the authority of the college rests in itself only and that resolutions can only be considered as outside advice. That this has no effect is obvious from this fact, which the president referred to yesterday—that a resolution passed unanimously for the last twenty successive years has been simply ignored. The president asked his audience to believe that the Council was not actuated by any hostility or opposition to the Fellows and Members, but only by a feeling that the proposal for them to be represented on the Council was an innovation which was not in the nature of a desirable reform. The resolution affirming that it was desirable was nevertheless once more passed, and further a motion of regret that the report contained no mention of the opinion expressed by the Lord President respecting an application to the Privy Council for a new charter providing for the admission of women. It was suggested that the Lord President on behalf of the Government had intimated that any new charter would have to contain provision for the representation of the Fellows and Members. The president replied to this that he could not give his own version of the conversation without the Lord President's assent. As to the admission of women, the president stated that the Council had passed a resolution in its favor and the question was referred, under the Joint Board agreement, to the College of Physicians. If that college decided in its favor a vote of the Fellows and Members would be taken and on the result of that vote the decision of the Council would largely depend. This is equivalent to a promise to consider the opinion expressed by the vote, with a determination by the Council to follow its own course, and that course for the last twenty years offers no inducement to the voters to expect anything. A member had the temerity to suggest that the reference to the sister college was only with the object of getting rid of the necessity, if a new charter were obtained, of including representation of Members on the Council.

The report mentions the question of a certificate in tropical medicine, which I have previously reported as decided on. Also that the cancer fund will be available for research in connection with other diseases when the inquiry into cancer is successfully ended. A resolution was adopted asking the Council to use its influence with hospital authorities as to staff appointments. Finally it was suggested that the college might join with the sister college and the London University, to form an Imperial University in the metropolis. But that suggestion is, of course, only outside advice.

The Surgical Section of the Royal Society of Medicine has been discussing the operation of goiter, Mr. James Berry having brought forward an account of 274 cases of removal. Many were encapsulated, which seems to exclude the agency of drinking water, though the majority came from districts where the supply was of doubtful quality. Reasons for operating were assigned as: Dyspnea, 64.5 per cent.; deformity, 12 per cent.; discomfort and deformity, with slighter dyspnea, 17 per cent.; malignancy and tumors, 3.6 per cent.; suspected malignancy, dysphagia, and increase in size, 2.5 per cent. The commonest and most urgent indication for operation, Mr. Berry said, was dyspnea, and this he held was always due to pressure on the trachea. No degree of severity of dyspnea need preclude operation. Hemorrhage into soft adenomata often caused extreme sudden and even fatal dyspnea. As to results, the mortality of innocent tumors was little over 1 per cent. and complications were insignificant. Out of seven malignant cases three died and three had recurrences. In most operations it was better not to remove the part next to the esophagus, recurrent laryngeal nerve, and side of the trachea.

Mr. Haward spoke of the excellence of the results indicated by the perfect scars in many patients shown. He asked why chloroform was always used and never ether, whereupon Sir Victor Horsley said ether should never be used in operations where dyspnea was so important a feature, as it provoked expectoration. He was for postponing operation in the parenchymatous enlargements of young patients, but in adults there was little hope of relief from other measures. Some encapsulated and outlying tumors were parathyroidal. Some were associated with nervous symptoms, which disappeared after operation, and they were not Graves' disease.

Mr. Spencer reported benefit to cases of Graves' disease from division of the isthmus and removal of small portions of both lobes. In goiter in the old or middle aged he thought it well to operate before any definite suspicion of malignancy and not to wait for dyspnea.

Mr. Paterson reported that he had lately been at a discussion on the subject at Rochester, U. S. A., and found that American surgeons favored operation in Graves' disease. Dr. Ch. Mayo reported 110 cases with 10 deaths. Cure followed in 50 per cent., relief in 25 per cent., and the other 25 per cent. were unsatisfactory. Ether by the open method was employed.

In the Clinical Section Mr. Openshaw showed a man of 27, the subject of recurrent dislocation of the shoulder, which was attributed to epileptic fits since 1896. The joints had been dislocated about fifty times a year. Injections into them, rest, removal of cartilage from their surfaces, and division of the pectoralis major had all failed to prevent recurrences. Then Mr. Openshaw detached the insertion of the subscapularis from the humerus and fastened it to the deltoid in each shoulder. No recurrence and natural movements of the arm resulted. He has done this operation in three cases and all were successful, as seen six years, two years, and sixteen months afterwards, respectively.

Dr. Murray Leslie had two cases of congenital cardiac disease in adults. A girl of 23, cyanotic from birth; temperature was low, heart enlarged to the right, probably patent septum, and other abnormalities. The other case was also a female, age 30, with pulmonary stenosis observed for twenty years, attacks of giddiness and breathlessness, cyanosis, club fingers, etc. The right ventricle was enlarged; a loud, harsh systolic murmur was heard, loudest in the pulmonary area. There was pulmonary stenosis and some patency of septum. Health of late better than ever. Red cells greatly increased.

Dr. Fawcett read an account of a case of pneumothorax aspirated under *x*-rays in a man of 22, admitted with much dyspnea from pneumothorax of the right side. As he did not improve for nineteen days a trocar and cannula were inserted into the pleural sac in the sixth or seventh interspace. The lung was seen by the *x*-rays to be compressed against the spine and therefore the trocar could be passed without touching the lung. On connecting the cannula with a partially exhausted bottle the lung was seen on the screen to expand. It at once acted perfectly and after twelve days the patient was discharged well and he has resumed work. It was remarked by members that recovery was usually so good that aspiration was only necessary when dyspnea was extreme. Sir William Cairdner's opinion was quoted as adverse to the operation.

On Tuesday the Duchess of Albany attended a meeting of the supporters of the Hospital for the Paralyzed and Epileptic, held to institute a fund to celebrate the jubilee of the hospital, which will occur two years hence. Considerable improvements and some building seem required, for which it is proposed to raise £10,000. A scheme was approved and the Duchess was asked to form a committee. Her Royal Highness accepted the presidency of such a jubilee committee and made an interesting speech, urging that none of the expense of the jubilee committee should fall on the hospital. Accordingly Her Royal Highness opened an expenses fund—not a guarantee fund—so that whatever remained after the expenses were paid would go to the hospital. In closing her speech she announced that already she had received £112 towards the jubilee fund, as well as a number of promises.

The next day (Wednesday) Her Royal Highness opened the Infants' Hospital, an addition to London's charities, which has been built and completely equipped by Mr. Rob Mond as a memorial to his late wife. The wards will accommodate fifty infants and there is also a lecture theater, a laboratory for milk and food preparations, and another for research work.

The meeting to establish a union of public health authorities, the calling of which I mentioned in a former letter, dated September 27, was duly held on the 15th inst., when some eighty representatives of these authorities attended, and it was resolved to carry out the proposal which had emanated from Newcastle. The "National Union of Public Health Authorities" was accordingly started, its objects being (a) to secure as far as possible harmony of interest

and uniformity of action among the authorities; (b) to stimulate and concentrate effort for effecting necessary sanitary reforms; (c) to encourage the study of practical hygiene and educate opinion on the national and local importance of the subject; (d) to consider the conditions and circumstances, general and local, whereby disease may be caused to man and to obtain their removal.

Sir Charles Frederick Hutchinson, M.D. and ex-M.P., died on Friday at the age of 57. He was the son of Dr. Hutchinson of Nottingham and entered his father's profession at the Edinburgh University, graduating in 1874. He practised for some years at Scarborough and was at one time on the staff of the Royal Manchester Infirmary. He spent the winter for several years in the south of France, but in 1898 gave up professional work and retired to Sussex, where he was made a Justice of the Peace. In 1903 he was elected M.P. for the Rye division, but lost the seat at last year's general election. He received a knighthood last November.

OUR PARIS LETTER.

(From Our Special Correspondent.)

FRENCH MEDICAL CONGRESS—HEMOPHILIA—GASTRIC ULCER—EXOPHTHALMIC GOITER—THE TRANSMISSION OF TUBERCULOSIS—THE USE OF RADIUM.

PARIS, October 20, 1907

THE ninth session of the French Medical Congress was held in Paris from October 14 to 17 under the presidency of Professor Debove, Dean of the Medical Faculty of Paris. One of the topics for discussion was hemophilia, and papers on this subject were read by Carriere of Lille and Marcel Labbé of Paris. As is well known, hemophilia is characterized by a tendency to spontaneous or traumatic hemorrhages, associated either with undue permeability of the vessels or abnormalities in coagulation. The etiology of the disease is practically unknown. The hemorrhages caused may appear at the surface through the natural channels, and in these cases are frequently the results of exertion. Epistaxis is the form most often observed. Cutaneous and mucous hemorrhages may also be produced either by contusions or abrasions. Hemorrhage sometimes occurs after the dropping off of the umbilical stump in infants; the bleeding may also take place into the joints, producing characteristic arthropathies. The treatment of hemophilia consists in the administration of iron or arsenic. Carriére speaks well of chloride of calcium in doses of 2 g. a day. Serum therapy may be resorted to, as suggested by Weil, and for this purpose the serum of rabbits, of the horse, the ox, or, still better, of man may be injected, but the effect of this treatment is only temporary and it must be repeated every ten or fifteen days in order to produce a continuous action. The results obtained by the use of gelatin are less reliable, but 20 to 30 g. a day may be administered by mouth, or by rectum 15 g.

The second subject on the program was the treatment of simple gastric ulcer and the speaker was Linossier. He considered that the simple gastric ulcer had a natural tendency toward cure. The measures adapted to bring about healing of the lesion were of three sorts. The most important of these was the regulation of the diet. The organ should be put at rest by resorting to subcutaneous and rectal feeding; this period of course was kept up for only a short time. Milk diet fulfilled the indications best and afforded proper nourishment with a minimum of disadvantage. The medicinal treatment comprised especially the administration of alkalis and of subnitrate of bismuth. Finally, surgical methods might be resorted to either for the excision of the ulcer or, as was more generally practised, for the performance of gastroenterostomy. Linossier concluded that the operative measures should be made use of only when medical treatment had been found to be entirely unsuccessful.

Castaigne and Dujarrier followed with a paper on the complications of gastric ulcer and their treatment. Among these they said some were especially acute: First, generalized perforative peritonitis, for which prompt surgery was necessary, and then profuse hemorrhages, for which operative treatment was less successful than medical treatment. Among the less acute complications were localized peritonitis and perigastric abscess, which might lead to gastric fistulas. The chronic complications included stenosis of the pylorus, hour-glass stomach, and productive perigastritis. Finally, gastric ulceration might frequently lead to the development of cancer. In the treatment a combination of medical and surgical measures was most desirable. While there were no complications the condition was strictly a medical one, but if complications arose the physician should immediately consult with a surgeon, although operation was not always indicated. After the operation it was indispensable that the patient should be kept under medical treatment, as lacking this serious sequelæ were possible.

Gilbert Ballet and Delherm presented a paper on the pathology and treatment of exophthalmic goiter. Of the surgical measures proposed for this condition they began by discussing the injection of remedial agents, which they said, in addition to involving the risk of sepsis, sometimes caused severe hemorrhage, dyspnea, and even sudden death. Exothyropexy was at present practically abandoned. Partial thyroidectomy was also dangerous and should be given up. Ligation of the thyroid arteries was likely to be attended by serious consequences and could not be recommended. The dangers of sympathectomy were so great as to discountenance this operation. The authors then discussed the various methods of organotherapy, including the administration of extracts from the thyroid, ovary, thymus, parathyroids, suprarenal, and testicle. Radiotherapy apparently had a favorable effect on the symptoms, but its value had not yet been fully determined. Electricity had also been resorted to and diminished the thyroid secretion and affected the sympathetic favorably. Among the pharmaceutical preparations salicylate of sodium was the most effective.

An interesting discussion was then held regarding the intestinal or aerial transmission of tuberculosis. Kuss pointed out that in experimental work it was very easy to infect animals by the respiratory route, while the results of intestinal infection were inconstant and inconclusive. Vallée of Alfort considered that in respiratory tuberculosis the rôle of inhalation was undeniable, but infection by the digestive tract was also very frequent. The purely pulmonary lesions so often seen in children could in animals be produced equally well by the ingestion and the inhalation of bacilli. It was to be hoped that the necessary measures would be taken to combat the serious danger involved in the use of milk from tuberculous animals. Calmette of Lille was also of the opinion that in chronic tuberculosis the intestinal route was the habitual means of infection. Debove, on the other hand, pointed out that in order to sterilize the milk it was necessary to bring it to 100°, and he suggested that the Congress adopt a resolution recommending that in all public establishments only boiled milk be delivered. This resolution was unanimously adopted.

Dominici spoke of the therapeutic applications of radium and reported the cure of gonorrheal arthritis, improvement in cases of urethritis, and in some forms of chronic rheumatism. Together with Barcat, he had studied the histological changes produced by the rays and had reached the conclusion that the cure of inflammatory affections and of certain tumors was not due to the destruction of the diseased tissues, but to modifications in cellular activity depending on chemical phenomena. Wickam and Degrais reported excellent results with radium in cutaneous epitheliomas, vascular nevi, and obstinate dermatoses. They considered that the use of radium should be definitely accepted in dermatological practice.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 28, 1907.

Anterior Poliomyelitis in the Adult.—Details of ten illustrative cases are given by G. L. Walton. He says that the symptoms of the malady are overlooked, not because they vary materially from the same disease in infancy, but because this diagnosis does not enter the mind of the practitioner in case the patient is an adult, whereas it is ever present when the patient is a child. In the adult appears the same stage of fever, during which signs of irritation appear, and during which the destruction of anterior spinal gray matter produces relaxed paralysis of various muscle groups, without loss of sensation or sphincter control (temporary loss of sphincter control did occur, however, in the first case reported); there are the same favorable prognosis as regards health and the same gradual disappearance of paralysis with more or less permanent residue. The essential features point, in the adult as in the infant, to an infectious process, of more or less diffuse onset, but having for its chief point of attack the anterior gray matter of the cord, to which region the ultimate injury is limited. The author's general conclusions are that the disease is not rare in young adults. The real seat of the infection is apt to be obscured by temporary symptoms pointing to the meninges and nerve sheaths. The implication of the meninges is probably independent, not an extension from the substance of the cord. The onset of paralysis is more retarded in adults than in infants, and the extension of paralysis from one group to the other is less immediate. No exten-

sion of paralysis is to be expected after fever has subsided. Prolonged rest of the affected muscles is desirable, as well as early orthopedic measures.

Diagnosis of Gastric Cancer.—R. F. Chase notes that cancers involve the stomach in about half of all cancer cases and that this localization accounts for two per cent. of the total mortality of the present time. As medical means of diagnosis he discusses the topics of history of the case, age, weight, chemical tests, and mechanical measures, such as aspiration of the stomach, inability to pass the tube more than 15 or 16 inches, and much delay or complete absence of the deglutition sound. Inflation and palpation often enable us to make out the presence of very small tumors. Concerning tests, the author mentions particularly that of Salomon, which consists in the detection of appreciable amounts of albumin by Esbach's reagent in salt solution which has been used to wash out the stomach several hours after the organ has emptied itself. In a limited number of cases Chase has obtained positive results in cancer cases only, while negative results appeared in mucous gastritis and other non-malignant lesions. As to the time to be allowed for carrying out the above medical diagnostic measures, the author notes that in advanced cases the diagnosis may often be determined at the first or second visit. In earlier cases two or three examinations in as many days or a week may be required. At this stage a condition is found occasionally warranting a radical operation or a gastroenterostomy. In still earlier cases two or three weeks are required. Frequently here, if the lesion is confined to the pylorus and metastases are not too extensive, resection may be done, or with adverse conditions for resection the physician should know at least and prior to the incision that a gastroenterostomy is indicated. As a general guide for operative measures the physician should have definite ideas on the following points: (1) He should be reasonably sure of the presence of the disease; (2) he should usually know when the case is beyond surgical relief; (3) in cases which he considers operable, he should have a pretty good idea that the conditions warrant at least a palliative, perhaps a radical, operation. Ulcer cases with stasis may be included here. Some of them cannot be differentiated from cancer by medical means. (4) In certain cases, either early or late, he should know if the cancer is located at the cardia, or lower end of the esophagus, and be aware that no operation, except a gastrotomy as a last resort, should be attempted. In advising regarding operation, the patient's age and his physical condition are features which should be duly considered. The above classes of patients (and Hoffmann figures it that the disease has then been present ten and three-tenths months) constitute the vast majority, perhaps 95 per cent., of all gastric cancers as seen by the consultant. In the remaining small portion of cancer cases, the true conditions perhaps cannot be learned by medical means within three weeks' time. In most of these cases, perhaps all, a surgical exploration should certainly be made, and the operation carried out which seems indicated. But even in these cases a radical operation cannot be done, unless the lesion is favorably located.

New York Medical Journal, November 30, 1907.

Ultra-Violet Ray and High Frequency Currents in Phlebitis.—S. Tousey describes the apparatus used in this form of therapy, and gives the histories of two personal cases. The treatment consists of two essential parts: (1) A glass electrode exhausted to about 0.001 of an atmosphere and yielding ultra-violet rays and visible violet colored light, when traversed by a high frequency current, is applied directly to the surface of the affected limb. (2) The affected limb is treated on general principles during the intervals of two days which elapse between the electrical applications. These measures include support by bandages, strapping, or elastic or laced stockings, massage, suitable ointments or lotions. One or more of these may be necessary in any particular case. Concerning the action of the currents from the ultra-violet ray vacuum electrodes in phlebitis, Tousey says that the ray itself may be demonstrated in the light given off by these tubes. A piece of willemite becomes fluorescent when held near such a tube in operation. This light has a stimulating effect upon the processes of metabolism in the tissues. It also is a powerful agent in the production of ozone, which gas can be detected upon the surface of the body hours after the application is finished. Ozone produced in this way and also by minute sparks from the vacuum electrode is absorbed by the tissues under the influence of the current. Additional quantities are generated in the tissues by electrolysis. This very active form of oxygen acts as a powerful vitalizer of the tissue cells. The electric current itself stimulates the circulation and favors the elimination of chronic exudates and indurations. It is also a stimulant to the vitality of the tissue cells.

Obstruction in the Nose or Throat as a Cause of Nervous and Mental Diseases in School Life.—R. H. Johnston regards the real nature of mental and nervous troubles in these cases as toxic from a deficiency of oxygen in the inspired air. The list of symptoms produced includes mental dullness, restlessness, night terrors, nocturnal incontinence, headaches, stuttering, and various other defects of speech, choreic movements of the face, etc. Mention may be made also of reflex nervous cough, irritability of disposition, pseudomeningitis, etc.

Serum Diagnosis of Syphilis.—A general review of work done along this line, both in its laboratory and clinical aspects, is given by W. J. Butler. He notes that the luetic organ extract is a difficult one to prepare, as it may undergo at any time such changes as render it useless. The mode of its elaboration is described in the paper, but cannot be reproduced here. Concerning one of its clinical applications, it may be said that it has been noted that in the majority of progressive paretics the spinal fluid reacts to syphilitic antibodies, and this fact led to the hypothesis that long years of antibody production on the part of the nervous system lead to pathological degeneration of it; that, therefore, progressive paralysis may be looked on as a wear and tear disease of the nervous system caused by too great a production of antibodies. In infectious diseases in general the immune bodies, as a rule, disappear in convalescence or soon thereafter. Not so with syphilis, as the antibodies may be found thirty, forty, or fifty years later. Just how long a patient who has been effectively treated remains free from antibodies, and probably from active syphilis, must by later work be determined, and upon this rests a point of incalculable importance to the syphilitic. That they do not remain free permanently is in some measure deducible from examinations already made, in that the reaction was often found + in patients who had undergone several courses of treatment at different times, and in whom in all probability the immune bodies after one or other of the cures disappeared. In support of this we may repeat the observation that some cases after effective treatment fail to give a + test. It would appear at this time that the serum reaction may prove a guide, an index, so to speak, to check up and control in a certain measure the destiny of our patient, and it seems not improbable that we might thereby be able to pilot him clear of assaults on his nervous system that result in cerebral or cerebrospinal syphilis, the parasyphilitic affections or visceral lues.

Possible Progressive Growth in Muscular Efficiency After Fifty Years of Life Without Systematic Muscular Exercise.—Horace Fletcher gives an exposition of the system known by his name, the initial factor of which is thorough mastication. Detailing his own experience, he says that he found by this means that many substances ordinarily considered tasteless were quite sweet; that much less food satisfied the appetite; he lost some of his fat, and after four or five months recovered sufficiently his former health to be accepted by a life insurance company which had formerly turned him down. He found himself able to take vigorous exercise without fatigue. The amount of food had been lessened, especially its proteid content, with only beneficial results. The author refers to series of experiments which have been made along these lines at various educational institutions and finds in them confirmation on a scientific basis of what he had already learned in his own case. There is no doubt, he says, but that meat or any form of superabundant proteid, like alcohol, gives certain immediate stimulation, and so-called systematic physical training, or hard work of any kind, will throw off or burn up the nephritic products of such poison breeding metabolism, but the result of a let up in work is disastrous. On the other hand, nutrition that has been prescribed by a healthy earned appetite, limited by an appetite which has been allowed to discriminate through careful buccal treatment, and the whole blessed with true epicurean enjoyment accommodates itself to the bodily and mental activities of the moment, and the body thus nourished, whether the possessor of big muscles or small muscles, is always in training and ever ready to endure unusual strain in cases of emergency.

Journal of the American Medical Association, December 7, 1907.

Spinal Localization.—J. H. Lloyd reports a case of rapidly fatal hemorrhagic meningomyelitis, of presumed

specific origin, with extensive secondary softening and cavity formation, originating in the lumbar cord and stopping abruptly in the eighth dorsal segment. There was complete loss of all modes of sensation below a line drawn around the waist at about the lower costal margin, a little higher at the middle and in front, and slightly so on the back. There was complete motor paralysis and the reflexes were abolished. Pain was complained of at the upper limit of the anesthesia and the spine at the level of the seventh and eight dorsal vertebræ was extremely sensitive. An interesting symptom was sweating above and dry skin below on the line of anesthesia. The case progressed rapidly to a fatal termination and post mortem revealed a large hemorrhage in the anterior fissure and an area of softening and cavity formation begun in the eleventh dorsal segment and extended upward, occupying a large space in the posterior columns, ending abruptly in the eighth dorsal segment. Above this, the cord was practically normal. This softening and cavity formation was probably secondary to the main lesion lower down, and occurred as the terminal process of the case. The localization in this case points to the eighth thoracic segment, and if Sherrington's views are correct, it tends to put the area supplied by the eighth segment in about the same location as given in the diagram of Head who places the umbilicus at the lower margin of the ninth area. It also corresponds closely with the mappings out by Sherrington on the body of one of his monkeys. The article is illustrated.

Mixed Malarial Infection and Gangrene.—E. J. Wood gives an account of a number of cases of symmetrical gangrenoid conditions occurring in his vicinity, probably associated with malarial infection, though this was not stated in some of the very brief histories he collected. One case, however, was observed carefully, and in this, in addition to the lesion mentioned and rather profound mental hebetude, the blood was found loaded with tertian parasites, though there was nothing else at the time suggestive of malaria in the symptoms. Later, however, the quartan parasites appeared in the blood with the other form, and chills and fever appeared. Wood discusses the case and states his conclusions as follows: 1. Malaria may be considered a direct or a provocative agent of symmetrical gangrene of the skin. The skin lesion differs somewhat from the classical description of Raynaud. 2. Tertian and quartan malaria may occur simultaneously, but such a combination is exceedingly rare. Usually one type predominates. 3. Latent tertian fever occurred in Case 8. It is very unusual. 4. Certain peculiar psychoses may be present in malaria and are probably of toxic origin. This question should engage the attention of the psychiatrists in malarial districts or physicians having patients from these districts.

Ventilation in Tuberculosis.—C. Denison describes the bed canopy or window tent as devised by him and emphasizes the importance of free and ample ventilation of the sleeping quarters in the treatment of tuberculosis. Fear of drafts, which he thinks is one cause of the unpopularity of such appliances and of outdoor sleeping, is a needless one. A sleeper, by having warm enough coverings on his bed and a thick woolen hood in winter, or a light soft nightcap in mild weather, can so temper the air movement that no danger of catching cold will result. It is only by such methods as the window tent or outdoor sleeping that thorough renewal of the air that is required can be insured. Denison says: The question of the necessity of sufficient air space, especially during the probably more susceptible sleeping hours, is the most vital one to consider in connection with the present tuberculosis crusade, not second in preventive importance to the quality of air in that space, nor to the infective germ of tuberculosis. He thinks it a mistake to attribute too much to the concentration of germs in habitations and not enough to the cramped and limited air supply.

Measles and Rubella.—The frequent errors of diagnosis between measles and rubella are remarked by H. M. McClanahan, who describes their respective symptoms as observed by him during a recent prevalence of both simultaneously in Omaha. The principal differences observed were the marked prodromal symptoms of catarrhal disorder, fever, etc., with the early appearance of Koplik's spots in measles as compared with the slight or absent prodromata in rubella, and the later appearing, more lasting and confluent eruption in measles. The papules in rubella are more discrete and they appear often as the first noticeable symptom. The fever is not so high as in measles and complications are notably absent. In three of his patients he had the opportunity of observing both disorders occurring in the same patient within a few weeks and noting the contrasting symptoms and course. There are doubtless borderline cases, but careful examination will usually lead to a correct differential diagnosis.

Dengue Fever.—J. Goldberger and G. W. McCoy describe the epidemic of dengue as it occurred in Brownsville, Tex., during the summer of 1907. The town is located on the bank of the Rio Grande, about ten miles from its mouth, and as the water for domestic use is kept in barrels or cisterns, the mosquitos are very much in evidence. The disease was probably introduced from Mexico, and between the middle of June and the middle of August it was estimated that there were about 1,000 cases. The incubation in the one case in which it could be accurately observed was not over six days, the onset was rather abrupt with general malaise, and aching, headache, and occasionally slight chill or chilliness. Pain, in the form of headache with or without rachialgia, lumbar pain, aching of the limbs and eyeache, was a constant symptom. Severe aching in the scapular regions was complained of in many cases, but no joint pains were noticed. The pains varied in intensity and disappeared as a rule with the fever. In many cases there was an initial flushing of the face for two or three days; the skin was usually warm and moist, and, in a little more than one-half of their cases, a more or less pronounced eruption appeared some time between the third and sixth day, lasting from twelve hours to three days. It varied considerably in character and extent, but in the majority resembled somewhat that of measles. Enlargement of the lymphatic glands was observed in only three cases. The rise of temperature began with the onset of the disease and was progressive for two, three, or four days. When it reached its maximum it began to decline, slowly or rapidly, usually reaching normal on the fifth or sixth day; the highest noted was 104.2° F. The pulse followed the fever; in no case was there the typical Paget's sign, a falling pulse rate with a stationary or rising temperature. In four cases nose bleed occurred, but there were no catarrhal or other respiratory symptoms. Blood examinations revealed no parasites that could be considered as of etiological significance. The tongue was usually moist and more or less coated over the dorsum, the appetite dulled and sometimes lost; thirst was almost invariably marked. In some cases there was nausea, and in a few instances vomiting, usually watery and sometimes bile stained, but not severe. Constipation was the rule, but was readily controlled. Albumin was absent from the urine, at least up to the fourth day, after which it was impracticable to obtain specimens, except in one case. One patient had a slight catarrhal icterus, antedating, however, the dengue. On the part of the nervous system, aside from pain, insomnia was observed in several instances, frequently as the result of the former. More or less marked adynamia followed the fever as a rule. A number of patients gave histories of previous attacks, and at least two had had yellow fever. The disease corresponded closely with that observed in the Philippines, but there hemorrhages were not observed and enlargement of the lymphatics was more common. The diagnosis in the presence of an epidemic was not doubtful. Yellow fever, the only disease demanding serious consideration, was readily excluded by the eruption and the absence of albuminuria and jaundice, which would certainly have been present with the fever of such severity and duration.

The Lancet, November 16 and 23, 1907.

Hemophilia Transmitted Through the Male.—A. J. Swanton reports an interesting family history. The disease originally appeared *de novo* in the father. Of his thirteen children the malady appeared in only one, a son, who had been a bleeder from infancy. This son, now a man of forty years, is the father of six girls and one boy, ranging from two months to nineteen years, all of whom, with the exception of one girl of eight years, have shown hemophilic tendencies. Four have died, two boys at eight months and four years respectively, from "convulsions," said to have been due to epistaxis, and one boy, aged ten months, and a girl aged two years and eight months, from pneumonia following measles accompanied by severe epistaxis and bleeding from the mouth. The disease in the father chiefly takes the form of spontaneous epistaxis which is difficult to control and is preceded by malaise and headache. He also suffers from painful swelling of his large joints. All the children look healthy; they have very soft white skin and fair hair. The only surviving son suffers frequently from epistaxis, which is most alarming in its persistence. It is preceded, for a few days, by an elevated temperature with frontal headache, faintness, loss of appetite, and pain in the back. The elbows, wrists, knees, and ankles are swollen and very painful. With the onset of bleeding he perspires freely. Any form of traumatic bleeding is only controlled with the greatest difficulty. He also bleeds per anum when suffering from diarrhea.

Aneurysm of the Right Subclavian Artery Treated by Ligature of the Axillary and Carotid Arteries.—After a reference to a case of this nature reported by the author three years ago with a good result to date, H. G. Barling reports a second case, his patient being a man of forty-four years who complained of pain in the right arm, due manifestly to a subclavian aneurysm. Dry diet, rest in bed and an iodide therapy failed to give any relief except a certain relief to the pain when the patient was perfectly quiet. The patient suffered somewhat from attacks of giddiness. At the time of operation the aneurysm was of the size of a Tangerine orange, and presented the usual physical signs. Details of the operative procedure are given in the original. The wound was drained for two days and union by first intention occurred. There was no disturbance of the general circulation. At the end of a week pulsation could scarcely be detected in the aneurysm, but was still marked over the first part of the subclavian and in the upper end of the innominate; at the end of five weeks, when the patient was allowed up, the aneurysm was quite solid, and slowly since that time pulsation in the first part of the subclavian and in the innominate has become less marked and, allowing for the division of soft tissues and the clavicle, which has, of course, left the arteries unusually exposed, the pulsation of these vessels appears now to be about what one would expect in normal arteries. For twelve months the right arm was kept to the side in the first instance by bandaging and later by a splint and sling, but the patient has been able to use the hand for writing and other details of that kind, and for the last nine months he has resumed his official duties, which fortunately do not involve any physical strain.

The Significance of a Hitherto Undescribed Wave in the Jugular Pulse.—A peculiar wave in the jugular pulse has been noted by A. G. Gibson. It is seen most typically in normal young adults who are in the habit of taking vigorous exercise or who are convalescent from acute disease. It is difficult to describe, but is perfectly intelligible when referring to the sphygmograms in the original paper. The author notes the general acceptance of the view that when the ventricle becomes moderately full the mitral and tricuspid valves float up by reason of eddies behind them in the ventricle, and the closure of the aperture by this means prevents regurgitation. An increase of pressure in the ventricles now causes these free edges to be closely pressed together in apposition. Apart from the filling of the ventricles, auricles, and veins which goes on during diastole and may cause an overflow wave in the jugular vein, this closure, at least in slowly-beating hearts with ventricles of normal size, must occur some time before the auricle begins to contract, for, if not, one must conceive either a slow filling of the ventricle for a slowly-beating heart or an enlarged ventricle. It is conceivable then that this extra wave may be due to the closure of the auriculo-ventricular valves by the natural filling of the ventricle with blood and the slight increase in pressure which the upward movement of the valves would cause in the venous system. Here it may be pointed out that the form of the wave suggests a mechanism of this kind, for no mere overflow wave such as could be caused by a gradual filling up of the ventricles, auricles, and veins alone could cause the nick which has been noticed as characteristic of many examples of the wave.

On the Treatment of Yaws.—A. Castellani gives the results of his experience in treating yaws (frambœsia) in Ceylon. The list of remedies employed includes mercury, the iodides of potassium and sodium, Fowler's solution, cacodylates of soda and of quinine. His conclusions herewith follow: (1) Drugs and preparations which are efficacious in the treatment of yaws are: iodide of potassium, atoxyl, sodium cacodylate, cacodylate of quinine, and mercury. These drugs have also probably a preventive action. (2) The best routine treatment for ordinary cases is iodide of potassium given in large doses. (3) In severe and persistent cases a mixed treatment consisting of a course of iodide of potassium followed by a course of injections of atoxyl or of the cacodylates is of great advantage. (4) The treatment of yaws patients should be prolonged long after the eruption has disappeared, as although the granulomatous eruption speedily subsides the infection in many cases is merely dormant, not destroyed. This fact is shown by clinical experience as well as by experiments on monkeys inoculated with the disease. (5) As regards local treatment it is sufficient to keep the skin clean by washing the eruption twice daily with a solution of perchloride of mercury (1 in 1,000). The ulcerated granulomata may be dusted with iodoform or boric acid. Mercury ointment applied to the ulcerated lesions may be beneficial, but is not sufficient to hinder secondary pyogenic infections. Caustics are not called for unless the ulcers become phagedenic; in such cases pure carbolic acid is the best.

Tubal Abortion.—The history of one case is given by G. W. Fitzgerald. The patient was a primipara of thirty-five years, married nine years. For three years she had had leucorrhea, irregular menstruation, metrorrhagia, and pain in the left side. In June, 1907, she had an attack of acute epigastric pain, and presented some evidences of internal hemorrhage, but her menstruation had been fairly normal, pulse was good, abdominal palpation caused no pain, and examination of the pelvis showed only a cervical polypus, a slightly enlarged uterus, and some infiltration of the right broad ligament. While in hospital for the proposed removal of the polyp, she was seized with sudden epigastric pain; apparently fainted and vomited much coffee-ground material. The next day the polyp was removed, the uterus lightly curetted, and an exploratory incision made through the posterior fornix. The findings in the pelvis at once led to a diagnosis of ruptured extrauterine pregnancy and the abdomen was immediately opened. The intestines were firmly matted by adhesions, and entrance was finally gained to the abdominal cavity by stripping the peritoneum from the muscular sheath and working down along the right of the incision. In this way access was gained to a small cavity and thence to a larger one lying lower down and which had been entered by the incision through the fornix. In this second cavity was a large clot in the middle of which was the amnion. The rest of the tube was much elongated, exceedingly friable, and formed a pedicle for the dilated portion which lay to the right and slightly above the level of the anterior, superior iliac spine under cover of a closely matted mass of intestines. The condition of the patient was now such that all that could be done was to pack hurriedly the cavities with gauze. The next day the packing was removed and bleeding recommenced. After a perilous experience the patient finally recovered. The operator notes that the difficulty in making a satisfactory diagnosis, previous to operation, was greatly increased by the protracted history, the persistent irregularity of the patient's menstruation, and the fact that though, as was subsequently discovered, she had lost a considerable amount of blood her pulse throughout was a normal one. Her anemic appearance, too, was regarded by her relatives as being her normal condition. Then, again, the absence of all pain or tenderness during examination of the uterus and its surroundings was a misleading feature. The presence of two cavities appears to be explained by supposing that there had been, at least, two serious hemorrhages. With each hemorrhage the dilated tube, which all the time appears to have been endeavoring to expel the ovum, was pushed higher up into the abdominal cavity and elongated. The position in which the dilated end was found is uncommon, as is also such a degree of attenuation of the tube. The control of the hemorrhage was rendered doubly difficult by the fact that one had so limited an opening into the peritoneal cavity through which to work, and even this was more or less diminished by the endeavors made to avoid damaging the bowel. On subsequent consideration one cannot but regret that the original incision was not abandoned and an opening made, through skin and muscle, directly over the opening into the peritoneal cavity. It would certainly have facilitated the operation. The introduction and removal of the gauze—which was several yards long—would have been simpler, especially the removal.

Treatment of Innocent Laryngeal Growths by the Galvanocautery.—A. Wylie reports six cases. He says that the use of the familiar forceps often causes injury to the surrounding parts of the larynx, especially when removing a small sessile growth, since they obstruct the view of the larynx and also are powerfully gripped by the glottic sphincters almost as soon as introduced. The galvanocautery burner being thin and light can be guided and observed during the whole of the operation. A fine cautery point should be used on an interrupting handle, introduced cold, and raised to a white heat on application to the tissues. General directions are given for preparation of the patient, anesthesia and after-treatment. Advantages of the method are: (1) Minute growths can be obliterated and do not return; (2) small vascular growths can be removed without risk of bleeding; (3) it is far superior to chemical caustics: (4) there is less danger to surrounding structures; (5) the whole operation is in view of the surgeon; (6) small sessile masses on the true cords are more thoroughly heated than by the forceps; (7) stumps of growths removed by various instruments can be obliterated by the cautery; (8) the galvanocautery cuts off the blood supply and thus kills the

growth, while the forceps often removes only the superficial portions; (9) the liability of local infectivity of papilomata is diminished. One serious drawback is that the galvanocautery destroys the tissue which cannot be subjected to the microscope. The crucial test in diagnosis cannot therefore be applied.

The Relationship between Avian and Human Tuberculosis.—A contribution to the study of this topic is made by S. G. Shattuck, who has been assisted by several of his laboratory helpers at St. Thomas' Hospital. The importance of the subject warrants the reproduction in full of the author's conclusions: (1) The human tubercle bacillus is pathogenic to the pigeon in a very limited degree only. It sets up no disease of the intestine or of the abdominal viscera when introduced (in sputum) with food into the alimentary tract, even for prolonged periods (six months), and in either moderate or excessive quantities. It sets up a local, or a local and glandular, disease only in the pigeon when injected (in sputum) into the muscles or subcutaneous tissues. It sets up a local, or a local and glandular, disease only in the pigeon when injected into the muscles or subcutaneous tissues from the organs of guinea pigs which have been infected by inoculation with human sputum. The impossibility of producing infection in the pigeon by means of tuberculous sputum does not allow the author to accept the statements which have been made in the other direction, for these statements do not rest upon experiment, but on the inferences based only upon possibilities. Although the disease may be spread from bird to bird, it has still to be determined whether there is any further source of infection. His experiments only show that if there is such it is not human. Neither can he accept the statement made by some that the subcutaneous inoculation of birds with human sputum will produce avian tuberculosis, *i.e.* the generalized and fatal disease as it is seen naturally in birds. In none of his pigeons has anything other than a local lesion or a local and a glandular lesion followed; moreover, the disease so induced instead of progressing has (as told by the examination of birds at different dates after infection) retrogressed, and in some disappeared. (2) The avian tubercle bacillus, as tested from various kinds of birds, is pathogenic to the guinea pig in a very limited degree. (3) The human bacillus is not convertible into the avian by inoculation into the bird, *i.e.* the bacilli are not identical. Theoretically it would, of course, be quite possible that the human bacillus after its insertion into the pigeon might lose certain of its characters and become incapable of exciting more than a trivial disease in the guinea pig or in the human subject from which it was originally derived. His experiments do not, however, support this theoretical possibility. Using pigeons into the muscular and subcutaneous tissues of which a salt emulsion of human tuberculous sputum had been injected, he adopted the method of making a salt suspension of the spleen from these birds, killed at different dates after their inoculation (one week, two, four, six, and eight weeks), and injecting this into the subcutaneous or muscular tissues of guinea pigs. In addition he similarly used the local lesion produced in the same pigeons. A fact of great importance to observe here is that the spleens of these pigeons in no case presented any naked-eye disease. In each bird there was a lesion at the site of inoculation; in the birds allowed to live the longest this was of the smallest extent. Although there was no disease of the spleen, the salt suspensions of this organ in every instance produced not merely a local lesion in the guinea pig, but a general tuberculosis. The human bacillus after a sojourn of as long as eight weeks in the spleen produced the glandular and visceral disease in the guinea pig as though it had been transferred directly to this animal from human sputum. It did not produce merely a local or a local and glandular disease, such as it should have done had it acquired the characters of the true avian microorganism.

British Medical Journal, November 23, 1907.

Some Types of Conjunctivitis.—H. H. B. Cunningham refers to the catarrhal and phlyctenular types and to ophthalmia neonatorum, presenting nothing essentially new. Under the heading of chronic catarrhal conjunctivitis, he refers to the form referable to the bacillus discovered by Morax and Axenfeld in 1896. This organism is decolorized by gram, is a diplobacillus, and difficult to grow in culture. This variety of inflammation is known sometimes as "chronic angular conjunctivitis." The subjective symptoms of this affection are very definite: an aching of the eyes, a feeling of heaviness in the lids and of sand in the eyes, which becomes more marked towards evening; the lids are glued together in the morning, and the patient will say that he has to bathe the eyes in order to open the lids. Objectively there is no swelling of the conjunctiva; the fornices and palpebral conjunctiva are injected; there is, if anything, diminished secretion. In angular conjunctivitis the edges of the tarsal plates are injected. This condition does not, as a rule, resolve spontaneously, but goes on to involve the edges of the lids, causing loss of the cilia and in elderly people it will cause eczema of the skin of the lower lid, which in its turn will set up ectropion. The treatment may be divided into general and local. In the first place, we must remove the patient into better hygienic surroundings, or protect his eyes by means of goggles from the effects of dust, etc., and prescribe suitable glasses for any error of refraction; locally, an astringent lotion, such as alum, tannin, or zinc sulphate, is used to bathe the eyes, and a simple ointment is placed inside the lids night and morning.

Berliner klinische Wochenschrift, November 11 and 18, 1907.

The Nature of the Leucocytes in the Urinary Sediment in Nephritis.—Schnütgen says that ordinarily the leucocytes occurring in the urinary sediment in cases of nephritis are spoken of as pus cells. Senator nearly twenty years ago pointed out that in Bright's disease, taking the term to mean nonsuppurative affections, the leucocytes of the urine were not polymorphonuclear cells, but mononuclear cells. This fact has not received the attention that it deserves. It is now known that lymphocytes also take part in chronic inflammatory processes and the cells present in the tissues in chronic nephritis are mostly lymphocytes. In ten carefully selected cases of nephritis in which the urine was collected under precautions designed to prevent contamination with smegma or vaginal mucus and was promptly examined, it was found that lymphocytes occurred in the sediment. In order to demonstrate these Pappenheim's methyl green stain was found very useful. This consists of three parts of methyl green and two parts of pyrolin in saturated aqueous solution. The sediment is first washed with salt solution and is then stained in the hanging drop. The author believes that examination with this end in view will be of service in differentiating suppurative renal affections from Bright's disease.

The Adrenalin-like Action of the Serum After Nephrectomy and in Nephritis.—Eichler has repeated the experiments of Schur and Wiesel and others who have stated that mydriatic substances are present in the serum of nephritics and of nephrectomized rabbits. This property is supposed to be the result of an increased activity of the chromaffine system consequent on the interference with or abolition of the renal function. As a test object the eye of the frog is used. After enucleation it is exposed to bright light to bring about maximum myosis, and it is then immersed in the fluid to be tested, the other eye serving as a control. Eichler investigated the serum of nephrectomized rabbits, that of nephritics, and of rabbits in which a nephritis had been induced by the injection of uranium nitrate. Both of the former gave evidence of containing a mydriatic substance, but the tests on the latter showed only a slight tendency in this direction, the serum having very little mydriatic power and the ascitic fluid none at all. The serum that reacted positively did not, however, raise the blood pressure when injected into rabbits, but the author regards this as natural, since the pupillary reaction is sufficiently delicate to respond to the presence of one part in a million of adrenalin, while one-tenth of a milligram is the minimum dose that will affect the blood pressure in the cat.

The Value of the Cytoscopic Examination of Transudates and Exudates.—Ettinger reports the results obtained in the cytoscopic examination of 103 effusions from 89 patients, involving the pleura, peritoneum, and cerebrospinal canal. He concludes that examinations of this sort by themselves not only do not afford positive information in regard to the etiology of individual cases, but may even be misleading in differentiating between exudates and transudates. The occurrence of lymphocytes alone in a fresh exudate is very much in favor of a tuberculous process, though not invariably so. On the other hand, the presence of neutrophiles, even in very great numbers, is not at all incompatible with tuberculous processes. Epithelial cells also are not pathognomonic of the latter condition, as they may occur in inflammatory effusions. The latter may also change very markedly from time to time in regard to the number of endothelial cells present. Cytoscopy is therefore to be regarded as a useful adjunct to the other clinical methods, but does not possess a decisive value. In regard to the technique of making the preparations, the author recommends washing the centrifuged sediment with salt solution before fixation on the microscopic slide.

Münchener medizinische Wochenschrift, November 5, 12, *and* 10, 1907.

The Genesis of Albuminuria.—Schmidt refers to the fact that it is generally considered that the albumin contained in nephritic urine emanates from the blood. It is assumed that inflammatory changes in the kidney interfere with the integrity of the renal filter and permit serum albumin to pass through and emerge in the urine. Only some of the formed elements are considered as being of renal origin. Schmidt suggests that this view may not be altogether accurate and that perhaps all or almost all of the albumin comes from the renal parenychyma itself. He points out that just as any inflamed organ, for example, the serous membranes or the epidermis deprived of the cutis, may pour out albuminous exudate, so the inflamed kidney may be the seat of an albuminous exudation which will be the richer in albumin the fresher, the more intense, and the more extensive the pathological process is. This exudate may therefore be considered as a sort of wound secretion from the kidney. The point is of more than theoretical interest, for the albumin in physiological or orthostatic albuminuria would probably not have this origin, and by the development of appropriate tests it might be possible to evolve differential diagnostic measures founded on this principle.

Experimental Hypertrophy of the Islands of Langerhans.—Lazarus describes experiments on guinea-pigs that were given phloridzin or adrenalin during long periods of time, either by injection or by mouth. The phloridzin animals showed a very great hyperplasia of the pancreas, in which the enlargement of the islands was most marked, and the adrenalin animals showed similar though less pronounced lesions. Well-marked arteriosclerosis was present involving particularly the abdominal aorta. The author considers that his experiments demonstrate the functional and anatomical independence of the islands, which are sharply differentiated from the gland tissue, and show that it is possible to increase the numbers and size of the islands experimentally as well as to augment their blood supply. It is likely that the islands have some function in regulating sugar metabolism and that it is possible that in human diabetes some therapeutic application may be made of this principle. Phloridzin diabetes is different from the disease in man, for in the former there is hypoglykemia with hypertrophy of the islands, while in the latter there is hyperglykemia and frequently atrophy of the islands. Further experiment is necessary to determine whether the islands of the human pancreas in diabetes are susceptible of stimulation by the use of phloridzin.

The Action of Pancreatin in Carcinoma.—Hoffman studied the effect of this ferment on a carcinomatous new growth of the external auditory meatus occurring in a woman of sixty-eight years. Sections of the tumor showed that it was a carcinoma, and it recurred after operation, finally becoming inoperable. Pancreatin was applied locally and the ulcerating surface became clean, the pain and hemorrhage ceased, and the growth became smaller. The action of the ferment was later restricted through the fact that epidermization took place over a large portion of the growth. This new formed skin was purposely not removed mechanically, as it was desired to study the effect of the pancreatin alone. The patient died suddenly, apparently of embolism, without any meningeal symptoms. Examination of the tumor tissue showed extreme edematous infiltration and moderate cellular growth of the connective tissue. The capillary endothelium was swollen and there were the evidences of deep-seated degeneration, but whether these were the result of the action of the pancreatin or not is uncertain. The lesions resembled those of erysipelas and the author suggests that the effects of this disease, the cautery, and in part the Röntgen rays may act on carcinomatous lesions in somewhat the same way as the pancreatin. He also suggests that pyocyanase, on account of its proteolytic and bactericidal properties, may be found of use in the treatment of inoperable cancers.

Vital Staining of the Spirocheta Pallida.—Mandelbaum describes a method of staining these spirochetes in the living condition. Serum from a chancre or fluid from a mucous patch is placed on a cover glass to form a hanging drop. To this drop is added a loop of Löffler's methylene blue and another loop of decinormal sodium hydrate solution. On examining with the oil immersion lense the spirochetes will be seen at the edge of the drop as delicate pale blue structures which are very different from the *Spirochæta refringens*. In some cases the movement of the spirochetes continues in the preparation and may be seen.

Pyocyanase in the Treatment of Infectious Diseases.—Emmerich describes the effect of the enzyme pyocyanase, formed by the growth of the *Bacillus pyocyaneus*, in inhibiting the growth of and destroying other bacteria. The preparation is obtained by filtering three-week-old cultures through Berkefeld filters and concentrating in vacuo to one-tenth volume. This enzyme destroys the cells of the *Bacillus pyocyaneus* itself as well as those of diphtheria, cholera, typhoid, plague, anthrax, and strepto-, staphylo-, and gonococci. In diphtheria, when sprayed into the throat two or three times a day for two or three days it causes the destruction of the bacilli in the false membrane and in the mucous membrane and prevents the development of those that are not killed. The pyocyanase also has the property of combining and rendering inactive the diphtheria toxin and through its proteolytic power dissolves the false membrane. It furthermore kills and inhibits the growth of the *Streptococcus pyogenes* and staphylococcus, and finally, encourages the return of the mucous membrane to the normal condition. Emmerich reports in detail the histories of a series of cases in which the remedy was used with good effect, one of the patients being the venerable Max Pettenkofer. The author does not recommend the pyocanase as a substitute for antitoxin, but as a very important and effective adjuvant to this.

Acute Circumscribed Edema of the Optic Disc.—Handwerck discusses the condition of acute circumscribed edema with which the name of Quincke is usually associated. Edema of this sort may occur not only on the surface of the body and in regions directly accessible to sight, but also in any of the internal structures, including the brain. On this assumption many acute transitory functional disturbances of the most varied sorts may be explained, and in particular the author calls attention to the possibility of cerebral disorders depending on this cause. In support of this contention he describes a case coming under his own observation in which the edema involved the optic nerve. The patient was a woman of seventy-three years, who for some time had been subject to the appearance of typical edematous swellings occurring about the head and neck, and in one instance involving one-half of the tongue. On one occasion she suddenly began to see objects like white butterflies dancing before one eye. Ophthalmoscopic examination revealed a swelling of the disc amounting to two diopters. The symptoms gradually subsided, and two and a half weeks later no abnormality of the eye ground could be detected. The author considers that all other possible explanations of the lesion, such as thrombosis or embolism of the central artery, could be excluded.

The Results Obtained in Tuberculosis Sanatoria.—Croissant presents an exhaustive series of statistics relative to the results obtained by the sanatorium treatment of tuberculous patients in various stages of the disease as compared with those obtained outside of institutions. While the results of this analysis are not particularly favorable to the institutions, the author considers that the spirit of pessimism that has lately made itself felt in this connection is not justified, even though it is unlikely that sanatorium statistics will ever be able to present results imposing from the numerical aspect. The greatest good is achieved not in point of numbers, but in individual cases, and this is not evident from statistics. In the earlier stages but little more is accomplished within the institutions than outside and therefore it is hardly necessary to set the standard for admission to these so high. More advanced cases must be kept long enough to effect a real cure, longer than is usually the case, and such patients when discharged serve as a very potent means of education and prophylaxis among the masses. A point of the greatest importance is to improve the social condition of the poorer classes in regard to dwellings and mode of life.

Experiments on the Localization of the Cerebellar Centers.—Negro and Roasenda, after exposing the cerebellum in rabbits excited it with the faradic current to determine the motor excitability of single points of the cerebellum. They give these conclusions: 1. By unipolar excitation of the cerebellum there are obtained constantly muscular contractions of the corresponding side, which coincide in time with the stimuli used, after a slight period of latency. 2. With a more intense excitation a contraction is obtained of the homologous muscles of the opposite side. By using electrolysis of the cortical substance to separate the cerebellum from the cortex of the cerebrum and repeating the foregoing experiments the same results were obtained. The conclusion was that faradic excitation of the cerebellar cortical centers reaches the spinal medulla and muscles without passing through the subcortical paths, and the cerebellar impulses are independent of the cortical motor zone.—*La Riforma Medica.*

Book Reviews.

Immune Sera. A Concise Exposition of our Present Knowledge Concerning the Constitution and Mode of Action of Antitoxins, Agglutinins, Hemolysins, Bacteriolysins, Precipitins, Cytotoxins, and Opsonins. By Dr. Charles Frederick Bolduan, Bacteriologist, Research Laboratory, Department of Health, City of New York. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1907.

The science of medical bacteriology, and especially that branch or development of it dealing with the chemistry of the blood serum, and the wonderful actions and reactions of the complex proteins which it contains or which can be developed in it, is advancing so rapidly that the ordinary practitioner, far from laboratories and research institutions, finds it increasingly difficult to keep pace with it. Many of the older men indeed, those born in medicine before the advent of this science, have but a hazy notion of what it all means. They would gladly acquaint themselves with the theories of bacteriolysis, hemolysis, toxins and antitoxins, agglutinins, and the host of other new things with strange names, but their time for study is limited and they shrink from the attempt to master the subject with all its complexities. By such as these especially this book will be welcomed. It presents the entire subject in the small compass of 150 pages, and presents it, moreover, in so tangible a form and expressed in such clear language that anyone, with careful reading and a little diligent study, can gain the knowledge of the mode of action and interaction of these serum constituents which is essential to an apprehension of the subject and to enable one to follow the further developments of the science as they are presented to him in the periodical literature. Ehrlich's side-chain hypothesis, which is the basis upon which the entire theoretical construction is erected, is very clearly described and illustrated, and once that is mastered one has the key to the entire subject. The main chapters are on antitoxins, agglutinins, bacteriolysins and hemolysins, precipitins, cytotoxins, opsonins, snake-venoms and their antisera, and serum sickness. The book would have been even more useful had the author added a glossary, for the language of the science is, literally, Greek to the beginner, and much time spent in turning back to look up the meaning of strange words would be saved by a list of definitions at the end of the book. The subject has outrun the dictionaries, and a glossary would widen the scope of a work such as this by making of it a supplement to any of the general medical dictionaries.

The Internal Secretions and the Principles of Medicine. By Charles E. de M. Sajous, M.D.; Fellow of the College of Physicians of Philadelphia; Member of the American Philosophical Society, of the Academy of Natural Sciences of Philadelphia, etc.; Knight of the Legion of Honor and Officer of the Academy of France; Knight of the Order of Leopold of Belgium, etc.; Formerly Lecturer on Laryngology in Jefferson College and Professor of Laryngology and Dean of the Faculty in the Medico-Chirurgical College; Formerly Professor of Anatomy and Physiology in the Wagner Institute of Science. Volume Second. With Twenty-five Illustrations. Philadelphia: F. A. Davis Company, 1907.

This is an effort, and an heroic one, to place the science of therapeutics upon a positive basis, to explain the curative action of drugs (disputed by those who cannot cure disease themselves and who will not accept facts unless the reason for them can be demonstrated), and to dispel the gloom of therapeutic nihilism which at one time threatened to annihilate the art, if not the science, of medicine. This volume is the logical complement of the author's first volume, published over four years ago, treating as it does of the practical application to the cure of disease of the doctrine regarding the internal secretions developed in the earlier volume. The chief of the internal secretions is probably the adrenal, as this, the author says, is the oxidizing agent in the blood and also the principle which sustains the life of the cells. The thyroid secretion, as is well known, is also of extreme importance as regards metabolism; how it acts, in the cure of myxedema for example, is unknown, but Sajous asserts that it indirectly promotes the adrenal secretion by exciting a center in the pituitary body which in turn stimulates the adrenals to increased secretion. The function of this pituitary body, the somatic brain as he calls it, is to protect the organism against disease. It is a test organ which detects the presence of toxins in the blood and then excites the adrenals to secrete their oxidizing principle; this principle, when in excess, stimulates the formation of leucocytes (hyperleucocytosis) and also excites the pancreas to produce trypsin, and these three agents—the adrenal secretion, the nucleoproteid (the product of the leucocytes), and trypsin—together constitute an auto-antitoxin to destroy the bacteria and their products. The thyroid, he says, is the source of the opsonins which prepare the bacteria for englobement by the leucocytes. This protective mechanism of the body may be sufficient in itself to repel disease, but often it is inadequate and then it must be stimulated to increased activity by drugs and other ordinary therapeutic measures. It is not by serum therapy, at least not wholly, that disease is to be combated, but by the remedies in common use. These, however, are no longer to be given empirically, for the doctrine of the internal secretions and of the interrelations of the various closed glands explains their action. They do not antagonize the disease directly, but by stimulating the protective agencies—the closed glands—to increased activity.

The theory developed and practically applied in this volume is a fascinating one and, if true, will explain many mysteries and will put the practice of medicine on a firm scientific basis; it will give the physician confidence in his remedies and certainty in their application, and will remove from therapeutics the reproach of empiricism and make of it in time an exact science. The book is one not to be read casually, but to be studied with care. Whether the reader accepts the logic of the author and agrees with his conclusions or not, the study of the work can but stimulate thought and make of the student a better and more enlightened therapeutist, one who will in future seek to know the mode of action of his remedies and give them with discrimination.

Dr. Sajous has written a serious work, one which must, if its conclusions are as correct as its reasoning is sound, revolutionize the practice of medicine. It has the merit of striking originality and it deserves the serious consideration of all thinking men in the profession.

On Treatment. By Harry Campbell, M.D., B.S., F.R.C.P., Physician to the Northwest London Hospital, and to the Hospital for Diseases of the Nervous System, Welbeck Street. New York: William Wood & Company, 1907.

This is not a formal treatise on therapeutics, but a series of chatty essays on various subjects more or less closely related to treatment—hygienic, dietetic, and medicinal. By chatty we do not mean superficial, for the author goes deeply into many of his subjects and treats of them in a thoroughly scientific and philosophical manner; but he does it all in an easy and colloquial style that charms the reader and leads him on from one subject to another, holding his interest and compelling attention without wearying. The essays are not all on treatment, but deal also with such subjects as the education of the physician, his personality, both physical and mental, the examination of the patient, consultations, quackery, etc. The book is one that can be read in leisure moments for recreation, yet not lightly, for it contains much to stimulate thought and is full of practical suggestions.

Surgical Diseases of the Chest. By Carl Beck, M.D., Prof. of Surgery in the New York Post-Graduate Medical School and Hospital, etc. With sixteen colored and 162 Other Illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

Dr. Beck in the preface to his book calls attention to the fact that abdominal surgery seems to have entirely absorbed the attention of those writers who desired to exploit some particular anatomical region in the form of a monograph. Thus the thoracic cavity has been very much neglected and but few special works on this subject have been published. The field is a most important one, made more so in fact by the development of three great aids to diagnosis and treatment of diseases of this locality—bacteriology, asepsis, and the Röntgen rays. Dr. Beck emphasizes the importance of these factors without ignoring, however, the value of the earlier work. The diagnosis of the various thoracic conditions is also made an important point, to a greater extent than would be expected in a book of a distinctly surgical character. The section on pyothorax deserves particular notice, for it is with this field that the author's name has been largely associated. Pyothorax can be treated only by thorough surgical exposure and drainage of the pus cavity, and this only accomplished by a sufficiently large opening, which involves resection of the rib. Strange to say, this method is still antagonized by many physicians. The interesting historical references contained in the book show that thoracotomy with resection of the rib and drainage were practised in early Greek and Roman times, and with good success if we are to believe the records. Dr. Beck's book constitutes a valuable addition to our array of special surgical treatises.

Stated Meeting, Held November 19, 1907.

DR. WARREN COLEMAN IN THE CHAIR.

An Inflammatory Abdominal Tumor.—Dr. ALBERT KOHN made this report. The patient was a Russian, a capmaker by occupation, 47 years old. He had been in this country twenty years. His family and past history were practically negative. His present illness began gradually one week before admission to Mt. Sinai Hospital, with pains in all the extremities, headache, and chilliness. Three days later he developed severe burning pains in the left hypochondrium and had to go to bed. His abdomen began to distend and he vomited twice. For three days he had to be catheterized; then he voided spontaneously. He lost all appetite. Had severe occipital headache. Coughing increased the pain in the left hypochondrium. The physical examination showed a man well nourished but pale. There was slight ophthalmos. There was a perforation of the septum and a fetid ozena. The abdomen was prominent and symmetrical. There was a slightly movable dullness in the left flank. In the left hypochondrium, extending from the left nipple line to the midline of the abdomen and down to the level of the umbilicus there was felt a mass the size of an infant's head, apparently spherical in shape, resistant, almost cystic to the touch. It was slightly tender on deep pressure. It moved up and down with respiration and over it was dull tympany. When the patient sat up, the lower border of the mass could be felt at the level of the umbilicus. The white cells numbered 6,800, the polymorphonuclears were 72 per cent., eosinophiles 2 per cent., large lymphocytes 6 per cent., small lymphocytes, 20 per cent. The temperature was 101.4°, pulse 80, and respiration 34. Two days after admission there was no tenderness over the mass. On inflating the colon, tympany over the mass increased and the tumor became distinct. Two days later the tumor had markedly diminished in size, and eight days later could no longer be felt. The diagnosis was made of an inflammatory abdominal tumor.

Chronic Splenic Anemia.—Dr. CHARLES H. LEWIS reported this case. Chronic splenic anemia was the term given to a condition of enlarged spleen, of unknown etiology, without leucocytosis or glandular enlargement, with a secondary cirrhosis of the liver and the subjective and objective signs and symptoms ordinarily accompanying or following these lesions, with or without an anemia of varying grades. The patient was an Italian, 40 years old, one year and a half in this country. Four or six months prior to his admission to the Columbus Hospital he experienced some dull and transient pains in the right hypochondrium and on investigating the painful area he encountered a hard swelling which was tender of pressure. Subsequently his pains increased in intensity and frequency and he noticed that his abdomen began to swell. His appetite failed, his breath became short, and his work grew unusually burdensome. He tired easily and finally was compelled to consult a physician who, after a period of medication, tapped his abdomen twice and then sent him to the hospital. During this period there were no skin or mucous bleedings, no hematuria or melena, and no pigmentation. The family history was irrelevant. He had practically been well until this present illness. He was a fairly well nourished man with well marked signs of ascites, and a large tumor of some sort was found in the left hypochondrium. Aside from that nothing material was noted. The leucocyte count was 8,500. After tapping the abdomen the tumor was easily recognized as an extremely large spleen in which two notches were plainly palpable. It was not notably tender on pressure. The border of the liver was readily felt, the left lobe extending well over the epigastrium. Its edge was firm and roughened. The aspirated fluid measured about two gallons; it had a specific gravity of 1.006 and the qualities of an exudate. The blood examination showed a moderate secondary anemia of a chlorotic type. No new symptoms manifested themselves during his stay in the hospital. The treatment was tonic and symptomatic but with no demonstrable retardation of the gradual and progressive loss of muscular and cardiac strength. The temperature remained normal until the day before the end, when it rose to 101°. He died nearly two months after admission, and at least six to eight months after his first symptoms. He was tapped ten times while in the hospital. No abdominal or retroperitoneal glands were enlarged. The stomach was dilated but the vessels were not varicosed; no hemorrhagic areas were seen. The spleen was of uniform dark blue color, of normal consistence, and the proportions were relatively normal. The notches were well marked. The weight was excessive, about four and a half pounds, about twelve times the weight of the normal spleen. The liver was enlarged and nodular and was nearly one-half larger than the normal liver. Its surface resembled closely that of the atrophic hobnailed liver, but the nodules were larger as though due to a hyperplasia rather than to the contracting connective tissue of an atrophic cirrhosis. While pathologically this case came well within the chronic splenic anemias, particularly the later stage known as Banti's disease, it lacked some features usually present.

The Bacillus Coli Communis as an Occasional Cause of Typhoidal Infection.—Drs. WARREN COLEMAN and T. W. HASTINGS presented this paper, which was read by Dr. Hastings. The close biological relationships of the various members of the typhoid-colon groups, and the fact that the paracolons were more nearly related to *Bacillus coli* than to *Bacillus typhosus*, naturally led to the suspicion that some strains of *Bacillus coli* also might be capable of producing the typhoid symptom-complex. Their attention was first called to the question of systemic infection by the colon bacillus pursuing a typhoidal course in 1903, when Buxton and another recovered colon bacilli from the blood of two patients in Bellevue Hospital who were considered clinically to be suffering from mild typhoid fever. These cases had already been reported. They reported the histories of the only cases they had been able to find which would bear analysis. They wished to emphasize the fact that they were not attempting to prove that all strains of *Bacillus* coli were capable of causing a typhoidal fever. It was well known that the cases were not numerous, that the colon bacillus might invade the blood and produce a typical sepsis. Fehling had recently stated that only eight cases had been published in which the colon bacillus had been obtained during life from the blood. While the number of such cases was undoubtedly small, Fehling placed it too low. It was probable that the colon bacillus might pass into the blood without developing there, and later appear as the cause, or as a secondary invader, of localized inflammatory processes. The frequency with which the *Bacillus coli* entered the blood immediately before or after death had been probably overestimated.

American Mineral Waters in the Light of Recent Analyses.—Dr. JAMES K. CROOK read this paper. He said it was well known that mineral waters possessed no mysterious or occult virtues in the treatment of disease. No mineral water would be accepted by the medical profession for alleged medicinal properties supported only by the testimonials from bucolic statesmen and romantic old ladies. In these days it might almost be said that the most important thing about a mineral water was a trustworthy analysis. It was a matter of keen disappointment to learn by these new analyses how much mistaken they had been in regard to the chemical constitution of some of their best

known waters. In forming conclusions in reference to the extremely unsatisfactory state of affairs developed by the Bureau of Chemistry investigations certain facts came up for consideration. 1. A great majority of the advertised analyses of our mineral waters were made many years since, when methods were not so exact as at the present day. 2. Some mineral springs are sensibly influenced by the wetness or dryness of the season both in strength and in volume; the greater the volume of the water the weaker it was in mineral ingredients. 3. While many springs were of deep origin and showed no apparent fluctuations in their rate of flow, there was no positive proof that even these had not become more or less modified in character during the long period since the old analyses were made. The subterranean aqueous current which constituted a spring when it reached the surface, could not be counted on continuously to come in contact with earth strata which yielded a uniform produce to its solvent power. Underground streams, as well as those on the surface, were liable to change their course and, while losing certain of their former contents might acquire new ones. 4. The fact must not be overlooked that the Government analyses were in each case made from samples purchased in the open market. It was therefore possible that some of the waters examined by the Bureau of Chemistry were spurious or adulterated. 5. The chemical ingredients set forth in the analyses of mineral springs represented hypothetical combinations only. No chemist maintained that the salts set down in his analysis existed in exactly that form in the water. With all due allowance for the above considerations, it must be confessed that we were in a state of inexcusable ignorance regarding the chemical constitution of these agents. Mineral water therapeutics must remain in a backward and unsatisfactory state until this was remedied. All of the mineral springs should be submitted to analysis at least once in ten years, or until we were able to arrive at a correct estimate of their potency, and whether they were gaining or losing in strength. The decennial revisions of the works of materia medica and pharmacy should present a brief acount of the mineral waters, so that the medical practitioner might be in possession of as authentic and authoritative a source of information regarding these as he had in the case of other therapeutic agents.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 14, 1907.

DR. GODFREY R. PISEK IN THE CHAIR.

A Case of Thyroid Implantation in a Child.—Dr. LOUIS FISCHER presented this case. The child was first seen by him December 8, 1902, when she was two years old. She could neither walk nor talk. The tongue was very thick and protruded constantly. The lips, eyelids, and the skin of the face were thickened, coarse and rough. The nose was short and flat. The skin had a jaundiced appearance. The fontanelle was widely open anteriorly and posteriorly. The face was broad and the eyes set very wide apart. There was a marked depression on each side of the temporal bone. There was also a frontal protuberance. She had nine teeth when twenty-two months old. The first tooth appeared one month after thyroid treatment was commenced, or when the child was sixteen months old. The body was well developed and fat. There was no evidence of rickets. The internal secretions were very torpid. Constipation was very obstinate. The child had a great fear of water. The hair was thick. The thyroid gland could not be felt. The pulse was 90 and the temperature subnormal. The respiration was 16 while the child was quiet, and 24 when crying. The urine was normal. Treatment was commenced by giving one grain of thyroid three times a day; this dose was rapidly increased so that after the first week the child took two and a half grains three times a day. This treatment, together with attention to diet, etc., was continued and the child developed very fast. The bowels became regular and the teeth appeared at regular intervals. The growth in one month amounted to 3⅛ inches. At the end of one year she had grown 13½ inches. She had measles in 1906, the rash remaining visible for about two months, particularly on the legs. She had a bad breath at all times. Her hair fell out about once a year. The skin peeled off, especially on the palms and soles. There was constant tremor. She had laughing spells which sometimes continued all day. Her mother believed the child masturbated. Her mental condition was about equal to that of a child eighteen months or two years old. She was taken to Mt. Sinai Hospital, where Dr. Lilienthal operated May 8, 1907, transplanting the thyroid through an abdominal incision. She remained in the hospital about two months. Normal conditions prevailed during the first month after the operation and she did not seem to suffer because of the stopping of the thyroid feeding. Later fever developed, the child became emaciated, and a diagnosis of pyelitis was made. She returned to her home and made an uneventful recovery. She was now taking five grains of thyroid three times a day. Her condition had greatly improved. She sang and played with her toys and was far more intelligent than before the operation. Implantation of thyroid grafts from animal to man by using sheep's thyroid had been done by Horsley. An entire lobe or part of the gland was removed from the animal and buried in the connective tissue. Human thyroids were used in 1883 by Kocher and others, but the combined results were no better with the homethyroids than those with the heterothyroid gland.

Report of a Case of Congenital Goiter in a Child, with Operation.—Dr. EDWARD WADSWORTH PETERSON reported this case. The patient was five weeks old when admitted to the hospital. The patients were healthy. There was no syphilis, tuberculosis, cancer, or goiter in the family. The mother had had one miscarriage at the second month. This was her first child. The labor was easy and uneventful. The child was normal except for a swelling on the right side of the neck. There was difficulty in breathing for the first two hours after birth, but this soon subsided and up to the time of admission there was no dyspnea or dysphagia. Apparently the tumor caused her no inconvenience whatever. Examination showed an enlargement on the right side of the neck anterior to the sterno-cleidomastoid muscle, just below the lobe of the ear, filling up the submaxillary space, and extending downwards nearly to the clavicle. It was smooth, moderately firm in consistence, and did not fluctuate at any point. Below and on the sides there were distinct palpable nodulations. At operation the tumor was dissected out without any difficulty. Several times during the operation work had to be suspended as the infant ceased to breathe. For twelve hours after the operation it was necessary to resort to artificial respiration occasionally. Except for the high temperature following the operation there were no special features until the ninth day, when the child had a convulsion lasting about five minutes. On the thirteenth day there was twitching of the extremities, and the eyes rolled from side to side. On the fourteenth day there were almost constant slight convulsive movements of the hands, arms, and legs, with twitching of the facial muscles, and rolling of the eyes. The pathologist reported the tumor to be a congenital goiter. The interesting features in this case were the presence of a congenital tumor which proved to be a goiter; the abnormal location of the thyroid; the accidental thyroidectomy; the development of tetany on the ninth day which continued until thyroid extract was administered.

DR. HERMAN SCHWARZ asked if the child was still getting thyroid extract. Also whether or not the tumor had

been examined to see whether the parathyroids were there or not.

Dr. Peterson replied that the child was still taking thyroid extract. In removing the tumor he split the capsule and enucleated the gland proper. The parathyroids were not removed. He did not know how to explain the tetany, a condition which only developed when the parathyroids were removed. He expected to show the patient at some subsequent meeting.

Proteid Incapacity in Infants and Children.—Dr. Henry Dwight Chapin read this paper. He said that a number of forms of proteid were used successfully in infant feeding, and no pediatrician in practice confined himself to any one form. The day had passed when it could be said that an infant had proteid incapacity merely because it did not tolerate whole milk or diluted cow's milk. In many instances when the character of the proteids was changed infants not well had commenced to thrive. These infants really had capacity for certain forms of proteid but showed great capacity for other forms. Infants could not thrive without proteids, and if they had real proteid incapacity they would soon die of inanition. Therefore, the use of the term proteid incapacity should be restricted to those cases where no forms of proteid were long tolerated, and the term proteid idiosyncrasy applied to those where one form was tolerated when another was not. The cases of proteid incapacity which were treated successfully were really those of proteid idiosyncrasy, caused possibly by impaired digestive organs or by conditions they did not understand but which undeniably existed. It should always be borne in mind that proteid did not mean a simple substance as did fat or carbohydrate, but a series of highly complex bodies which differed in form, taste, composition and nutritive value. It was possible that many of the poor results in infant feeding were due to the exclusive use of proteids deficient in iron and phosphorus. In conclusion it might be said that the class of cases which actually showed actual nently physically unfitted, and those who might be only proteid incapacity was made up of those who were permatemporarily unfitted, through digestive disturbances, for digesting proteids. Those in the first class would die. Many in the second class could be saved by mother's milk only, or by the use of very light fluid diet that remained fluid or soft in the stomach, until digestion became stronger. In some of these cases the use of vegetable proteid with milk proteid, especially vegetable proteid rich in iron (oat or legumen), which he had termed mixed proteid feeding, might cause a general upbuilding, and improved digestion would follow. Whenever there was difficulty with proteid in a fairly well nourished child mixed proteid feeding, using high proteid gruels with the milk, should be tried, for there might be only proteid idiosyncrasy.

Carbohydrate Incapacity in Infants and Children.—Dr. Charles G. Kerley read this paper. He said the results of clinical observation drawn from his own work without theories would be given. Among the sugars the most usual manifestation of sugar excess or sugar incapacity was regurgitation between the feedings. This was particularly apt to happen if cane sugar was used. Maltose might produce this symptom but in lesser degree. The capacity for milk sugar was greater than for maltose or cane sugar; it was assimilated with less disturbance than the other sugars, and might be given in larger amounts. It would thus serve a better purpose as a food in supplying a greater amount of energy and heat producing material. Cane sugar, on account of its sweetness and difficulty of digestion, could be taken ordinarily in but half the amount that milk sugar might be taken. He used cane sugar only under conditions in which the expense of milk sugar was a burden. Vomiting and regurgitation often attributed to fat incapacity would be found dependent upon sugar excess. Fat and sugar might produce this regurgitation with sugar as a most prominent agent. In vomiting sugar should be reduced as the first step in the treatment for the reason that fat was the more valuable nutritional factor of the two, supplying twice the number of calories. The claim that milk sugar might produce alimentary glycosuria in infants was not without foundation. Maltose incapacity was evidenced by regurgitation and vomiting and through its laxative properties. A useful field for this form of sugar was to supply carbohydrate to the constipated bottle-fed. The systemic manifestations of sugar incapacity in infants were few. Irritability, scalding urine, and eczema were the most frequent signs of intolerance or excess. There was no age limit for cooked starch feeding. Starch indigestion was supposed to manifest itself through a distention of the abdomen by reason of fermentation of starch in the intestine. This might take place, but it was a very inaccurate sign. The stools of starch-fed children presented practically the same gross appearance whether they contained free starch or not. If starch was not digested it did but little harm. The removal of the starch from the food in children with distended abdomen produced but little or no effect on the tympanites in most cases, the distention being due to other causes. The chief harm from starch feeding was in constipation, which sometimes followed its use. This might be prevented in the use of some dextrinizing agent which converted the starch into a laxative maltose. It was rarely wise to use starch in stronger mixtures than three per cent. in children under one year of age. Cane sugar capacity of older children varied greatly. The so-called lithemic children were all sugar susceptibles. The most usual manifestation of sugar poisoning was a persistent hyperemia of the mucous membrane of the upper respiratory tract. There was not the slightest doubt in his mind but that the consuming of large quantities of sugar by the growing population was one of the great dietetic errors of the day.

Fat Incapacity in Infants and Young Children.—Dr. John Howland presented this paper. He said the radical belief that the fat was decidedly the most disturbing element in infant feeding was gaining ground rapidly in this country where top milk modifications had been so generally used. It was by clinical observations that attention was first directed to the question of fat incapacity. The limit to fat incapacity could not be expressed in percentages, for it differed so with each individual child. One saw the greatest differences in infants apparently of equal health in their ability to handle fat. Fat incapacity was very commonly developed under artificial feeding, much less often under breast feeding, and it showed itself suddenly even when the offending diet had been apparently well borne for weeks or even months; when once it developed it had a pronounced tendency to persist. The symptoms of fat incapacity might be roughly divided into gastric, intestinal, and constitutional, although these were more or less associated. Keller first showed with great exactness that an increase in the fat of the food beyond certain limits caused a great increase in the ammonia-nitrogen in the urine. He was led to believe that acids were absorbed presumably from the intestines which passed through the organism without being burned and were paired with ammonia for their excretion. Steinitz, however, was able to prove that with the ingestion of a quantity of cream there was an excessive loss of alkali by the intestine; he also showed that more fixed alkali was actually eliminated than was absorbed. This meant that a constant loss of fixed alkali was going on and fixed alkali was absolutely necessary for the performance of normal processes in the body. The result of this withdrawal of alkalies was the same as if an acid intoxication was present; in fact it was a relative acid intoxication. Any acid intoxication meant that the fixed alkalies ordinarily available to neutralize the acids formed in metabolism were insufficient for this purpose. The ammonia furnished, if for more than a short time, must come from proteid either circulating in the

blood fluids of the body or already built up into an integral part of the organism. In the one case it was depriving the body of materials for building; in the other it was wrecking a part of the structure already built. An acid intoxication interfered with the most important functions of the body and were this the only result would still be sufficient to prove the dangers from an excess of fat.

Dr. John Lovett Morse of Boston, Mass., considered Dr. Howland's paper a most admirable one. But he feared that it might create a wrong impression on people who were not familiar with infant feeding. He was afraid that people who tried to fill in the proper amount of fat were going to do harm. Every one who had much experience in infant feeding knew that too much fat caused symptoms. On the other hand, they knew that a normal breast-fed baby got four per cent. fat in the food. They knew, too, that they could feed babies for years on a modified mixture of three or four per cent. fat, and the vast majority of the babies would do well. Babies did not do well on milk that ran 6, 8, 10, or 12 per cent. fat. This was a point that he thought should be emphasized. It was not the ordinary and proper amount of fat that did harm, but the excessive large fat.

Dr. Rowland G. Freeman believed that, in infant feeding, the element that most often gave trouble was the proteid. He believed that curds influenced and diverted proteid digestion; when one made the proteids more digestible the curds diminished. Pepsin had a marked effect upon the curds, while peptones had no effect whatever. Dr. Chapin had spoken of one class of cases with deficient proteid digestion which would die; he thought it was well to emphasize the fact that this was a small class. Almost all babies, when properly fed, and given proteid in digestible form, would thrive. The babies that died were hospital babies. It was a rare thing for a baby with deficient proteid digestion to succumb to this trouble. When the proteid was not well digested a cereal decoction was most valuable, or whey mixtures, or better peptonized wheys. As to sugars, he thought it was very rare, if the lactose was in normal amounts, that trouble resulted. In a series of experiments made for the purpose of comparing cane sugar and sugar of milk, taking two groups of cases, it was found that a large proportion of the children did as well on cane sugar as on sugar of milk. Still there were many cases that would not do well on sugar of milk. Many did well on cane sugar, but a certain number only did well on sugar of milk. As to the matter of fat, in spite of Dr. Morse's warning, it should be emphasized that fat in large amounts caused disturbances, and he believed that delicate children would do better if the fat was no higher than the proteid.

Dr. E. H. Bartley said that in listening to the papers read he asked why putty-like stools were always composed of either fatty acids or soaps; and in case of alkaline stools, ammonia soaps. That was hardly a correct statement. That was true to a considerable extent, and he had examined many stools and found fatty acids easily dissolved out by ether soaps; there was also proteid in considerable quantities, perhaps not a curd but the residue left from digestion of casein or other material. Many passed stools composed of fatty material which indicated proteid rather than fat indigestion, and strangely enough the two seemed to go together. In cases of fat indigestion, or difficult fat digestion, one was likely to have an excessive amount of ammonia produced; therefore the alkaline stools were not from soaps or fats but from the proteids. An alkaline reaction could come from only one of two sources: either an excessive amount of serum in the intestines, or the administration of an alkali; a possible source was in the alkaline fermentation, so that it often happened that proteid fermentation went on with fat indigestion. It was difficult to analyze what did take place. The alkaline reaction of stools should be more emphasized. Again, there were many stools that were acid in reaction and in the presence of fat indigestion. It seemed to him that the buttocks were often reddened through the irritation of butyric acid rather than from the alkali. An alkaline stool was rather the exception than the rule. In speaking of carbohydrate incapacity, especially of the excessive use of sugar in children from two to ten years of age, he said he had been studying this for many years, and he had tried to fathom the cause of certain symptoms, symptoms to which he himself had been subjected. He said he could develop a headache by eating invert sugar, that was sugar cooked with acid salts. He could eat rock candy or crystallized sugar without producing that effect. But it was the invert sugar that did it. Glucose would do it. He, therefore, concluded that it was the invert rather than pure cane sugar that caused the symptoms. Maltose did not do it to the same extent. Lactose did not do it in his particular case. In children who had sugar incapacity the invert sugars seemed to have a worse effect than cane sugar. He had seen these effects in eating ordinary candy. In such a case there was fermentation or absorption into the circulation; then it passed directly to the liver; therefore, the symptoms might not entirely be due to the fermentation. They came too soon. The effect of the excessive use of sugar in children was most likely to occur from ten to twelve hours after eating. If one did not get vomiting soon after, then next day.

Dr. T. S. Southworth said it was interesting to note the position the different readers took concerning the meaning of the term incapacity. The fact should be recognized that there might be a real incapacity and an apparent incapacity, as well as an absolute incapacity at times and a relative incapacity. So that when the question of capacity was brought up one should look at it from different standpoints. Dr. Chapin had spoken of proteid incapacity and of proteid idiosyncrasy. An incapacity for casein did not imply incapacity for the other types. Dr. Dunn of Boston had brought out admirably in a recent paper a fact, showing that where casein was badly digested, casein could be reduced by the introduction of soluble whey, and so successful gains could be inaugurated. It made a difference in considering the question of incapacity, or relative incapacity, how the foods were manipulated. When one analyzed the methods of men prominent in infant feeding one saw that they arrived at good results in different ways. There were those who by keeping the proteids low were believed to run the fats up considerably higher than perhaps seemed advisable. There were others whose work showed that by keeping fats low they could get the children to take larger amounts of the muscle-making proteid. These results could sometimes be obtained upon proteids and sometimes upon fats by additions made to the mixtures. The results of such additions depended upon the chemical and physical changes produced, whether they were cereals, alkalies, or malted preparations. All agreed with Dr. Kerley's position as to the excessive use of sugars. A good stool was supposed to be a yellow one, yet many such were poor stools. With the further study of them he believed they could have better ideas of the difficulties in infant feeding than they now had simply from a consideration of symptoms alone. He said he would like to take exception to what had been said regarding the so-called curd. When this mass was examined microscopically it would be seen to consist of fatty acids and soaps. But that was not the way they were formed. When one subjected fat to the action of rennet, fat was enclosed in its meshes; there was both proteid and fat. As this passed through the intestine there was a great deal of proteid decomposition. When the mass was spread out and examined there would be found an immense quantity of bacteria scattered throughout. They had destroyed the proteid framework of the mass.

Dr. Louis Fischer said that, in studying the digestive capacity of a given infant, one must consider first, were they dealing with a normal infant and a healthy stomach plus normal functions, or were they feeding a sick infant with abnormal digestive powers. There was a decided difference in the capacity or incapacity of such infants in dealing with the required percentage of fats, proteids, and carbohydrates. A healthy infant might assimilate two per cent. or more of fat during its first month without gastric disturbance. A dyspeptic infant might show gastric disturbances with a two per cent. or less fat. The same rule applied to the digestion of proteids. Proteid indigestion might result from the feeding of one per cent. of proteid in a weak stomach and the same symptoms might continue until one cut down the caseinogen to 0.25. It was in this class of cases that one might be forced to dispense with caseinogen and feed nothing but whey proteid. His experience was that the newborn infant would tolerate almost any formula of fat, sugar, and proteid for a number of weeks because the stomach was healthy. The advocates of whole milk feeding from birth were fortunately not many. In the few cases in which he had seen this method used there invariably was a "stomach breakdown" due to an overtaxing of the individual function from excess of proteids plus the high fat. In artificial feeding one must study the individual condition and if, for instance, there appeared an intolerance for proteids one might be forced to reduce the proteids to such a low percentage that serious consequences, such as rachitis, might follow. The tendency to-day was to overfeed. This overfeeding was not limited to fats and proteids but especially to carbohydrate feeding. The laity had been educated to the belief that infants could not be healthy unless they showed weekly gains; hence stuffing with cream mixtures was in vogue. Rotch, in speaking of a feeding mixture that contained three per cent. of fat, mentioned an anxious mother who added a teaspoonful of cream to each feeding, thus changing the formula which should contain three per cent. of fat to one containing six per cent. of fat. The use of more than a level teaspoonful was another instance where the anxious and well-meaning mother intended to help the physician but usually to the detriment of the baby. If proteid or fat incapacity caused severe gastric disturbances, such as vomiting, colic, or lumpy stools, then the temporary substitution of whey, with or without condensed milk, was useful. Dr. Fischer said he had reported elsewhere several cases of pyloric spasm and, in one of these, the constant vomiting was due to a very high fat. The chemical examination of the breast milk cleared the mystery, showing a five per cent. fat. By pumping off the milk and diluting the same with two parts of water the food was tolerated. Thus it was apparent that what appeared to be an intolerance or a milk idiosyncrasy was really an irritability provoked by the abnormal ratio of the food elements. He mentioned this as an instance of the mother's own milk which disagreed because of the high fat content. In some cases of artificial feeding the gastric machinery would not respond. In addition to dyspeptic symptoms the infant would show atrophic symptoms and emaciate. In this class of cases cow's milk and all modifications of it should be stopped and human milk, and nothing but human milk, would prolong life and develop the infant.

Dr. Herman Schwarz said that some German claimed that the difficulty in cow's milk was chiefly in the casein and a greater number of cases of indigestion were due to the casein, which was due, in turn, to the high fat. Yet Czerny had made the statement that there was no such thing as casein indigestion. There was no doubt that infants could digest starch. He did not believe that by examining the stools and testing for starch with iodine one could determine the child's capacity for starch. High fats were very injurious to infants.

Dr. Chapin said that perhaps he had not made himself clear on the point referred to by Dr. Freeman. He did not mean that complete proteid incapacity was at all common, but he made a distinction between incapacity and idiosyncrasy, real capacity and idiosyncrasy. By changing the proteid often it could be kept down to the right point. In some institutions where one could have fresh air and proper hygienic surroundings proteid capacity would be contributed to. He said he would like to take up the cudgel for fats. Many years ago the pendulum swung for high proteids, while now it swung for high fats. While Dr. Howland's paper was very valuable, he assured Dr. Morse that he had obtained a wrong impression. There were top milks and top milks. The greatest advance had been made when Dr. Meigs brought out the top milk system. Top milk feeding was the best method of giving the baby the proper amount of fat.

Dr. Kerley said that cane sugar was digestible, but one could not give it in equal quantities with milk sugar, grain for grain. In regard to the bacteria in the stools affecting starch, all knew that starch in the intestines was acted upon in adults as in children and a certain amount was destroyed in that way. A great deal was utilized in the youngest children for nutriment.

Dr. Howland, referring to Dr. Morse's criticism, said that he purposely had kept off percentages of fat used. He had tried to point out clinical symptoms met with and how explained. Excessive high fat was dangerous, as all knew; the amount should be between 3½ and 5½ per cent. of fat. The chemical labor involved in metabolic experimentation was tremendous and it was impossible to decide the limit of fat a child could take; he said that that limit was variable. He did not mean to say that skimmed milk mixtures should be used by any means. He believed it was the greatest mistake in infant feeding to use a too high percentage of fat. Steinitz, in considering the alkali in the intestine which caused a relative acid intoxication, meant thereby that not enough alkali in the body to neutralize the ordinary acids formed in metabolism.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 25, 1907.

The President, Dr. Walter Lester Carr, in the Chair.

Annual Reports.—The reports of the Comitia Minora, Treasurer, Board of Censors, Committee on Public Health, Committee on Audit, Committee on Legislation, and of the Milk Commission were read, as well as that of the Counsel, and were ordered to take the usual course. The society had one hundred and ten new members, and thirty-eight were lost by death. It now had a total membership of 2,064 in good standing. The Treasurer's report was listened to with interest. He had a balance of $5,193.21, of which amount $4,917.46 were in the Knickerbocker Trust Company and $12.00 were in checks of suspended banks. The Milk Commission reported that there were nineteen dairies supplying the city with certified milk. The inspectors had visited over three hundred dairies, and had spent two days each week in laboratory work.

Report of the Counsel.—Champe S. Andrews, Esq., made this report. He said that the prosecutions that had been conducted up to May 13, 1907, were instituted for violation of Chapter 308 of the Laws of 1905. The prosecutions since instituted had been under Chapter 344 of the Laws of 1907. The routine work of the society had been conducted as heretofore, but with more effect because of the strength of the new medical law and the increased cooperation from the public authorities. Prosecutions had also been begun in Kings and Westchester Counties, and the effectiveness of the new medical law was shown in every line. He said this law was important because it defined the practice of medicine, it conferred upon the Re-

gents the right to revoke the license of any physician who was guilty of crime or fraud or deceit in his practice; the penal provisions of the Act were changed to make the following violations under the Statute a misdemeanor: (*a*) The practice of medicine by a person other than a regular physician. (*b*) The practice of medicine under cover of any license or diploma illegally obtained. (*c*) The use by a person other than a registered physician of a title or designation tending to imply or designate him as a practitioner of medicine. (*d*) The practice of medicine by a licensed practitioner of medicine under any name other than the name under which he was registered. (*e*) The advertisement to practice medicine by a person other than a registered physician. He said that previous to the passage of this law it had been almost impossible to secure conviction against a professional abortionist. The Police Department being confronted with this matter from time to time asked the society to devise ways and means by which the evil could be corrected. In the Hoffman case, which he outlined, they had succeeded in convicting the defendant of maintaining a nuisance in that she maintained a house where there was reason to believe that abortions were habitually performed, though there was no proof of any specific act of abortion. Formerly before a conviction of an abortion could be made it was necessary to prove beyond a reasonable doubt that an abortion had been produced and that the person charged committed it, but under the Hoffman case this proof was not necessary. Circumstantial evidence including an advertisement in a newspaper was brought to show that there was reasonable ground to believe the woman engaged in the abortion business. Upon this the Court of Appeals recently affirmed the decision of the Court of Special Sessions, saying that the theory advanced in this case was without precedent, either in this country or in England. Under this holding it is possible for the public authorities to rid this county and State of physicians and midwives who are engaged in the abortion business. The Woodbury case was of special importance in that a corporation advertised to practice medicine without being a registered physician. It was a well-known principle that a corporation was a person within the meaning of the law, and on this theory it seemed fair to presume that no corporation had a right to practice medicine. This case would no doubt mark a milestone in the legal work of the medical society. The unlicensed midwife had always been a menace to the community, and the Legislature at its last session had passed a law defining the practice of midwifery, placing the regulations of midwives under the control and supervision of the Department of Health of this city. Since the passage of this law the Board of Health had prepared a set of rules and regulations, which, if adopted, would restrict the practice of midwifery to those capable of being midwives, and placing them under the supervision of the Board of Health. The total number of persons prosecuted since the last annual report was 80 under the old law, and 700 under the new law; the total number convicted under the old law was 47, under the new law 439; cases disposed of otherwise than by conviction, 9 under the old law and 180 under the new law. There were 20 cases still pending. There were four persons imprisoned. The aggregate fines imposed under the old law amounted to $4,675; under the new law, $35,062.95.

The Legal Work of the County Medical Society, with Special Reference to the Principles which Guide Its Conduct.—Dr. Floyd M. Crandall presented this paper. He said that each county society might be denominated the business agent of the medical profession. One of its most important duties was the enforcement of the medical practice laws and the protection of the public against illegal and criminal practitioners of medicine. It was the first of a group of societies to which had been entrusted the duty of enforcing certain provisions of the criminal law. If the impostor could be debarred from the newspapers and mails he could be practically exterminated. Little had been said of the efforts that had been made to place the work of enforcing the medical practice laws on a more sound and comprehensive basis. To this end certain systematic series of prosecutions had been taken up for the purpose of establishing legal principles and precedents. Many prosecutions had been instituted not alone to convict an individual criminal, but more as a step toward establishing a principle of law, as in legal practice precedent was a most important and necessary factor. The enforcement of medical practice laws had been an almost unworked field until within the past six years, and there were but few precedents, principles, or guiding landmarks. Prosecutions were conducted along well-established lines, and the worst offenders and up-to-date criminals had learned to operate outside of those lines. In regard to the practice laws the old idea seemed to be that the practice of medicine consisted in the administration of drugs, and in times past medicine and drug giving were indeed synonymous terms. As a result of this limited definition a swarm of new systems of practice had arisen, having one feature in common, namely, they used no drugs. This repudiation of drugs circumvented the medical law, and escaped those annoying requirements of preliminary education, four years in college, and a State examination. Test cases were taken to court in which the question was raised as to whether the defendant undertook to diagnose and cure disease. The method of treatment, whether with or without drugs, was made incidental to the main question. These cases established the desired precedents. In the decision of the Appellate Division there was a clause which stated that to limit the practice of medicine simply to the administration of drugs or the use of surgical instruments would be to eliminate the very cornerstone of successful medical practice, namely, the diagnosis. The determination of what the trouble was must be the first step in the practice of medicine. The judges in this case then asked the pertinent question, "Would the physician, who by his skill discovered incipient consumption, advised open air treatment, and refrained from administering drugs not be practising medicine?" It was by this kind of work that a definition of the practice of medicine was finally obtained. The next important work of the society was the campaign against abortionists. There was substantial ground for the belief that one hundred thousand abortions were committed annually in New York, and while the crime could not be stopped it could be limited. This work was forced upon the society by complaints from members, from the Police Department, the Health Board, and the District Attorney's office. Action was first taken against the midwives in Manhattan borough, where there were about one thousand. Miss Crowell, who made an investigation and study of their work, classed 176 out of 500 investigated as probably abortionists. These women used instruments, and many had been convicted under the new law for agreeing to perform a surgical operation and doing any overt act tending to consummate that agreement. The counsel advanced a theory that to conduct a house where abortions were habitually performed constituted a nuisance, and as such could be abated. The Hoffman case was appealed, and in the decision of the Appellate Division the conviction of the lower court was affirmed, and in the decision the court said: "While the offense of abortion was one thing; that of maintaining premises open to the public for the purpose of consummating that crime was another and separate offense against the peace and good order of the State." This was a most important decision, and rendered easy a problem that three years ago was considered almost impossible of solution. Very recently this conviction was further affirmed by a unanimous decision of the Court of Appeals. There were also,

men in the profession who advertised themselves as specialists in this kind of work, and the conviction of one of these after two appeals served to establish the principle of law that it was a crime to attempt to commit abortion. In referring to the charlatans who played upon the credulity of young men, he said that they were mostly registered physicians, and were very hard to reach. The work of the society, however, had been very successful, and they had reached these offenders on such charges as grand larceny and extortion. The advertisements of this class of men were most objectionable, and half a hundred extortionists were put out of business through the Post Office Department, without going to court. There was at present a case before the Court of Appeals, which, if decided as in the Appellate Division, will mean that in New York a man, even though he hold the degree of M.D. from a college not recognized by the Board of Regents, and may use that degree in a social or literary way, he cannot use it for professional or business purposes, unless he is licensed to practise medicine and is lawfully registered. The case against Woodbury, in which it was shown that the business was established by a layman and owned by a layman, but in which registered physicians were employed to do the professional work, will, if upheld by the courts, establish the principle that the license to practise medicine was a strictly personal one, and hence a corporation, having no personal license could not legally practise medicine, or advertise to do so. Other principles of law had been established and other methods of legal attack had been adopted, but these instances served to give an idea of the work. The high character of the legal work was shown by the fact that among more than nine hundred prosecutions but one case of false arrest had been brought against the society, and in that case the society easily won. In every case the principles of law had originated with Mr. Andrews, and had been developed by him. He acknowledged the aid given by the District Attorney's office and by the Police Commissioner. He said the Medical Unity Bill was in reality a general medical law, one of the most important and comprehensive that had been enacted since the great law of 1806. A very important provision was the one relative to the revocation of the license to practise medicine. Lawyers had long been able to disbar their disreputable brethren, but the medical profession had stood with tied hands when a physician had turned quack and resorted to a personal or professional life of dishonor. The license could now be revoked for many misdemeanors, including fraud in practice. To those who felt that the work of the society should be limited to scientific and professional work, he said that legal work was one of the essential objects for which the society had been organized. The title of the legislative act which called this society into existence read "An Act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State."

The Relation of the Medical Society of the County of New York to the District Attorney of New York County.—Robert C. Taylor, Esq., made an extemporaneous speech, and said that the medical society bore no other relation to the office of the District Attorney than did other societies or citizens. He called attention to the great difficulty in getting evidence; when he was counsel for the society all kinds and sorts of complaints were made by all sorts of people, and the office was greatly handicapped by lack of sufficient evidence. Evidence, of course, must be secured before anyone could be sent to prison. The processes for getting such evidence interfered greatly with their work, and naturally made them go slow. In the District Attorney's office there were thirty lawyers, but they had no detective functions. Of the great mass of complaints brought to their office there was not one out of a hundred that gave any well determined and distinctly sound set of evidence which could be submitted to a jury, grand or petit. It was essential that some outside body should procure evidence, as by detectives, etc. If they could get order out of chaos, they would then be able to get results from the District Attorney's office.

Report of Special Committee on the Examination of School Children. — Dr. Colman W. Cutler, Secretary, made this report. He said that under the present system the Department of Health had the medical oversight of the public schools, especially directed to the detection of communicable diseases. Physical defects were noted as they were discovered in the course of the routine examinations, and many such children were referred to physicians and to institutions. There should be an adequate method of indexing each physically defective child, which record should contain a statement of the condition as diagnosed by the medical inspector, or of the vision, as noted by the teacher, the treatment and the result, and which record should be on file in the school, so that it would be available for the principal or teacher and for the medical inspector, in order that the future progress of the child and his attendance might be controlled. In cases where children were sent to physicians or dispensaries for treatment, the medical profession could aid the school authorities by noting briefly on a card whether the disease was contagious or not, and such facts as would aid the teacher in showing a proper consideration for the child, as when hearing or vision was defective. The termination of treatment should also be noted, so that the child might be readmitted to the school without unnecessary loss of time. Until a definite census of the physical defects of school children was obtained, with information regarding the adequacy or inadequacy of present methods of meeting such defects, hasty action of a paternal nature by the city or State authorities was not favored by the committee; but it was the expression of the committee that there was a proper economic standard for this work, as children physically defective were less liable to be charges on the community if the physical weakness were corrected. The public school system failed to provide for the increasing number of mentally backward and deficient children. Such children were unable to benefit by the regular school instruction, and it was an injustice for the normal children to associate with those mentally backward and deficient children. In many European countries secondary or supplemental schools were in successful operation. In view of the foregoing, the Sub-Committee on Mental Defects of School Children suggested: First, that under the supervision of the Board of Education a census and record of the mentally backward and deficient children in New York be made. Second, that a paid commission be formed, under the supervision of the Board of Education, to examine and classify the mentally defective and deficient children. This commission should comprise at least two neurologists. The commission should classify all new pupils, and at stated intervals reclassify them. The commission should be empowered to remove for institutional care and training all those mentally defective children who had shown themselves unteachable or incapable of such instruction as to render them ultimately self-supporting. The commission should have the power to reinstate in the regular school for normal children those pupils of the ungraded classes whose mental condition had improved sufficiently to warrant the transfer. The commission should outline the organization, equipment, teaching, personnel, and general management of these secondary schools for mentally defective and deficient children. Feeble-minded and imbecile children should be regarded as ineligible for these secondary schools; they should be at once transferred to State institutions for this class. These suggestions were in process of being acted upon by the Board of Education. This report was signed by Drs. Walter Lester Carr, Chairman; Charles E. Atwood, L. Pierce Clark, Colman W. Cutler, Arnold Knapp, and Henry Koplik.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 7, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	422	180
Diphtheria	326	33
Measles	476	19
Scarlet Fever	372	19
Smallpox	2	..
Varicella	167	..
Typhoid Fever	71	18
Whooping Cough	8	1
Cerebrospinal Meningitis	15	5
Malarial Fever	..	..
Totals	1855	275

Bacteriological Treatment of General Paralysis.—At a recent meeting of the Edinburgh Medico-Chirurgical Society, a discussion was held on the relation of bacteria to general paralysis. Dr. W. F. Robertson and D. McRae, in speaking of the treatment of this disease and of tabes dorsalis by vaccines and antiserums, declared that the two types of diphtheroid bacilli used by them both showed marked virulence to mice, and produced in rats a disease resembling general paralysis. Probably there were several different but closely allied species of diphtheroid bacilli which were capable of producing the same effect. They had treated by vaccines 8 cases of general paralysis and 1 of tabes, in most of which there was a distinct improvement in the patients' physical and mental condition, followed by relapse after several weeks. In one case of general paralysis the improvement persisted for a year, when the patient was removed from the asylum. Their antiserum they obtained from sheep, administering it hypodermically or by the mouth in doses of 20 c.c. A temperature reaction followed, and in their opinion this was diagnostic. It consisted in a rise to 100° F., when the serum was given hypodermically. The rise occurred within twelve hours, and had passed away in twenty-four hours. Out of 12 cases of general paralysis thus treated for over a period of three months, 10 had shown marked improvement. Two cases of tabes which had been similarly treated showed progress, the severity of the lightning pains had diminished, and the length of the periods of remission had increased. Nine control cases had been subjected to the antiserums and in none did any specific reaction occur. Several cases of general paralysis had also been subjected to treatment with the serum of normal sheep and also with antistreptococcic serum, and in no case were the injections followed by any reaction similar to that which ensued upon injection of the antiparalytic serum.—*British Medical Journal.*

Acute Miliary Tuberculosis Following Intubation of the Larynx.—Arturo Primavera says that traumatism has a great deal to do with the generalization of the tubercle bacilli from a local focus so as to produce acute miliary tuberculosis. The inflammatory reaction caused by traumatism may set in movement the bacilli or break the capsule of fibrous tissue that encloses a tuberculous focus. In general acute miliary tuberculosis is not a primary process coming from without, because the tubercle bacillus has not the power of such rapid proliferation. There must always be some focus of tuberculosis which prepares the enormous number of bacilli that are needed to create innumerable miliary tubercles. Hence there is an endogenous infection, an autoinfection, resulting from a focus in some one of the organs. It may appear in a person apparently perfectly healthy from a latent focus, or in an apparently cured individual. Tuberculous vessels are the most frequent starting point of miliary tuberculosis. Surgical operations may cause a generalization of the process. The author reports two cases of miliary tuberculosis which followed intubation of the larynx and the frequent removal and reintroduction of the tubes due to continued difficulty of breathing. In both cases there were marked tuberculous changes of an advanced type found in the larynx, which in all probability had begun before the process that necessitated intubation. An acute miliary tuberculosis occurred at an early date after the intubation; the traumatism of the tube had much to do with generalizing the tuberculous process.—*Giornale Internazionale delle Scienze Mediche.*

Optic Neuritis in Endocranial Affections.—Gaetano Samperi calls attention to the importance in the diagnosis of endocranial affections of the ophthalmoscopic picture, which by showing alterations in the vascularization and nutrition gives important diagnostic data. According to the old theory of the causation of ocular changes any reduction in the intracranial space will compress the cavernous sinus and cause venous stasis resulting in atrophy of the optic nerve. The author analyses three cases observed recently by himself so as to show that mere pressure is not the cause of the optic neuritis. According to his theory it results from poisonous products generated by the endocranial process mingling with the blood and producing poisoning of the nerve sufficient to cause inflammation, just as uremic poisoning does in Bright's disease. The location of the lesion is of great importance in determining optic atrophy, on account of the intimate connections of the lymphatic system. A tumor of the anterior cranial fossa or the region of the chiasma quickly brings on neuritis, because its metabolic products are easily and rapidly carried to the connective tissue spaces of the optic nerve.—*Giornale Medico del Regio Esercito.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending December 6, 1907:

SMALLPOX—UNITED STATES

			Cases	Deaths
Colorado, Five Counties	Oct.	1–31	13	..
Illinois, Belleville	Nov.	17–23	1	..
Springfield	Nov.	22–28	8	..
Kentucky, Covington	Nov.	24–30	1	..
Indiana, La Fayette	Nov.	19–25	1	..
Massachusetts, Fall River	Nov.	20–23	2	..
Montana, Seven Counties	Oct.	1–31	13	..
Pennsylvania, Altoona	Nov.	3–9	2	..

THE SALICYLATES IN DIAGNOSIS AND TREATMENT.

BY A. HAIG, M.A., M.D., OXON.

LONDON ENGLAND.

THE cure of acute rheumatism by salicylates is today regarded as a matter of certainty. In so many hours and with a proper dose we are certain to find that the temperature has fallen and that the pains are relieved. I sometimes think that on this account but little attention is given either to the mode of action of these drugs or to the exceptional cases in which they seem to fail, though these are the very cases that throw most light, not only on the action of the drugs, but also on the causation of rheumatism.

Again, though the favorable action of salicylates is almost a certainty in acute cases, it is a very different matter when we come to deal with chronic disease. And here again I think the matter is well worth going into if only in the hope of effecting some improvement in the results obtainable in chronic cases.

But salicylates do not always succeed at once and completely, even in cases that must be classed as acute or at least subacute rheumatism. The ordinary dose is given, but the temperature does not fall, and the joints are not relieved of pain. On investigation you probably find that the patient is somewhat debilitated or that the joints are encased in cotton wool. In the latter case it is generally sufficient to remove the wrappings and keep the joints cool to insure a speedy and satisfactory convalescence. If the patient is debilitated the same result may be obtained by keeping him moderately cool, and thus preventing profuse perspiration.

Profuse perspiration was a favorable condition in the treatment of acute rheumatism by alkalies, but it is another matter altogether, and often a most unfavorable condition, in the treatment of these cases by salicylates. If the case is acute, with high fever, a little perspiration is a matter of no consequence, but in subacute cases, with debility, a profuse perspiration may entirely prevent the favorable action of salicylates.

A hot climate may again prevent the best action of salicylates to such an extent that other treatment has to be used, and some have even gone so far as to say that the arthritis met with in hot climates is not rheumatism. But even in moderate climates in the warm season the action of salicylates may be upset by heat and perspiration; but here their good action can be insured by keeping the patients cool and applying ice to the joints.

But perspiration was a favorable condition in the treatment by alkali because it was equivalent to an increased dose of alkali, for perspiration eliminates acid from the skin and thus increases the alkalinity of the blood. But when we come to deal with the salicylates, increased alkalinity of the blood is an unfavorable condition, for we know that they act best in acute cases with high fever in which the alkalinity of the blood is diminished, and they relieve at once the worst joints in which the tissue fluids are most acid.

And this has a chemical explanation, for the compound which salicylates form with derivatives of uric acid is more soluble in dilute acids than in dilute alkalies. (See my Researches in "Uric Acid," Ed. VI.) Further, I have for many years pointed out that salicylates relieve in acute rheumatism in direct proportion to their power of eliminating uric acid compounds; that salicin has least power, while salol comes next to it; salicylate of soda is still better, while salicylic acid is again better (and it contains no alkaline base), and acetylsalicylic acid (aspirin), in which there is an added acid, is best of all. In all these compounds it is the salicylic acid which acts; but dose for dose its power is diminished by associating it with alkali and increased by associating it with an acid. Before aspirin was invented I used to give small doses of acids concurrently with salicylate of soda, and could then relieve cases in which the soda salt alone might fail. In all cases salicylic acid relieves in direct proportion to its power of eliminating uric acid compounds.

Further, we know that by giving first alkalies and then salicylates we may not only fail to relieve acute rheumatism, but may even produce a very decided relapse; of this I have recorded several instances in my book on "Uric Acid," and I have heard of many similar cases, in fact many relapses are due to something of this kind. It seems, then, that the action of salicylic acid is dependent on its power of eliminating from the body the compounds of uric acid, and that if this power is interfered with by association with alkali, by perspiration, or by debility (the two latter being equivalent to alkali), it may fail to relieve or cure.

Here, then, is the explanation of the comparative failure of salicylates in chronic disease, for this is practically always associated with debility and an increased alkalinity of the blood.

Where there are dyspepsia and increased action of the bowels the action of salicylic acid is aided by drugs which diminish the diarrhea and hence reduce the alkalinity of the blood; and in some cases of this kind the addition of a little pulvis opii compositus to the salicylic acid will greatly increase its power.

Hence the rule in chronic disease with debility is "feed up, give tonics, acids, etc., restrain dyspepsia or diarrhea, feed up on acid-forming foods (*e.g.* meat, fish, fowl, and eggs), give wines which are acid, get the patient strong, send him to a bracing climate, give tonics to prevent the depressing effects of salicylates, and then try salicylic acid and opium, and now they may succeed and do well, when without this assistance they only failed or did harm."

If the patient cannot be got into good or at least moderate health by the above means, if there is morbus cordis or other organic disease which renders this impossible, then salicylates will fail to help the arthritis and it is better not to give them, especially in cases of morbus cordis, when they may do harm and increase the depression.

Again, it is always a mistake in starting to treat a patient for rheumatism (except in acute cases where it does not much matter) to cut down food and leave off wine or beer. For the same reasons, when a patient is convalescing on salicylates, acid-forming foods, wine, etc., should be kept on, and they are the more necessary the more the temperature falls and the more evident are the signs of debility.

And now with regard to diagnosis: The mere failure of a salicylate to cure or relieve an arthritis is no proof that it is not rheumatic. Only when we have looked into all the concomitant conditions can this be said.

There must be no external heat sufficient to cause profuse perspiration, no great and general debility tending to the same result, no severe dyspepsia or chronic diarrhea, no severe respiratory or circulatory disease causing dyspnea and its result, increased alkalinity of the blood.

If all these disturbing factors are absent and if salicylates given in correct combination and proper dose (as for acute rheumatism) quite fail either to relieve a severe arthritis or to lower the temperature, search should be made for those conditions other than uric acid which may produce arthritis and on which salicylates have no influence, *e.g.* septic arthritis or that due to traumatism or new growth.

Indeed, I would go further and say that when salicylates promptly and decidedly relieve any acute febrile trouble associated with local irritation in the fibrous tissues of any part or organ of the body, such inflammation and temperature are probably due to uric acid and not to microbes, traumatism, or new growth, etc.

But I need hardly remind my readers that microbes causing fever and diminished alkalinity of the blood may, and often do, precipitate an arthritis in those subject to it, in other words, having plenty of available uric acid in their tissues or viscera; and a traumatism also in a gouty or rheumatic subject (*i.e.* one well charged with uric acid compounds) very often precipitates a urate irritation and will therefore be relieved to a greater or less extent by salicylate treatment. This is well seen in the arthritis which may complicate enteric or scarlet fever in such subjects and here salicylates will relieve the pains and lower the temperature, but not completely reduce it, for the other lesions of the specific fevers account for a part of the febrile movement.

Hence, in any case in which a salicylate relieves pains and lowers temperature, but does not bring it down completely, the possible presence of enteric or other specific fever must be kept in mind.

Again, it is, I think, common experience that fractures of bone or old scars in fibrous tissue generally react to changes of weather and season by some increase of local irritation or pain, and this is so because they form centers of defective circulation and diminished alkalinity in which urates most tend to congregate; but let such sufferers shut out (as far as possible) urate compounds or xanthin from their food, and in a few years' time, when the tissues begin to get relatively clear, such irritations will cease to trouble and salicylates will no longer be required to relieve.

I may also mention here that in many of these local troubles the application of a little oil of wintergreen will often suffice both to relieve the patient and give the doctor a key to diagnosis. And as the dose absorbed into the blood from a local application is generally small this treatment may be used even in some of the cases above mentioned in which there is organic disease, sufficient to contraindicate the administration of salicylates on a larger scale.

And in some of these cases an external application may be all that is required, combined with tonics, feeding up, and a bracing climate as mentioned above.

Salicylates affect *under favorable conditions* all irritation and fever due to uric acid even when such uric acid irritation has been precipitated by microbes, but they have no influence on irritation and fever produced by septic conditions alone.

THE ANTE-MORTEM CLINICAL CONDITIONS AND THE POST-MORTEM FINDINGS IN AN IRREGULAR CASE, WITH PRESENTATION OF PATHOLOGICAL SPECIMENS.*

By MARGARET A. CLEAVES, M.D.,

NEW YORK.

Mrs. ——, age 62, widow, consulted me first October 31, 1906, and was under my care from that time to the day of her death, October 8, 1907. The father died of Bright's disease at the age of 48, the mother of Bright's disease, aged 65. During childhood she had measles; was ill only one day. Menstruation was established between 12 and 13, normal, every 28 days, regular, duration 5 days. At 16 she became very anemic, attributed to the use of camphor, which she ate because she liked it.

She was married at the age of 27, gave birth to three living children, and had two miscarriages. Births were normal in every way and patient was well during pregnancies. Miscarriages occurred during the third month, without any apparent cause, and between the first and second births.

While in Rome, soon after marriage, she contracted a fever, probably malarial, which lasted three months; was confined to bed part of the time, and became very thin and weak. At times during adult life she had severe asthmatic attacks; none of late years. The menopause was established at 50 years, no profuse flowing and no bad symptoms of any sort.

Present condition: In 1900, six years previous to consultation, she began having uterine hemorrhages, staining clothes slightly at first. This continued to increase. In 1903 she had severe hemorrhages, and consulted a physician in San Francisco, who upon examination made a diagnosis of uterine polypus hanging in the vagina and "as large as his fist." For a period of fifteen months he administered electrical treatment. The polypus "disappeared in six weeks" from beginning of treatment, but the flow continued just the same.

The patient returned to New York in September, 1905. Had no further attention, although hemorrhage continued until, in February, 1906, a very severe hemorrhage led to a physician being called.

*Read at a meeting of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, November 26, 1907.

No examination was made, but drugs were administered. The flow was unchecked. For the year prior to consultation she was continuously more or less constipated. She suffered also from irritative cough of gastric origin. During this year impaired heart action was pretty constantly present, evidenced by attacks of sinking and fainting. She was unable to go about for months, could not be left alone because of threatened heart failure, and had lost much weight. She was practically taken out of bed to come to the city for the purpose of medical care.

At the time of consultation, her skin was very sallow, even jaundiced, and cheeks brightly flushed in the afternoon. This had been habitual for a year or more. She had little strength, breathless upon the slightest exertion, flowing profusely, able to sit up but a part of the day. Appetite was fair, digestion more than fair, but the bowels were constipated. Urine contained albumin and much indican, at first excessive. Soon after coming under care, granular, then hyaline, casts were present. Toxemia present. No pain, save discomfort of enfeebled heart.

Physical examination: Liver enlarged with some hepatoptosis; gall-bladder enlarged, protuberant. Heart feeble, fluttering, irregular, and inefficient in its action. Whiskey and ammonia carried constantly to combat characteristic sensation of sinking and fainting.

Pelvic examination: Vagina free, no adhesions, vaginal vault stretched taut or widely dilated, cervix completely effaced, cervical canal patulous, mucous membrane of cervix and vagina intact, uterus enlarged, lower segment through taut vaginal vault giving the impression of a superincumbent mass, as does the fetal head, although of less resistance and size.

Vagino-abdominal examination showed the uterus to be movable. Recto-abdominal examination yielded to the sense of touch the same impression as conveyed by a pregnant uterus and also of a fibromyomatous uterus, but lacking in the characteristic density of the latter. The uterus was very freely movable and could easily be rocked back and forth between the suprapubic hand and rectal examining finger, much more freely than on vagino-abdominal examination, as the tension of the upper vaginal vault limited the former. There was constant hemorrhage.

By speculum, introduced with great difficulty owing to the vaginal tension, the wide gaping os was revealed. Absolutely no evidence of the severance of a uterine polypus, but an appearance suggestive of a retained uterine growth. There was no rectal complication other than a slight proctitis.

Diagnosis: Because of the remoteness from the menopause, the question of malignancy was carefully considered from the first, but was excluded in the absence of uterine pain of any sort and evidences of infiltration and fixation. No glandular enlargements. Despite many irregular symptoms, and in the absence of any evidences of a pedunculated growth, although she positively stated that she never passed the polypus per vaginam, a uterine fibromyoma was diagnosed and the question of beginning degeneracy raised.

Treatment: For the six years prior to my knowing the patient she had positively refused operation and was in no condition for surgical measures when I first knew her. Therefore, every possible remedial measure was utilized to secure control of the hemorrhage and to establish more nearly normal metabolism and nutrition. Under the use of vaginal hydroelectric applications of the continuous current 20 to 40 M.A., supplemented by exposure of the body superficies to the energy of a 25-ampere arc, the hemorrhages were under control in from four to six weeks after treatment began.

An examination of the blood made three weeks after coming under care gave the following result: Hemoglobin, 65 per cent.; leucocytes, slightly below normal; differential (200 cells counted); polynuclears, 66.0; transitional, 6.5; lymphocytes, 23.5; large mononuclears, 4.0; eosinophiles, 0; basophiles, 0. While the red cells were, on the whole, uniform in size and shape, there were a few larger than normal, and a number of microcytes, but the lack of uniformity was not marked. Poikilocytosis, basophilia, and chromatophilia were not present, nor was there an increase of blood plates. No nucleated red cells were seen. Pallor was found in more than moderate degree. The number of leucocytes was slightly diminished, but the differential was within normal limits.

The electrical applications used were characterized by current distribution, rather than current density, while the vaginal cavity afforded one contact and the abdomen the other. Static electricity was used for the purpose of assisting tissue change and improving nutrition. Tonics were administered and the heart controlled by the administration of nitroglycerin, digitalis, and strychnine. Patient became able to walk several blocks, heart action stronger, but evidences of toxicity never disappeared. After some eight weeks two apparent bits of tissue were passed within two to three days of one another, which upon examination showed the following: Ovoid, moderately firm specimen about one inch in diameter. Surface dark red, smooth, and covered with a thin layer of yellowish-white matter closely adherent to the surface on section, mottled white and red.

Microscopical examination showed the tissue to be made up of fine fibrillæ arranged in a close network, the meshes of which were filled with amorphous matter. Here and there at long intervals were a few polynuclear leucocytes. In places the outlines of numerous bodies of red cells were seen and scattered thickly through the tissue were many fragments of cell nuclei. The tissue was degenerated and stained with difficulty.

Diagnosis: Fibrin, red blood cells, and leucocytes; blood clot degenerated.

Microscopical examination of second flattened pieces of tissue 1¾ inches by ½ inch, showed degenerated, partly organized blood clot, similar in appearance to the previous specimen.

Subsequent to the passage of these blood clots, she began to have a dirty, watery discharge with a slight odor at first which became more marked as time went on.

From the cessation of hemorrhage to the time of her death October 8, 1907, she continued to have a dirty, watery, sometimes blood-stained discharge, with the passage of bits of necrotic tissue and a large volume of pus (from 0.25 to 2 per cent.) in the urine when not removed by catheterization; albumin, granular and hyaline casts, and quantities of indican were uniformly present. Appetite not uniformly good, but a very considerable quantity of nutritious food was ingested. Bowels moved every day in response to enema, but not freely. All laxative drugs set up nausea and griping, and as the enema had to be administered because of pressure of the uterine body on the rectum, laxative medication was avoided as much as possible. Olive oil was administered in ordinary doses from time to time. With the continuance of the discharge, the

uterine tumor grew smaller, the vaginal vault became flaccid and wrinkled, the os less widely gaping, and the cervical canal less patulous. Coincident with these changes, noted in from three to three and a half months, the bowels functioned without the use of the habitual enema. Toxicity remained. As a result of the heart's failure to compensate in connection with the hepatic complication, the abdomen and all the tissues of the body, but especially the back, buttocks, and lower extremities filled with fluid in February, 1907. The ascites was extreme, the legs being enormously distended, and the skin tense and shining.

Under a further reinforcement of the heart and the daily exposure of abdomen, back and legs, as well as the precordial region, to the energy of electric incandescent light, carried to the point of excessive sudation, the fluid entirely disappeared in from four to six weeks, and never reappeared.

After the passage of the organized blood clots because of the discharge, the uterus was kept carefully irrigated from three times a week to daily with physiological salt solutions, peroxide of hydrogen, weak solutions of bichloride of mercury, but nothing controlled the odor and quantity of discharge as did the pancreatic lotion, which was used from the middle of July to within a week of death after the cleansing irrigation.

During my absence from the city from the 3d to 8th of July the patient was intrusted to the care of another physician. Upon my return I found her more toxic than usual, bowels less active, heart very feeble and uncertain, and tissues waxen to translucency.

On July 15, at my request, Dr. H. C. Coe saw the patient. Upon vaginal examination he found a mass to the right of the uterus, which led him to raise the question of a superposed secondary growth or a possible thrombosis. This mass, in addition to the condition originally noted, I confirmed by touch. It had not been present upon examination prior to July 3. Dr. Coe regarded the condition as a degenerating uterine tumor and the case as an absolutely inoperable one. In his opinion curetting was inadvisable owing to the danger of penetration and further infection. He estimated length of life at from two to three months and regarded the condition as initially some form of degenerating growth. It was after this visit that I began to supplement the uterine irrigation with pancreatic lotion. This I did because of the beneficent action of this lotion in modifying the odor and discharge in malignant cases, and while I could not regard the case as malignant, I felt it incumbent upon me to give her the benefit of the doubt after the question had been raised. Enteroclyses of physiological salt solution were used to reinforce the heart, and acted as well to very thoroughly clear out the upper intestinal tract. Holadin was administered internally, and ox-gall exhibited more frequently than before to stimulate hepatic function. Under this régime appetite, which never absolutely failed until the last, improved, also nutrition, and from July 29 to August 17 hemoglobin increased from 36 to 92 per cent. The red cells, however, presented the appearance of secondary anemia.

Despite slight nutritional gain, lessened discharge and odor, a marked increase in the polynuclears was noted early in August, with corresponding decrease in lymphocytes and slight increase of blood plates.

There had been an understanding for some time between myself and an absent son that if it could be arranged, Dr. Howard A. Kelly should see the patient. This was for the son's satisfaction, as I had the most perfect confidence in Dr. Coe's judgment, and felt that nothing had been or was being left undone to save the patient's life. I wrote the son, however, that I was willing to have Kelly or any reputable physician in consultation.

On September 1, when I was absent from the city professionally, Kelly saw the patient. He was secured en route from the woods to Baltimore, to minimize expense, and I was unable to return to meet him on account of the professional engagement calling me away, but had him met by the physician whom I left to look after the patient during my absence. The following letter contains his opinion:

"September 2, 1907.

"Dear Dr. Cleaves:—I saw Mrs. ——, with your assistant ——, and went carefully into her condition. She has an enormous gall-bladder, with some hepatoptosis, but the great trouble, of course, is the condition of the uterus, with its foul discharges. This must be either a sloughing fibroid or a carcinoma; I believe it is the latter. I am at a loss to account for her excessive anemic poisonous condition, unless it is due to reabsorption.

"I think that her condition offers but little hope, but what little there is I would give her by using an anesthetic of gas, which, skilfully given, ought not to upset her, and allowing five minutes for a thorough curettage of the uterus. This ought to remove a great deal of débris and to open up the uterus, so that it could be washed out thoroughly day by day. If, after getting good drainage in this way, and cleaning up the surface, she showed any decided improvement, I would then think of a radical operation, either under gas or cocaine anesthesia. I would do these things if she were my own near relative, difficult and almost hopeless as the case seems to be.

"Always faithfully yours,

"Howard A. Kelly."

In Dr. Coe's absence from the city, as well as of the other men suggested by Kelly, Dr. W. Healy was asked to operate. After a thorough examination of the patient, he made a diagnosis of uterine fibroid, but absolutely refused to operate upon the ground that there was great danger of perforation as well as further infection. This decision relieved a position of great strain.

So intense was this patient's dread of pain that when I attempted at one time to give a necessary hypodermic injection of medicine under ether spray every drop of blood seemed to leave the surface of her body, while her look of abject terror exceeded anything I ever saw in a human being.

The night of September 5 my assistant reported to me that within ten minutes after the uterine irrigation she had a violent chill lasting ten hours accompanied by excessive sweating, necessitating many changes of night dresses and bedding.

After this the patient was very lethargic, sleeping almost continuously, and very inattentive to things about her. She was never told that she had a condition which meant death, and, despite her constantly recurring heart attacks, had splendid courage as long as there was no question of pain. Her temperature fluctuated pretty constantly from subnormal to 102°. Soon after my return on September 11 her lethargy diminished, she slept less, and became more alert. This alertness, even to extreme nerve irritability, was contrary to a lifelong habit of quiet and calm, and bore a direct relation to the question of operative measures which had been raised. The last of September she began passing by the rectum much pus intermingled with blood. There was no pain, simply the distress oc-

casioned by constant desire for the bed-pan and some burning. On September 30, within half an hour of the uterine irrigation, she became very chilly. I remained with her for several hours, as I feared another chill, but there was no exacerbation. Temperature rose to 102°, and the day following the rectal discharge became profuse, continuing during the week that remained of her life. During that week she passed at least one-half a pint. With this excessive rectal discharge the vaginal discharge practically ceased. During this time there was great nausea, vomiting of pure bile, inability to take or retain food, dry and brownish coating of the tongue, changing to white, dry, and fissured lips, and every indication of some severe gastro-intestinal disturbance. There was, however, no abdominal pain, tympanites, and no pelvic soreness then or ever. In the last days there was a discomfort in the splenic region upon lying on left side. The vomited matter was largely pure bile, and throat and lips felt scalded from contact. The stools were at times greenish in color, varying to a light yellow; semisolid, slight, and on two days there were found some tiny concretions. These upon examination gave no response whatever to biliary tests. The intense wakefulness and alertness was so great that on October 2 and 3 veronal, 5 grains, was administered, and again on the 5th. This induced a desire to sleep almost all the time. None was given after the 5th, but instead, on the 6th, 7th, and 8th, 1/8-grain doses of morphine by mouth were administered to secure the inward euthanasia so acceptable to patient and friends alike when hope no longer exists. In all but little more than one grain was given, but it held her peaceful, happy, and comfortable to the last. Nausea and vomiting were not so bad the last day or two, while the lips grew more moist and the tongue less coated.

The evening of the day of her death in the private apartment in which she lived an autopsy was held by Dr. W. M. Higgins and assistant, with the following result:

Specimen No. 17,502.—Mrs. ——, age 64, frame spare, muscle fair, adipose fair; diaphragm: right side, fifth rib; left side, fifth space. Pericardium normal, surface smooth, not adherent. About half an ounce of clear, colorless fluid in cavity. Heart: The wall of the right ventricle is about 5/16 of an inch thick, of the left ventricle, in systole, 5/8 inches. Both the inner and the outer surface of the walls are smooth and show a moderate degree of fatty infiltration. The cusps of the aorta are free but stiff, very much thickened, and are covered with a layer of calcareous matter which extends into the aorta, forming a solid, thin tube. The cusps of the mitral valves are also thickened, and on the adjacent wall are a number of vegetations, hard and firm, the largest about the size of a small hazel nut. The other valves appear to be normal. Arteries: The coronary arteries are patent, but show a number of small, calcareous patches. The aorta is calcareous, the whole wall being covered as far the descending portion, and there are numerous plaques throughout the entire length. Pleura: Each cavity contains a small amount of serous fluid. The entire surface is free, no adhesions. All the lobes of the lungs are emphysematous; the lower lobes are very slightly congested. Liver: The liver is enlarged, projecting two inches below the ribs on the right side and extending across to the ribs on the left side covering the spleen as far as the seventh rib. The right lobe is divided into two parts, between which the gall-bladder projects. The outer surface is smooth, consistence firm. On section the surface mottled throughout with many fine light-yellow and reddish spots.

The gall-bladder is closely adherent to the under surface of the liver; the organ is about 6½ inches long, extending as far as line drawn through the umbilicus. It is tensely distended, and in form is about the shape and diameter of a large, long potato, the distal end being a little smaller in diameter. The wall of the bladder is very thin and a little roughened. The cavity is filled with a turbid, thin, gray fluid, and in the upper half firmly imbedded in a small pouch is a stone 1⅝ inches long by 1¼ inches wide and 1 inch thick. The stone is hard, dark gray in color, and is covered with a thin layer of dark-brown granular matter. In the distended opening of the duct there is a second stone, freely movable ovoid, with surface rough and irregular, ⅝ of an inch in diameter. The duct is somewhat thickened, but is patulous throughout. The surface of the spleen is smooth, consistence very firm, size 6½ inches by 4½ inches, adherent to the surrounding tissue, and on section dark, bluish gray in color, very firm, and with a number of dark-red areas. The stomach is normal. The intestines are normal. The surface of the rectum is congested and shows a number of small, dark patches. Kidneys: Capsule is a little adherent in places; surface generally smooth, congested; consistence, firm. On section, markings distinct. The suprarenals are normal. The peritoneum is normal. Pelvic organs: The uterus is 3¾ inches long and 3 inches wide. The outer surface is smooth and without any adhesions. On section the uterine wall is moderately soft and flabby and on the average ⅛ to ⅜ inch thick. The cavity of the uterus is occupied by a fungoid growth of moderately firm consistence, closely adherent to the wall of the uterus. On the left side, throughout the entire extent the mass is soft, necrotic, and broken down, forming an abscess cavity about 2½ inches long, filled with soft, necrotic matter. The cervix is patulous. The ovary is small, about 1 inch long, firm, cirrhotic, and shows a few small cysts. The tubes are of normal size and appearance. The bladder appears to be normal. The brain was not examined.

Microscopical Examination.—The heart muscle, on the whole, is of normal appearance. There is a slight degree of fatty and some round-cell infiltration, with a very slight replacement by fibrous tissue. There are no marked changes in the lungs; slight evidences of congestion. The liver is congested. The intercellular spaces are distended with red cell and pigment, and very many of the cells have undergone fatty degeneration. There is a marked degree of round-cell infiltration throughout, especially around the interlobular vessels, and in many places there are large foci of round cells with fibrous formation and cell degeneration and necrosis. The spleen shows chronic congestion with marked pigmentation. In the kidneys the larger blood-vessels are somewhat distended, and in some of the sections there is some fibrous tissue formation, but on the whole there is a very slight deviation from the normal. The ovary is markedly cirrhotic, with many small follicular cysts. Uterus: In the sections taken from the body of the uterus there is a decided increase in connective tissue, running in fine fibrillæ between the muscle fibers with congestion and infiltration. On the outer half the inflammation is comparatively slight, with some round-cell infiltration and small foci of pus cells. The inner half, next to the canal, the tissue is intensely infiltrated with small, round and epithe-

lial cells, and there are large areas of necrotic matter. Sections from a nodule in the wall of the cavity near the cervix consist of small, round and lymphoid cells, blood, some fibrous tissue, and granular, necrotic matter. Sections from near the cervix are largely blood and fibrous or necrotic matter. In the sections from the cervix there is marked increase in connective tissue, with a moderate degree of inflammation. The epithelium is hypertrophied, but regular, glands few and distended, forming a number of very small cysts.

Diagnosis: Chronic endocarditis with hypertrophy, arteriosclerosis, hypertrophic cirrhosis, chronic splenic congestion, chronic cholecystitis, with gallstones, chronic inflammation of uterus.

Dr. Higgins examined the lumen of the large intestine most carefully to find the source of the purulent discharge, but without result. At first I had suspected a retroperitoneal abscess and questioned whether it had broken through and discharged itself into the rectum. No post-mortem evidences of such a condition could be found. The character of the pus and blood passed was such as to indicate a quick passage through the intestinal tract. There were no post-mortem evidences of any suppurating foci either in the intestine or in the pelvis. Taking into consideration all the clinical symptoms and post-mortem findings, it can only be accounted for by the condition of gall-bladder and duct. There was no pus in the gall-bladder, post mortem, however. At my request Dr. Higgins will present the uterus and appendages, also the gallstones removed.

The fungoid growth noted in the uterus is very clearly shown, and there is a line of demarcation between it and the uterine wall despite its firm adherence to the latter. The small amount of fibrous tissue in the nodule near the cervix should not be lost sight of, nor the fungoid growth.

The pathologist's diagnosis of chronic inflammation of the uterus is not questioned, but it is clearly recognized that he had to do with the end product, so to speak, not with the original pathology. It will be agreed that in her chronic endocarditis with hypertrophy, arteriosclerosis, hypertrophic cirrhosis, chronic splenic congestion, chronic cholecystitis with gallstones, she had sufficient pathology to have caused her death at a much earlier date.

Chronic endocarditis was given as the cause of death and the complications were numerated. But it is the uterine condition which is regarded as irregular and which led to varying opinions and recommendations by unquestioned authorities.

1. This patient was in the habit, a habit continued in defiance of orders to the contrary, of placing cotton within the vagina to prevent extreme saturation of her clothing with hemorrhagic discharge. This was constantly done prior to and at the time of the passage of degenerated blood clot as well as afterwards.

2. The vaginal douches were administered by a member of the family with the os dilated and the cervical canal patulous. Absolute asepsis was oftentimes questioned.

3. A uterine polypus was found hanging in the vagina in 1903. The patient received electrical treatment with the continuous current. The method of application was unscientific, the administration unskilled, and dosage extreme. This polypus disappeared between treatments, *i.e.* from one day to the next, but hemorrhage was not controlled. The patient, an observing woman, says she never passed it.

4. With the cessation of hemorrhage blood clots were formed, remained *in situ,* and degenerated, interfering with free drainage. In some way there must have been an infection. Of its source I do not know.

5. What was this tumor which was felt upon examination and which showed itself post mortem in a fungoid lining as it were of the organ?

A uterine polypoid growth suspended in the vagina was subjected to the action of the constant current. In this instance the current was short circuited through a vaginal bipolar electrode. The patient was permitted to turn on the current from a wall plate switchboard, while lying on the operating table, and instructed to take all she could.

The continuous current has an especial action upon unstriated muscular tissue. If uterine contractions are to be avoided the current should flow interruptedly. According to the history given it was not so administered. The os was wide open and cervical canal also. It would be possible for the uterus to withdraw within itself, a polypoid growth attached as the post-mortem conditions would indicate, in this case, just inside the cervical canal, but by no means could such electrical applications cause it to drop off unless it gradually sloughed away.

Deduction: under the influence of the treatment given, the source of hemorrhage was not acted upon, but the uterine organ in contraction drew the polypus (probably a fibroid polypus) back within. I have no authority back of me for this deduction and know of no other instance and only make it from my knowledge of the action of the current, the clinical conditions, and the post-mortem findings.

The patient gradually failed from then on, presenting symptoms of toxicity which steadily increased. Free drainage was maintained until degeneration of blood clots. The presence of a degenerated blood clot was sufficient to interfere with free drainage, and in its absence an infection became, opportunity offering, a simple matter.

I can only raise these questions and vouch for the absolute asepsis other than indicated.

The amount of dirty fluid and necrotic discharge thrown off was sufficient to disintegrate and diminish a tumor of very considerable size. Post mortem as compared with my vaginal examination there remains but the smallest part of it.

In 1903 a simple surgical operation could have been readily performed. Electricity skilfully used accomplishes much in many pelvic conditions and works no harm when so used, but under no circumstances should it be used against a polypus, especially when already delivered and suspended in the vagina.

The patient herself was responsible for non-surgical interference. To many patients the thought of a surgical operation is a living death. But in the hands of a skilful physician a pedunculated growth could have been removed as a part of treatment without the patient's knowledge by means of the perfected electrothermic angiotribe. There would have been no pain nor hemorrhage and complete asepsis. At the time of coming under my care her attitude towards surgical measures was the same as before, her heart was very inefficient and she was toxic. The only pelvic operation admissible at that time would have been a complete hysterectomy, as a curettement would have been inadmissible. Another indicated operation was one for the removal of the gallstones. In all probability she would have succumbed, if not immediately, at

least from the ultimate effects thereof. Her life could hardly have been prolonged to any greater extent in any event, and while she had the unpleasant discharges from the uterus, a misfortune and not foreseen, they were no more exhausting than the hemorrhage had been. She never had a pain, the thing she most dreaded, and lived her days hopefully to the last.

The excessive anemic and poisonous conditions constantly present from the first and referred to by Kelly in his letter could readily be accounted for by the heart and liver condition with consequent imperfect functioning.

In the absence of any evidence of an abscess or a new growth I am at a loss to account for the condition of enlargement and tumefaction to the right of the uterus found in July by Dr. Coe and substantiated by myself other than as a periuterine inflammation. In the absence of post-mortem evidence I can only believe that the exudate thrown out became fully absorbed under the constant régime of uterine irrigation, vaginal douches and bipolar application of the induced (faradic) current.

Conclusion.—1. The case is of especial interest because of the years (six) intervening between the menopause and beginning of hemorrhage.

2. The differing and incorrect diagnoses as to the uterine condition.

3. The difference of opinion as to surgical measures.

4. The disappearance of a polypoid growth which had been delivered, with post-mortem evidence of its return to the uterus.

5. The prolongation of life without pain under so tremendous a pathological handicap.

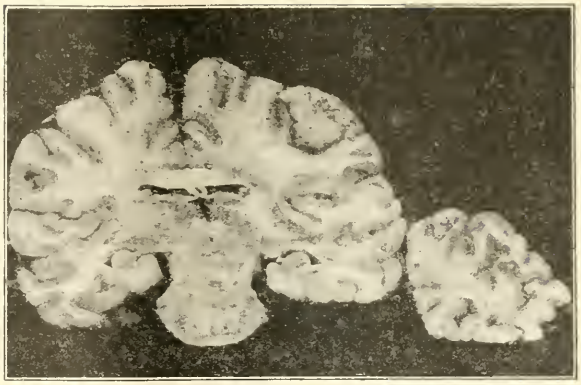

Fig. 2.—Sections across brain through foci.

EPILEPSY; GENERAL TUBERCULOSIS; SYPHILIS.*

By J. F. MUNSON, M.D.,
SONYEA, N. Y.

This patient, M. H., a negress, was admitted to the Colony, October, 1906, aged 17 years. She was the second of eight children, only two of whom are living. The mother died of tuberculosis at the age of 32. The patient states that she has a younger brother aged 7 years, who is deformed in the chest and back and is not very bright mentally. She was strong as a child. Walking and teething began at 2½ years. She had measles at 10 or 12 years of age and about this time she also had typhoid fever. Puberty occurred at the age of 12 years. At 15 she had nervous prostration followed immediately by "St. Vitus's dance."

The patient has both nocturnal and diurnal seizures. During her residence at the Colony seizures were reported as follows: October, one petit mal; November, two grand mal, one P.M.; December, one g. m.; February, one g. m., one P.M. The first attack occurred at the age of 17 years. "A woman enticed her to C——, and she was unconscious for about twenty-four hours. They think she was drugged and used for immoral purposes. She also fell down stairs while there; she was not in bed after this fall. After this her courses ceased and she had her first attack." There has been amenorrhea since the onset of the epilepsy. The seizure "began with a smothered feeling, and then she did not know anything. Those who have seen her in later seizures say she always stiffens out in seizures and lies quiet but froths at the mouth." The second attack occurred one month after the first and was of a similar nature. Since then she has had seizures of increasing severity. The last attack (before history was given) was in August. This attack "began by her feeling smothered; she thinks she was in the attack about half an hour. She felt very weak afterward and the left side began to twitch." The patient is said to have no warning; but "sometimes her hand begins to twitch just before an attack"; there is also the description of the smothered feeling and also the statement that before some seizures she is "nervous and feels as though pins were sticking into her." The left side is most involved. Consciousness was lost in all but one attack. She is said to bite her tongue. After the attack "she feels hateful and sometimes cannot talk." She "sometimes cannot see and sometimes sees double." Once "she knew what was going on, but could not open her lips for five minutes." There is no definite history of specific disease.

*From the laboratory of the Craig Colony for Epileptics.

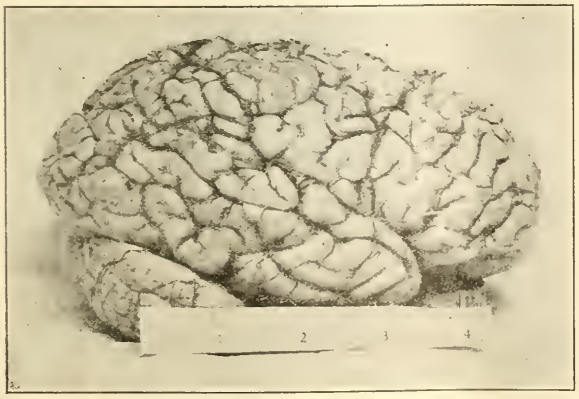

Fig. 1.—Lateral view to show foci on cortex

On admission, October, 1906, the patient states that during seizures she is never unconscious, but knows what is taking place and feels herself coming to in half an hour. She says she never bites her tongue. Temperature on day of admission at 6 P.M.,

Fig. 3.—Tuberculous ulcers at the ileocecal valve and in the cecum.

was 99.8° F., pulse 98, respiration 20. Next morning temperature 98.9° F., pulse 80, respiration 18.

Status Præsens: Height, 5 feet. Weight, 90¼ pounds. Skin dry and scaly. A few large indolent patches resembling beginning ulcers. Many small, dark-red papules. Considerable itchiness. Lymph glands not enlarged. Left cornea shows three opacities. Counts fingers with left eye at 9 inches, distinguishes objects at 6 inches. (These distances are probably too great.) Reads with right eye at 10 to 12 inches. Pupils negative. Taste slightly impaired.

Expansion of the thorax (4.5 cm.) is slightly better on right side. No cough or pain in deep inspiration; no dyspnea. Impaired resonance over left apex. A click is heard below left clavicle during deep inspiration. Breath sounds indistinct over both lungs posteriorly but in no place absent. There is apparently hypercesthesia of left side of chest. Cardiac dullness is limited by the border of the sternum on right, by the third rib above, and is just within the midclavicular line on left. Apex beat in fifth intercostal space. Some accentuation of pulmonic second sound. In sitting posture, pulse rate is 114, small in volume, easily compressible. Spleen not enlarged. Must get up to urinate every two hours during night since seizures began. Urine negative.

Has some headache in left frontal region, but says right frontal region is more sensitive under percussion than left. Wrist jerks active, no tendo Achillis obtained at time of examination. Other reflexes negative. Dynamometer shows 35 left, 25 right hand. No paralysis; coordination normal. No tremor. Mental state good. An effort was made to dilate the pupils but they did not dilate beyond half normal excursion and both were irregular, showing adhesions (synechias). As specific disease was suspected, mercurial treatment was begun, with continued improvement. Left eye did not improve. (W. T. S.)

In January, the note states that her health is apparently quite good but always complains of not feeling well. There is no pain, only slight nausea after meals. In February, rapid mental deterioration is noted. She is frequently confined to bed for one or two days with intestinal autointoxication. Late in February, progressive mental and physical deterioration again noted. Enuresis. (S. H. P.)

March 5. The patient has steadily failed. Yesterday noon she refused food and in the afternoon was found in collapse in the day room. The pulse was regular in force and rhythm but weak and small, rate 120. Heart action good: there is systolic murmur at the apex following but not replacing the first sound. Temperature 96.4° at 4:30 P.M. Pupils equal and moderately dilated. Both sides of thorax showed impaired resonance and blowing breathing, no râles. The abdomen is retracted. Cheyne-Stokes respiration present. She did not respond to stimulation. At 7:55 her temperature was 92.1°, respiration 8. A mild attack was reported at 8:00 P.M. She died at 8:05 P.M. (G. E. R.)

An autopsy was performed March 5, at 2 P.M., eighteen hours after death. Brain: Both convexities congested. Left side negative. On right side, there is an area the size of a half dollar at the middle of the posterior central convolution and extending on to the supra marginal gyrus, which is firmer and lighter in color than the surrounding cortex and feels almost cartilaginous. (Fig. 1.) On the inner surface of the dura over this focus are two or three

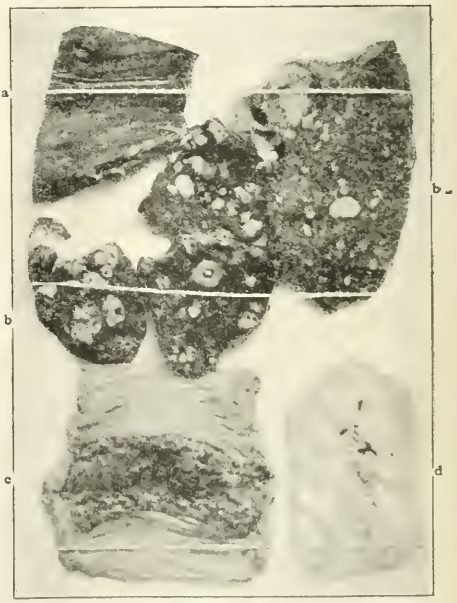

Fig. 4.—*a*, Liver showing tubercle in the left upper corner; *b*, lungs; *c*, intestinal ulcer; *d*, osteoma of the dura.

osteomata (Fig. 4, *d*). There is a focus the size of a penny at the anterior end of the middle occipital gyrus. This is similar to the above. On section through these areas (Fig. 2) they are seen to be masses of firm yellowish cheese-like material, ap-

parently beginning outside but involving the gray matter. There are in places a few blood-vessels seen on the cut surface of the larger focus. There was a small area of clot on the dura just anterior to the osteoma.

Both lungs have the appearance shown in Fig. 4, *b*, the right, however, being less involved. Some of the white areas are nodules with soft, cheesy center, while others, those with central openings, are tubes which branch (bronchi). There is emphysema. There is a cavity the size of a hen's egg on the surface of the upper lobe of the left lung. The heart contained mixed clot. The mitral valve is 3 inches in circumference and the flaps are short and irregular in thickness. Mediastinal lymph glands much enlarged and caseated. The aorta shows patches of endarteritis. Peritoneal cavity contains whitish, cloudy fluid having some fecal odor. Intestines adherent in places, especially around the ileocecal valve and lower two inches of ileum, which seems to be the site of the perforation (Fig. 3). Omentum, parietal peritoneum, spleen, and liver contain nodules of caseous matter. In the lower ileum are several ulcers about an inch in width encircling the gut, and others less advanced; the ileocecal valve and cecum also show these typical tuberculous ulcers. The anterior wall of the stomach also shows points of caseation. The peritoneal covering of the urinary bladder is studded with tubercles and its mucosa is coated with mucopurulent material. The Fallopian tubes are almost 1 cm. in diameter and filled with caseous material. Small nodules can be seen below the uterine mucosa.

The histological changes found are caseation necrosis (tuberculous). There is no sign of repair about the tubercles and giant cells are present in sections from the liver and lymph glands. In places there is hyaline change. The caseous nodules in the lung are in part simple tubercles and in part caseous degeneration of the bronchial walls.

In the above case we have an individual whose heredity is tainted with tuberculosis and who has a younger brother who is deformed and defective. The patient's personal history is likewise unfavorable. She has had typhoid fever and has suffered from nervous prostration and St. Vitus's dance. While the assigned cause for the epilepsy is the introduction into immorality above mentioned, we must consider this as a coincidence only, or at most as the last increment necessary to touch off the already unstable equilibrium of the patient. It would seem that during this experience, she contracted syphilis. The anatomical distinction between tuberculosis and syphilis is hard to make in some cases, and in this case, in view of the clinical history, we must make this differentiation. Apparently, both the gross and microscopical appearances are in favor of tuberculosis. There is no evidence of a tendency to repair, and microscopically giant cells were found in several organs. It was not possible, however, to stain the tubercle bacillus in any specimen.

From the anatomical findings, it seems as if the cause of the epilepsy lay in the focal lesions of the right cortex. This is confirmed by the observation above recorded, that the seizures begin on the left side. There were no other symptoms of cerebral tumor except for the slight nausea reported. The eye condition may or may not have been due to the focus in the occipital region. We do not know just what the condition was; the condition of the iris suggests that there had been inflammatory processes which might acount fcor the poor vision.

The frequent attacks of intestinal autointoxication are easily accounted for by the intestinal infection. This was of high grade and a perforation through one of the ulcers situated near the ileocecal valve was the cause of death, permitting the escape of fecal contents into the peritoneum. That the intoxication with the products of absorption was intense is shown by the temperature during the fatal illness.

THE HIGH-FREQUENCY METALLIC DISCHARGE.

A NEW TREATMENT; ITS POSSIBILITIES.

By FINLEY R. COOK, M.D.,

NEW YORK.

Recently we have had brief and incomplete reports from the Paris Surgical Congress, where Dr. de Keating Hart demonstrated a new treatment for the eradication of cancer. The method is described as one of fulguration, and consists in the application of electric sparks from an insulated probe, charged with a high-frequency current of considerable voltage, to a malignant growth, after which the growth is alleged to have softened and finally vanished by volatilization.

In the autumn of 1904 I began to experiment with the high-frequency current discharged from the point of an insulated wire. Very early in my experience I was led to believe that this method of application of the high-frequency current possessed considerable value as a therapeutic agent, and in its escharotic action in morbid growths differed widely from any other mode of treatment, differing radically in its action from the galvanic current.

It differs from the electrolytic action of galvanism in that it is more powerful, more rapid, and affects a much wider area of tissue; it also appears to have a peculiar selective action on morbid cells, or cells of lowered vitality, as well as a stimulating action on healthy cells. It was these peculiar features of the metallic-point high-frequency discharge which led to its employment in the treatment of epithelioma. It will be interesting to learn in just what varieties of malignancy Dr. Hart has used this form of treatment, but personally I have had no experience with this method in the treatment of deep-seated growths, and doubt very much its adaptability in any but superficial cases. In all the malignant cases in which I employed this method the same results undoubtedly could have been accomplished by the use of radium or of the *x*-ray, and in all but one of very recent date a number of *x*-ray exposures were given as a preventive measure against recurrence, making it impossible to estimate its value as a radical cure. It is not, however, the purpose of this article to consider the high-frequency current in the treatment of cancer, but simply to review in a general way various other affections in which this technique has been employed with very unique and gratifying results.

In the first place, this current has been found exceedingly useful in the reduction of morbid and hypertrophied tonsils. Its application is practically painless, causes the tonsil to shrink and undergo rapid degenerative changes, and is followed in from three to five days by complete exfoliation. In the case of soft and moderately enlarged tonsils, complete reduction is readily accomplished at one sitting. Inasmuch, however, as a reaction of more or less intensity is apt to ensue, it is preferable in aggravated cases to divide the operation into a number of sittings. This method seems to be especially adapted to the removal of tonsils in the adult, where

more or less danger from hemorrhage attends the operative procedure.

As the growing tendency to consider morbid tonsils a menace to health has resulted in an increased demand for their removal, and the electrical treatment appeals more to the majority of patients than any operative measure, it would seem that in these cases we would have a wide field for the employment of the metallic high-frequency discharge. Though I have had no personal experience in utilizing this current for removal of adenoids, I believe by some modification of technique these cases could be treated with equal success.

In certain cutaneous lesions, the high-frequency metallic discharge was found to be effective, especially so in those characterized by hyperplasia, namely, acne, acne rosacea, papilloma, moles, etc. In the treatment of simple acne, where each individual lesion receives a separate charge, it seems possible to accomplish as much in a few minutes' treatment as would require as many days or weeks by any other method. The papules shrivel, the contents of the sebaceous glands escape, and desquamation is rapid, leaving no scars. The latter fact deserves special emphasis. It is this peculiar property of the high-frequency metallic discharge which particularly recommends its employment on the face.

Very satisfying results were also obtained by using this method in the removal of scars, it being found superior to the *x*-ray treatment, which requires very strong and prolonged exposures and a tedious wait for results. The same technique was employed in two cases of suppurating sinuses from broken down tuberculous glands; one was of six months, the other of three months' duration. Likewise in these cases both its escharotic action on the remaining pathological tissue, and its highly stimulating action on the surrounding normal tissue were quite manifest. Healing resulted in a comparatively short time, and the scars were insignificant.

A number of cases of acne rosacea were submitted to this treatment, one of which, of over eleven years' standing, was in a stage of marked development; the nose was of an immense size with marked nodulations, and caused an unsightly disfigurement. The patient had been under the care of several specialists and had apparently received every treatment usually employed for this affection, including the *x*-ray, galvanic needle, and scarification. Multiple discharges were made over the entire nose, during which process large cavities containing sebaceous material were opened and shriveled, leaving a thick layer of necrosed tissue surrounded by an active area of hyperemia. Subsequently the necrosed area dried, shrank, and assumed a blackish hue. Six days later it began to loosen, and was readily removed *en masse* without any sloughing. The underlying surface was in an active, healthy condition of granulation, and new skin was already rapidly encroaching upon the denuded area. Epidermatization was complete ten days later. The result was highly gratifying, and it would seem that in these cases particularly the high-frequency metallic discharge was unique in its effects and probably the only reliable mode of treatment in severe cases.

Appreciating the peculiar escharotic properties of this current, one would naturally expect it to exert a favorable influence in the treatment of hemorrhoids. About a dozen cases were submitted to this treatment, some of which were unusually severe, and one in particular was the worst case I have ever seen. The treatment was successful in every case, and I am firmly convinced that in this current we have a positive electrical cure for both internal and external hemorrhoids. So far in my experience the results of this treatment have been as positive as those obtained by any radical operative method ordinarily employed. Inasmuch as the treatment is attended and followed by little or no pain, it would seem to appeal especially to that large army of sufferers who, for one reason or another, refuse to submit themselves to any surgical method requiring the administration of a general anesthetic. Two of the patients treated were past 70 years of age, and one, a female, was a neurasthenic.

The high-frequency current discharged through an ordinary glass vacuum electrode, the routine method for delivering the high-frequency current has been claimed by some workers in this field to exert a favorable influence in these cases. It is undoubtedly true that this discharge is capable of reducing congestion, of contracting hemorrhoidal veins, and of alleviating pain, but no minor measure, possessing only a sedative influence, can accomplish an absolute destruction of hemorrhoidal tissue. The metallic discharge produces an immediate escharization.

In the majority of cases the operation was divided into a number of treatments. In no case was it necessary to dilate the sphincter, and in sensitive subjects local applications of a 10 per cent. solution of cocaine or a hypodermic injection of sterilized water controlled the pain. For bringing down the internal hemorrhoids, suction obtained from an ordinary ear-pump operated by an electric motor was used. By reversing the valve of the pump compression was utilized for replacement. In this manner both retraction and reduction were quickly performed without manipulation, and not only accompanied by no pain, but without the patient being aware of it. In no single case did the treatment cause an hour's confinement to bed or interrupt the patient's daily routine duties. The favorable results so far obtained lead us to believe there is a still wider field for the use of the high-frequency metallic discharge.

The following are a few illustrative cases in which this therapeutic measure has been employed:

Case I.—Miss N. H., aged 55; examination, February 7, 1907; gave the following history. Stated that as far back as she could remember she had suffered from tonsillitis during the winter months. The past six years these attacks had been more frequent and more severe. The past two years she had had an irregular cough and expectoration, lost twenty pounds in weight, had irregular chills and fever and night sweats, lost all interest in work, and was about to abandon her position as a teacher. One physician had treated her for malaria, another thought she was suffering from pulmonary tuberculosis. Examination of chest negative. No enlargement of spleen. Blood examination negative. Both tonsils were moderately swollen and flabby, and multiple crypts were filled with cheesy deposits. There was chronic catarrhal pharyngitis.

Moderate high-frequency discharges were made over the surfaces of both tonsils. The application was not painful. At the end of a week (February 14) the tonsils had markedly shrunk, no morbid crypts were in evidence, the cough had subsided, and there was only slight expectoration. The patient had improved greatly in general health and had gained five pounds; she complained no more of chills and fever. Although it seemed hardly necessary, another slight treatment was given. The patient was seen again October 15. There had been

continued improvement in the general health. On exposure to wet and cold, she had contracted a mild laryngitis, but the tonsils were in a normal condition, and she has had no tonsillar trouble since her first treatment, February 7. She had gained twelve pounds.

Case II.—Master K., aged 14; examined April 2, 1907; weight, 94 pounds. Came to New York from boarding school, where he had just recovered from an attack of follicular tonsillitis. Mother stated that he was subject to sore throat, was lagging behind his class at school, was irritable, nervous, and mentally dull. Tonsils markedly enlarged, interfering with breathing. Nasal voice, a few small patches on tonsils in evidence. Naso-pharyngeal catarrh.

Both tonsils received the high-frequency metallic discharge. The lad stated that the treatment was not painful. April 4, tonsils covered with a whitish membrane. Being anxious to complete the reduction of tonsils as soon as possible, that he might return to school, I made a few more light discharges. The patient was seen again April 10. He stated that three days previously he had expectorated several masses of whitish material. Weight, 99 pounds, an increase of five pounds in eight days. He had noticed an increase of appetite, and there was a marked improvement in spirits. This patient was seen two weeks later, having returned home for a short holiday. Tonsils were remarkedly reduced in size and normal in appearance. His mother stated that she had received excellent reports of his improvement in his studies. His weight was 104 pounds, a ten-pound gain in three weeks.

Case III.—Mr. P., aged 56. Seen March 28, 1907. Stated that for many years he had suffered from sore throat. On examination tonsils were found to be swollen, and several crypts were distended with exudates. Complained of loss of appetite and chilly sensations. Treatment applied. March 29, both tonsils were covered with white patches; moderate reaction had followed the treatment. Patient was seen again April 3. Upon examination the tonsils were seen to be markedly reduced in size; the surfaces was cleared of escharotic tissue and presented a normal appearance. He spoke of a decided improvement in general health. The patient was seen again October 15 when he stated that he had had no further trouble with his throat; he had gained in weight and was enjoying better health than he had for many years.

Case IV.—Mr. L., aged 46. Examination April 10, 1907. Patient had suffered from attacks of sore throat as far back as he could remember; had always been susceptible to changes in climate, and exposure to wet or cold resulted in tonsillitis. Many of these attacks had resulted in tonsillar abscess. The past two years follicular tonsillitis occurred more frequently; the past two months his throat had given him constant trouble. Complained of a loss of appetite and general malaise. Both tonsils were enlarged and congested: the crypts were hypertrophied, containing mucous plugs and inspissated exudates. The right tonsil received several discharges. Two days later it was found covered with a thick white necrosed layer of tissue. Slight reaction followed treatment. April 15 the tonsil was clear. The left tonsil was now treated in a similar manner. The tonsil cleared four days later. Patient stated that he had never felt better. The tonsillar stumps remaining were such as usually result from tonsillotomy. This patient was heard from October 15; he had gained in weight, and his general health was excellent. Had had no trouble with throat since treatment.

Case V.—Miss K., aged 26. Examination, December 4, 1906. The past six years or more patient had had an extensive eruption on her face. During the greater part of this period she had been under the care of the family physician at various times. Although the condition had improved from time to time she had never been entirely free from an embarrassing disfigurement. Many small papules, pustules, comedos, and pits covered the face, including forehead and chin. Diagnosis, acne.

Albolene was applied, electric massage, numerous comedos expressed, alcohol applied abundantly; several individual papules received high-frequency discharge. Under treatment these papules shriveled, leaving crusts of devitalized epithelial cells. The treatment being moderately painful, the following change was made in the technique. An ordinary glass high-frequency electrode was held in the left hand of the operator, his body charged first with the high-frequency current of 5 amperes; the right hand, holding the insulated metallic electrode, was applied to the face, and quick and intermittent discharges made by placing a finger on and off the proximal end of the metallic conductor, while the fine distal end rested against the face. One week later, desquamation was nearly complete, leaving no marks of treatment. The same method was adopted at each visit once a week until the entire face had been treated. Four weeks after the first treatment the face was absolutely free from any eruption, and has remained so up to the present time. Moderate exposures to the *x*-ray were subsequently given to stimulate the sluggish sebaceous glands and to act as a preventive measure.

Case VI.—Mrs. X., aged 50. Examination, October 1, 1906. For the past ten years the patient had suffered from acne rosacea. She stated that she had been under the care of many physicians, two of whom were specialists. One of the latter told her she never could be cured and that she must never allow anyone to treat her with the needle, as the resulting scars would make matters worse. She was assured that the treatment about to be applied would leave no scars, although a needle-point would be employed. The nose was enlarged and of a bright-reddish hue and nodular about the tip. Dilated blood-vessels covered the cheeks and sides of the nose. Because the application was somewhat painful and the patient very nervous, it was decided to treat only a small area at each sitting. The treatment was applied every other day, and continued for two months. After each sitting the area contracted and dried, leaving small crusts. A few days later the crusts would loosen, and were then removed. She returned to her home in the South with her nose and face absolutely cured. The patient was seen again September 13, 1907, and has had no return of the trouble. She spoke again of the feeling of mortification which she had so long endured, not only in the presence of strangers but in the presence of her own family. She said her gratitude was more than she could express.

Case VII.—Mr. S., aged 30. Diagnosis, acne rosacea. This patient stated that he had been afflicted for seven years with an increasing enlargement and deformity of the nose. Married, had a family of three children to support. He was employed as a waiter in one of the leading New York hotels, and was given a leave of absence by the proprietor, who told him he could not return to his position until he was cured. He had been in many hands, among them two noted specialists, and had lost all hope of being cured. The nose was of an immense size, nodular, covered with pustules, red,

and inflamed. The same treatment was applied as in the previous case and in a similar manner, with the same result. The treatment covered a period of ten weeks, after which he resumed his position.

Case VIII.—Mrs. N., seen September 5, 1906, presented a mole on her right cheek of long growth and of unusual size; the presence of coarse, black hairs made it very conspicuous.

A 2 per cent. solution of cocaine was used hypodermatically, after which the high-frequency discharge was applied until the entire growth was shriveled to the level of the surrounding skin. On the following day there was slight redness with swelling around the seat of application. This patient was not seen again until October 10, 1907; at this time no scar was visible except upon minute examination, when a small, white spot was seen to be the only trace of the former disfiguring lesion.

Case IX.—Mrs. W., aged 56. Was seen October 3, 1906. For the past seventeen years she had been afflicted with painful and bloody stools. At times the pain was most excruciating, and during this period she had also suffered from obstinate constipation, requiring the daily use of cathartics. For many years she had suffered with headaches and nervousness. She had tried all manner of local applications, which gave but temporary relief. She had a morbid fear of undergoing an operation. There were three external hemorrhoids of moderate size, swollen, inflamed, and exceedingly painful to the touch. There were also four or more internal hemorrhoids, varying in size from that of a marble to that of a hickory nut; they were inflamed, as was also the surrounding mucous membrane.

These were exposed by means of suction obtained from an air pump operated by an electric motor. At the first treatment the high-frequency metallic discharge was applied to the external hemorrhoids under local anesthesia. During the discharge they dried up and contracted. One week later healing was nearly complete. The internal hemorrhoids were attacked one at a time to minimize the pain and reaction which might follow. Five days intervened between treatments, and at the end of a month the patient was completely cured. She had suffered but trivial pain and had gone about during the entire time. The patient was seen again in October, 1907. She had gained in weight and general health and no longer suffered from constipation.

Case X.—Mr. T., aged 72. Seen July 16, 1906. The patient stated that he had suffered from hemorrhoids at intervals as far back as he could remember. He had a strong prejudice against an operation. Bleeding had always been the dominant symptom, and there had been times when he had lost large quantities of blood. There was an internal hemorrhoid about the size of a walnut, indurated and inflamed; there was also moderate prolapse of the mucous membrane.

Employing no local anesthetic, it was thought preferable to make as mild discharges as possible with the high-frequency current at each sitting. There were four treatments at intervals of five days. At the end of three weeks a radical cure was effected. This patient was seen again in September, 1907, and stated that he had had no recurrence of his former trouble. This elderly patient, although quite feeble, came from a long distance to the city for each treatment, and at no time after any treatment had he suffered as much as he usually did at periods of exacerbations.

Case XI.—Mr. L., aged 70. Seen February 9, 1907. This patient stated that his rectal trouble dated as far back as the Civil War. For the past two years or more his symptoms had become much more severe. He complained of pain in the back, very profuse rectal hemorrhages, prolapse of the rectum, and an enlarged inflamed tumor. For the past six months he had lost considerable weight and strength, and his suffering had been so great that he was about to give up business, although he was a remarkably well-preserved man for his years. During the latter period the prolapse was almost constant, and he was repeatedly making ineffectual efforts to replace the swelling; in fact, the prolapse had become practically constant. His hemorrhages became more profuse, and at times actually saturated his clothing. Notwithstanding his critical condition, he was positively determined not to undergo any surgical operation. He presented a swelling somewhat larger than a walnut indurated, inflamed, and ulcerated. The rectal mucous membrane was relaxed, inflamed, and showed evidence of a prolapse of long duration. There were several bleeding points in the area of ulceration.

The high-frequency metallic discharge was applied at each treatment, given once a week for twelve weeks in succession. The tumor was reduced in size at each sitting, and at the end of this time there was absolutely no trace of the hemorrhoidal tumor. No local anesthetic was employed, although the applications were moderately painful. He complained of no reaction after treatment, but, on the other hand, felt better. During this time the patient continued uninterruptedly with his regular employment.

So far in my experience it has not been deemed advisable to attempt a radical cure of severe cases in one treatment. I believe, however, that it could be accomplished in all cases.

120 East Thirty-fourth Street.

FIBROID TUMORS OF THE UTERUS AND THEIR TREATMENT.*

By FRANK DE WITT REESE, M.D.,

CORTLAND, N. Y.

SURGEON TO THE CORTLAND CITY HOSPITAL.

We are all aware that the specific cause of fibroid tumors of the uterus is still obscure, although many seeming causes have been brought to light. To the writer the most plausible cause, the one which keeps most prominent in his mind, and the one upon which he bases his method of treatment, is that of irritation or inflammation. Edmond B. Wilson says that "cytologists are laboriously endeavoring to ascertain in what measure the chromosomes are qualitatively different, in respect to the process of growth and differentiation. If such qualitative differences are definitely proved to exist, a new and great field will be opened in cellular physiology and pathology. . . . . Already attempts have been made to bring the facts of tumor formation and the like into relation with disturbances in the chromosome groups."

He further says, "it should not be forgotten that in nuclei which show little or no visible differentiation of the chromosomes, profound changes *might* take place without giving visible sign of their presence. Such changes might be immediately induced by any one of many conceivable causes, by parasites, perverted form of metabolism, the presence of a specific form of toxins, and so on, and having once arisen might persist for an indefinite number of cell

*Read at Ithaca, N. Y., September 24, 1907, at the first annual meeting of the Sixth District Branch of the Medical Society of the State of New York.

generations, long after the initial exciting cause had passed away."

It is claimed by the most competent authorities, whose names are too numerous to mention, that the fibromyomata of the uterus contain essentially the same cell elements as the uterus itself, namely muscular tissue and fibrous tissue. The quantity of each tissue is quite variable, in some fibromyomata the muscular, and in some others the fibrous element predominates. This led some of the older surgeons like Tait to classify these tumors according to the predominant tissue of which they are composed, but it does not matter at this time which cell in these tumors outnumbers the other.

The essential point for us to know and consider is that the cell tissue in the fibroid tumor is like that which is found in the organ from which it springs. Now, if these facts, which are authenticated by every writer on fibroids, are kept before our minds, we shall have the premises whereby we can form a theory of the cause of these tumors that will be of as great assistance in the treatment of them as Erlich's "side-chain" theory of immunity has been in developing the serum treatment of bacterial infections.

The cells of the uterus have special power to reproduce themselves in response to a special stimulus; this stimulus is a physiological one, pregnancy.

We must bear in mind that the cells of the uterus, as all cells of the body, are endowed with life, and that they have a physiology and a chemistry which, if disturbed by some new environment, may bring about great changes in the cell function.

If the conditions for cell activity are normal, such as nutrition, nerve stimulation, etc., then we have a normal functioning uterus; but if the environment is changed we must expect an excessive function of some of the cells, while others are dormant, producing possibly an asymmetrical uterus.

A knowledge of the experiments of Burke and Loeb must cause the thinking physician to pause and seriously consider the effects of cell irritation, as he studies the histological and pathological conditions of a fibroid tumor. Burke's sterilized bouillon responds to the quickening influences of radium, and Loeb's unimpregnated ovum, when subjected to the irritating influence of cyanide of potassium, assumes the first stages of growth as in the normally impregnated ovum. If these experiments of Burke and Loeb are true, why are we not justified in believing that the normal cell of the uterus is influenced to reproduce itself under the stress of a continuous irritation? This is practically the Theory of Veit, Cohnheim-Ribbert in regard to the origin of myomata of the uterus. The etiology of fibroid tumors is in a large measure undetermined, yet there are many obvious causes that may be grouped as (1) mechanical and (2) infectious; under the first, mechanical, we have congenital and acquired causes.

Congenital causes would embrace the embryonic inclusion theory of Durante, as well as congenital deformities, such as anteflexion, constriction at the os uteri, undeveloped uterus, etc.

Acquired mechanical causes include displacement from weakened ligaments, lacerations of the cervix uteri, with a large amount of cicatrical tissue, a partially occluded cervical canal as a result of faulty trachelorrhaphy where the scar tissue was not fully removed, and spasm at the internal os due to a hyperesthesia of the mucous membrane at this point.

The enumerated mechanical causes of fibroid tumors operate by obstructing the free flow of the natural secretion of the endometrium from the uterus, thus causing an irritation and stimulation of the structures of the uterus that cannot be unlike the normal stimulus to these structures by pregnancy. It is well known that the sinuses of the head must have good drainage or an infection will sooner or later occur. This is true of that uterine cavity which retains its products of membrane secretion. This secretion is a natural medium for infection, after which it becomes a chronic cell irritant. Howell says "irritability is that property of living matter by virtue of which external influences are responded to by changes within the cell. The changes may, in turn, induce secondary phenomena." Cell irritation is, I think, the real cause of fibroid tumors.

Prolific causes of uterine fibroids are the infections that are introduced from without; therefore they are preventable. I may mention gonorrhea as one source of infection. I am sorry that I have no tabulated statistics on the results of gonorrhea in women as a cause of fibroid tumors, but will say that my observation has been in practice that quite a percentage of women who have been afflicted with uterine fibroids have the characteristic marks denoting that once they had been victims of gonorrheal infection. I have observed that it is possible to locate foci of inflammation somewhere in the genital tract of all women who have ever suffered from this disease, and this is the reason why I believe that gonorrheal infection is a cause of uterine fibroids. Gonorrheal infection has a degenerating influence upon uterine tissues.

Infection during miscarriages, whether due to instrumental interference or to other causes, is a source of constant uterine irritation. I have seen a few cases of uterine fibroids that I thought were due to an infection following curettage. One case in particular, the patient was thirty-eight years old, who had a curettage and in about two years developed a small fibroid. There had been ever since the operation a subacute endometritis.

Fibroids are said to occur more frequently in the unmarried and sterile than in the child-bearing women. This can be accounted for when we are reminded that the reproductive organs in these women have no rest (from puberty to the menopause) from menstruation, which is accompanied by an extra amount of blood to the uterus every twenty-eight days. The uterus of the child-bearing woman has a rest from menstruative congestion for eighteen months, and sometimes longer, with each child.

The *diagnosis* of a fibroid tumor of the uterus is made with comparative ease. Usually when the patient consults the physician the tumor is of such proportions that to determine it from other pelvic tumors is only a matter of a few minutes' time.

The tumor is always a part of the uterus. Introduce the uterine sound into the uterine cavity, and then, by the aid of bimanual examination, it will be readily ascertained whether the tumor is a part of the uterus or not.

A careful study of the history of the case will reveal its benign or malignant nature. It is with some difficulty that a differential diagnosis is made between a large edematous retroflexed uterus and a small fibroid tumor of the fundus of a retroverted uterus.

In the case of an edematous uterus, on digital examination it is possible to indent or pit the uterus on pressure, whereas in the fibroid uterus it is not possible to indent the enlargement.

Treatment will also clear up this point. When the retroflexed uterus is restored to its proper place, if the enlargement is due to edema it will soon subside, while if due to a tumor it will remain the same.

If the diagnosis is not easily determined the patient should be examined under an anesthetic.

It is agreed that all fibroid tumors of the uterus develop from the muscular coat and grow, either towards the peritoneum or the uterine cavity, or out into the pelvic tissues. If the tumor is wholly confined within the muscular wall of the uterus it is called an interstitial or intramural fibroid. This tumor is usually accompanied by hypertrophy of the uterine walls. When the tumor is beneath the peritoneum it is called subperitoneal. When it projects into the uterine cavity it is called a submucous fibroid. If tumors are found in the broad ligaments they are called intraligamentous.

The *treatment* of fibroid tumors should be (1) prophylactic, (2) surgical, (3) medical, (*a*) constitutional, and (*b*) local.

Prophylactic treatment of uterine fibroids should be, in part, educational, while the girl is yet a child. The best of hygienic surroundings and a sensible mode of dress should be adopted. The girl up to puberty should be allowed to live the free and easy life that is accorded to her brother of the same age, with romping, horseback riding, outdoor games, fishing, etc. The girl should wear garments that will not restrain the freedom of muscular movement. She should wear low-heeled shoes, so her poise can be maintained without tax to the nervous system. If obedience to such hygienic rules is insisted upon for the little girl, it will favor a normal development of the generative organs, with less tendency to the development of uterine fibroids. The girl, as she approaches puberty, should be informed of the evil consequences of illicit sexual intercourse. She should be informed that gonorrhea and syphilis not only cause sterility, but also by their irritation cause a chronic hypertrophy of the muscle of the uterus, which sometimes terminates in a uterine fibroid.

I am satisfied that dysmenorrhea at puberty is a symptom that should engage the serious attention of the physician and a symptom whose cause should not go untreated. Of my last fifty cases of fibroid tumors, forty-nine women gave a distinct history of having had pain at the first menstruation. The other patient gave a history of having a miscarriage followed by infection. Many of these cases, no doubt, could have been averted if the cause of the dysmenorrhea had been removed at puberty.

A constant irritation, acting chronically, as the symptom dysmenorrhea indicates, is a menace to any woman, and I believe a direct indicator that some day a fibroid tumor will develop. Therefore, the physician who does not impart this information to a patient who suffers from dysmenorrhea at puberty sadly neglects his duty to that patient. The discussion of this question alone could profitably engage our attention during the whole of this session. I appeal to my fellow-workers to give this subject, dysmenorrhea at puberty, and its relation to uterine fibroids, their serious, earnest thought.

Surgical Treatment.—Should all fibroid tumors be treated by removal, as might be advocated by Noble of Philadelphia, Kelly of Baltimore, and others, who are equally efficient in operative technique? I am free to say that many times tumors might better be removed if patients could always be in the hands of such expert operators, for it would shorten their period of invalidism, with but a slight death risk. Noble says if the operation is done early the mortality is reduced from 5 per cent. to 1 per cent.

In view of this death rate, conceded by Noble, which increases in less expeditious and skilled hands, I would say that there are many cases of fibroid tumors of the uterus that should not be removed by the knife, because they are amenable to constitutional and local treatment. Noble argues for an early operation when the tumors are small and are not pressing on neighboring organs, before the patient becomes anemic, and possibly a malignant degeneration has taken place. Noble wishes to operate early, because of the great tendency that fibroid tumors have toward malignant degeneration and other complications, such as twisted pedicle, cystic degeneration, etc., which complicate about two-thirds of all cases of fibroid tumors.

The constitutional and local treatment of fibroid tumors should begin at the time or before that at which Noble regards the operative treatment on debatable ground, namely, when the fibroid tumor is subperitoneal. If patients suffering from fibroid tumors could reach the physician in the very early stages of the tumor's development, it would be fair to say nearly 100 per cent. could be cured by constitutional and local treatment. During my experience I have not as yet a failure to report when the patient was seen early in the progress of the tumor's development.

The symptom above every other symptom that should lead a physician to explore the pelvic organs with the view of finding an abnormality of the uterus, and to detect a tumor in its earliest stages is *dysmenorrhea.*

Who has not examined the pelvic organs of women and found retroverted uteri, enlarged and edematous, with an uneven surface of the fundus, and perhaps in a few years has examined the same patients again and found that well defined fibroid tumors have developed? This must be a common occurrence with all of us if we are observant. At this stage of the tumor's development is when the physician can do the greatest good in treating fibroid tumors without the knife.

I should give these rules for operating: (1) If the patient has neither time nor means to take the knifeless method; (2) if there is severe hemorrhage or sign of cystic or malignant degeneration; (3) if the patient has the tumor cachexia with complications; (4) if the tumor continues to grow, after a few months' knifeless treatment; (5) if the tumor is submucous.

The knifeless treatment is based upon the supposition that all uterine fibroids are due to a chronic irritation, which is a result of an influence which is chemical, and that favors an overnutrition of a special group of uterine cells. These uterine cells multiply as they would if normally stimulated by pregnancy until they become an aggregation of cells which keep up the irritation by their changed physiological and chemical action.

It is for the gynecologists to imitate nature in instituting a treatment that will be effectual in the cure of this trouble. We all know that at the menopause many uterine tumors disappear. This is due, no doubt, to the change in the blood supply, with a more favorable condition for absorption by the lymphatics.

We must consider that the uterus is an organ of a peculiarly large blood supply. "It is supplied by four arteries which divide and subdivide until that portion of the womb which is not made up of muscle tissue and nerves is composed of a highly complex and finely divided blood supply." (Griffith.)

The blood supply of these organs is affected by the mind, and this should be taken into consideration as we treat the patient constitutionally. Remedies that quiet the nervous system are beneficial, such as asafetida, valerian, etc. These remedies, combined with fluid extract of hydrastis, are the ones upon

which I rely. The hydrastis should be given for a long time, in small doses (10 minims) before meals. Hydrastis is, as you know, a stomachic, aiding digestion and assimilation, in this way building up the body resistance through a more perfect metabolism. I believe that some day a serum which will be effectual in the treatment of tumors will be discovered, and will be more reliable than that now used in the treatment of exophthalmic goiter.

By local treatment we should try to establish good drainage. Women who have uterine fibroids usually have a characteristic smelling leucorrhea, and many of them will complain of having a disagreeable odor about them.

If the uterus is retroverted or retroflexed it should be placed in its proper position and sustained there with proper support, and all causes, as far as possible, of irritation or passive congestion should be removed. Uterine douches as a daily routine should be prohibited. I am not so sure but that the uterine douche is the cause of many of the ills peculiar to women.

I have no specific remedy to offer, to be used locally, but the one I have mostly relied upon is picric acid in glycerine, 3 grains to the dram. Two or three drams of this is placed in the vagina, twice weekly. I also use ichthyol and glycerine, boroglyceride and pure glycerin. Sometimes it is well to alternate with these remedies. The cotton tampon should be placed at each treatment and the patient instructed to remove it the following morning, but not take a douche. The tampon acts as a brush to thoroughly distribute the remedy over the neck of the uterus and walls of the vagina, which will remain until the next treatment. This treatment should be persisted in for one, two, or three years. Persistence is the price of the reward in these cases.

You might ask, What do you expect your local remedies to accomplish.

First, they deplete the tissues of serum, diminishing capillary pressure, which favors a normal cell function and also favors a normal function of the lymphatics.

Second, I am persuaded that a small amount of the drug works into the uterine canal by the ascending mucous currents, as described by Bond, of England. If this is so, and I have no reason to doubt it, the inflammatory foci of the endometrium are disinfected, become gradually removed, and the function of the uterine tissue is restored to its normal state.

My paper is based upon my last fifty cases of fibroid tumors treated in private practice.

Of the fifty, forty-nine complained of dysmenorrhea at puberty. Three were operated on by an able surgeon, with two deaths. One has been advised to have the tumor removed, but refuses to be operated upon; her general condition is improving under treatment. Twelve others are still taking treatment. The remaining thirty-three were fully cured, or so much relieved that they discharged themselves.

It was Sir Charles Dilke, we believe, who once called the banana the curse of the tropics, and held that where it abounded human progress and ambition disappeared. In a measure, the knife applied to fibroid tumors of the uterus is the curse of the physician, because it is easier to remove the growth than to study its cause, which may be removed before the tumor develops into a formidable affair.

In conclusion, I wish to say, any physician or surgeon who wholly disregards the elements of irritation in the cause of tumors will utterly fail; but he who bears this in mind, and assists the uterine cells to a normal functioning activity, will not wonder why some one else does succeed, but will himself succeed in the removal of the cause, and in the treatment of uterine fibroids without the knife.

THE IDENTITY OF VISUAL AND COLOR SENSATIONS.

By GEO. H. TALBOT, M.D.,

NEWTONVILLE, MASS.

Every form of matter when sufficiently heated has the property of emitting rays of light. "Heat," says Locke, "is a very brisk agitation of the insensible parts of the object which produces in us the sensation we call heat and dominates the object hot, so what in our sensation is heat, in the object is nothing but motion." No body in nature is absolutely cold and every body not absolutely cold emits rays of heat, due to the molecular motion or vibration of the atoms throughout its entire structure. Thrust a piece of iron into the fire and as it begins to warm its atoms begin to vibrate through wider ranges. The old vibrations are intensified and new and more rapid ones generated. As the augmentation increases a faint glow appears and finally it becomes white hot. The molecular motion has increased to such a degree as to cause an undulation visible to the eye. If heat is motion and increased motion develops light, it is obvious that light is likewise a form of motion. This molecular vibration is a mode of motion exerted by all natural forces when in action. Sound, heat, and light are all produced by it. It is the motion of the atoms of which the objects emitting light or heat are composed, that is conveyed by some medium but not by any sensible part of the bodies themselves. It is the cause of that which our sensations designate as heat, light, or sound.

We are indebted for our knowledge of light, in a large measure to our knowledge of sound, our conceptions of one being defined by the conceptions of the other. It was only by our knowledge of waves of sound that we suspected the existence of waves of light. And while sound and light are apparently so widely different in their effects, they have many things in common. They may be even more closely associated than we have yet conceived. There are some individuals in whom certain sounds give rise to certain definite sensations of color.

We may compare them in another way. The pitch of a note depends upon the number of vibrations per second, or, in other words, upon the length of its waves. Pitch corresponds in a way to color. At one end of the spectrum we have the color red, at the other extreme violet, with all the prismatic colors intervening. Beginning at red, the pitch of light increases, the sensation of blue, indigo, and violet resulting from more rapid vibrations than red or orange.

Sound is conveyed by the undulations of the air. Where there is no air there is no sound. There is no sound from a bell in a vacuum. Exhaust the air from a glass globe so that it is reduced to an hundred thousandth of its density and the transmission of light through it is not appreciably affected. Hence it must have some medium other than air for its transmission. An ancient theory of light held it to be something emanating from the eye, not something from without entering it, and it was only by assuming the existence of some medium other than air that the undulatory theory became tenable.

These vibrations, generated by a luminous body, are conveyed to the eye by a hypothetical medium

that we call luminiferous ether. It is supposed to fill all interstellar space, however vast, as well as all interatomic space, however dense. This ether, then, pervading all space, transmits each wave of light through it. It is not disturbed by wind or water or by any other force but light. We have never seen it, yet we know that it is a substance of some kind and has elasticity and density, or it could not transmit light and radiant heat at the enormous velocities it does. It must be homogeneous and continuous, that is, free from structure of any kind. The nearest analogy to it is a jelly, although it is, of course, infinitely less material. By passing a ray of light through a prism, we break it up into its constitutent parts or decompose it, forming a spectrum. Light in passing from a rarer to a denser medium, as from air to glass, is, unless it strike the medium at right angles, bent in its course. The velocity of light in glass is less than in air; it is, so to speak, compressed. If it strikes the glass at an angle and is bent from its straight course, if the surfaces of this glass are not parallel, as in a prism, a specturm is formed. The more waves in a given distance, the greater will be the angle; or, in other words, the greater the refraction. A red ray has about 39,000 waves to the inch, a violet about 57,000, hence the violet is refracted the most and the red the least. This difference in refraction is due to the difference in wave lengths of the different colors. Each color of the spectrum, then, must have a definite number of vibrations or wave lengths. Though we have never seen these waves of light, their length has been definitely ascertained. The number of vibrations, per second, necessary to produce the different colors are as follows: Violet, 699,000,000,000,000; indigo, 658,000,000,000,000; blue, 622,000,000,000,000; green, 577,000,000,000,000; yellow, 535,000,000,000,000; orange, 506,000,000,000,000; red, 477,000,000,000,000.

To complete the proof that white light is the sum total of all the colors, we can recombine the constituents so as to form a white light, either by reversing the process of decomposition and sending the colors of the spectrum through a prism, when they will recombine and form a white light, or if instead of one prism we use two. In this case, the first will form the spectrum and the second reunite them. Another way to prove this is to take a circular disk and color the sectors or spaces from the center to the circumference with the colors of the spectrum in the proper proportion and place. Rotate this disk rapidly and it will appear white; owing to the rapid motion, the colors will blend and the impression of a white color is due to their joint effect. Red, green, and violet combined in certain proportions will produce white, therefore all possible colors may be made from these three colors, and hence they are the primary or fundamental colors, and the ultimate spectrum may consist of three instead of seven colors. Light falling on any surface is either reflected, refracted, or absorbed. There is no color generated by a natural body whatever. We see all non-luminous bodies by reflected light. When the white light of the sun strikes an object, there is thrown upon it the sum total of all colors of the spectrum. Some of these colors are absorbed and some reflected. Those that are not absorbed determine the color of the object. If a ray of light fall upon a black surface, all the colors are absorbed and there is no color, for black is an absence of all color. If the same ray fall upon a blue surface, all the colors but blue are absorbed and we have the sensation of blue and call the object blue. In other words, the portion of light that is rejected determines the color of the object.

That the vibration of light brings about some change in the retina and is thence conveyed to the brain, whereby the form of an object is made apparent, is accepted without question, but as to the perception of color, there are several theories. At one time the discovery of visual purple, as it is called, a highly sensitive substance diffused throughout the outer segments of the rods, bade fair to explain the phenomenon. The fact that it is wanting in the cones and especially at the fovea, proved that it was not essential to distinct vision. It disappears when the eye is exposed to light, but is restored by darkness, so that while it is undoubtedly of some use in the visual process, just what part it plays has not been determined. We know that the percipient part of the eye is the retina, that the optic nerve fibers are insensible to light, that, however perfect the retina may be, if this medium of communication be cut off there is no vision and if there be disease at the central organ there is likewise blindness. So all three of these organs are necessary to vision.

At the present time it is practically assumed that we have two kinds of vision, one for form and another for color. In accounting for the perception of color there are many ingenious theories.

In 1807 Thomas Young propounded the theory that the retina contains three sets of color perceiving elements, red, green, and violet, all other colors resulting from a mixture of these fundamental elements. Helmholtz supposed that every kind of white light excited these three elements with varying degrees of intensity. This is the Young-Helmholtz theory. It assumes the existence of fundamental color sensations and the existence of three end organs and conducting fibers. These end organs each contain their own photochemical substance, capable of being decomposed by a certain color. Each one of these ends sets into action all kinds of light, but with varying degrees of intensity. Some are stimulated more strongly by red rays, less so by green, and least by violet. They are designated as the ends for the perception of red. Each kind of light affects all three groups, but with less intensity. The red ray excites most strongly the ends for the perception of red, and we get a red sensation, because the degree of excitation for the perception of red exceeds that of other colors. A green ray excites the ends for the perception of green more strongly than for the other two kinds and gives the sensation of green. A violet stimulates the ends for the perception of violet more strongly than for red or green, and we have the sensation of violet. Orange excites strongly the ends for red and less so those for green, with a resulting sensation of orange. When the ends sensitive to red, green, and violet are stimulated simultaneously and to the same degree, the resulting sensation is white. All these end organs are present in the most sensitive part of the retina and each has separate nerve fibers connecting them with the cells in the special part of the brain where each produces the distinct sensation of its particular color.

Hering's theory starts from an analysis of the sensations which we have in looking at a color. All but four pure colors excite a mixed sensation. In orange we see a certain amount of red; one shade of yellow has a tinge of green. Among all the

various shades we can distinguish a distinctive shade or tint of some color that excites in us a simple mixed sensation. Of all the shades of yellow there is one in which no other color save yellow is perceptible. There are but three colors, except yellow, that excite in us a simple unmixed sensation, pure red, pure green, and pure blue. They are called the primary colors and form two pairs—red and green and yellow and blue. They are contrary to each other, as they can never be seen at the same time in the same color. If the two colors of a pair are present in the same part of the retina at the same time, the color sensation perceived is of that color which is in excess, never both. We can perceive a blue which affords simultaneously the impression of some red or green, but never yellow. If they are blended in certain proportions so that they neutralize each other, the sensation is white or gray.

Each color may occur in different degrees of intensity, depending on the fact that every color produces, besides its own color, also the sensation of white. That is to say, colors in addition to their own valence, have also a white valence and the brilliancy of the color depends upon the mutual relation of these two valences. The primary colors have but one valence with the white valence, but the mixed colors possess two. There are visual substances in the retina at the terminations of the nerve fibers, the action of light upon which produces chemical changes. The visual substances are of three kinds, the white black, the red green, and the blue yellow. The white valence which all possess depends upon the dissimilation which they exert upon the visual substance for the perception of black and white. Assimilation of this substance, in the absence of light, produces darkness. The red green and the blue yellow are not altered by every kind of light, but only by that kind that has a corresponding color valence. Pure red would only dissimilate red green substance; pure green would cause its assimilation. If pure red and pure green fall upon the same spot on the retina at the same time, it depends upon the proportion between the two whether decomposition or regeneration takes place, and the sensation may be either red or green, but never both. If assimilation and dissimilation are simultaneous in the same substance, they antagonize each other and there is no color sensation, only that of white, because of the decomposition of both colors in the white black substance.

Oliver's theory is as follows: "The peripheral portion of the human visual apparatus is adapted to the receipt of undulations equivalent to those existent between the extremes of naural color vibrations. As all natural imponderable stimuli are the resultant of a mere difference in the number of vibrations of one and the same ether, the organs for the receipt of the different varieties must be but analogues and modifications of each other. Therefore the most rational theory that can be brought forward is that color perception takes place in each and every nerve filament, and consists in the passive separation of a specific nerve energy equal to the exposed natural color, from a supposed energy-equivalent resident in the nerve tip, by an active chemico-vital process of the impinging natural vibration upon the sensitized optic nerve tip; the separated energy being transmitted to the color center, where it is recognized, the healthy nerve tip returning to its energy-equivalent the moment the specific energy, separated by the received natural vibration has been forwarded for recognition, when it is again ready to receive any other natural color vibration that may be cast upon it."

Preyer believes that the color sense is due to an extremely refined sense of temperature. The spectrum is divided into a warm and a cold half, opposed to each other. The colors with the longer waves furnish the warm colors, while the shorter furnish the cold ones. This sense of temperature is present only at the most sensitive terminations of the nerves. Color sensations vary only in quality and intensity, the quality depending on the rapidity of vibrations and intensity upon the degree of stimulation. At the termination of each optic nerve fiber are two cones, one excited by cold and the other by warm colors. The ganglion cells of the retina receive these excitations and transmit to the brain either one or the other, never both at the same time. The cones are so arranged that the warm cones, sensitive to red and yellow, are at equal distances from each other and from the cold cones, sensitive to green and blue. Thus all color excitations are present even in the smallest retinal image. There must be simultaneous excitations of the two pairs of cones for any color perception. The increasing excitation of any color results in white and the decreasing in black. If red and green are excited equally, neither produces any effect upon the brain.

Muller held all visual sensations to be based on six chemical processes of the retina corresponding to the sensations of white, black, red, green, yellow, and blue.

Carpentair distinguishes three functions of the retina, luminous sensibility, chromatic sensibility, and visual sensibility, while Paunard concluded that the retinal elements involved in distinct vision are the same as those involved in color perception. Carpentair denied this, but pointed out that luminous sensations of very small dimensions, although corresponding to a retinal field smaller than the rod itself, are recognized in their proper colors, and concludes therefrom that the same rod must be capable of transmitting different colors.

At the fovea centralis, or point of most distinct vision in the retina, the two external layers of the retina, the outer nuclear layer and the layer of rods and cones are practically the only layers present, and it is known beyond all doubt that the essential percipient elements of the retina are in these two layers. Probably one is as necessary as the other, and their interdependence makes them both necessary for the function of seeing, although the layer of rods and cones has been assumed to be the only layer concerned in the light perceiving process. However this may be, a ray of light on entering the eye passes through the outer molecular layer before it impinges on the rods and cones; whether it affects them or not is a matter of conjecture.

The outer nuclear layer is so called because of the characteristic elements it contains, the nuclei or nucleated cells, sometimes called granules. These are of two varieties, differing in size, the larger being from 9 μ to 13 μ in length and the smaller from 4 μ to 9 μ. They are known respectively as the rod or cone granules according as they are connected with a rod or a cone. They are enlargements or varicosities of the delicate filaments which extend uninterruptedly through the whole layer, these fibers being modified nerve fibers and directly or indirectly a continuation of those derived from the optic nerve. The rod granules contain an elliptical

nucleus, and are composed of a strongly refracting substance. The cone granules are distinguished by a somewhat pear-shaped enlargement and by their closer relation to the rod and cone layer. They are essentially molecular in structure, as are the rods and cones. According to the theory of luminiferous ether, these granules and rods and cones, however minute they may be, contain this ether and their molecules are vibrating like those of larger bodies, the rate varying according as some external force or stimulus is applied. Sound waves and light waves may be compared for the purpose of illustration. A tuning-fork is struck sharply against the table and its prongs are set to vibrating. A sound is heard. Each to and fro movement forms in the air waves or undulations which rush forth in all directions. Some of them strike upon the tympanum of the ear and produce synchronous vibrations which, stimulating the auditory nerves, are transmitted to the central organ and there interpreted as sounds. In a similar way, a luminous body gives off rays of light. In place of a blow to create the undulations, as with sound, we apply heat, which increases the molecular vibration to a point when the body glows; these rays then, speeding at the enormous velocity of 186,000 feet per second, enter the eye, and by the intricate mechanism of that organ are accurately focused on the retina. Here a somewhat similar process takes place to that in the ear. The molecules of the constituent elements of these two layers are already in a state of vibration, but their amplitudes are not sufficient to create in the brain the sensation of light. Their molecular motion is similar to that in any body before it is heated sufficiently to emit perceptible rays of light. By the stimulation of the ray of light these molecules are immediately set into an increasing vibration until they are in unison with the entering wave of light. If the ray be red, the rate of vibration will be less than that of violet, but whatever the color, the molecules of the cones, rods, or granules will be in unison with it, and this vibration acting as a further stimulus, creates a nervous energy that, transmitted to the visual centers in the brain, is there properly interpreted as red or violet or whatever color the original cause of the vibration may have been. Each cone, rod, or granule vibrates to but one color at a time but is capable of so doing to any color, just as the nerves of the fingers can tell us whether an object is hot or cold but not giving a hot and cold sensation at the same time.

That this molecular motion can be imparted at a distance is easily proved by the action of the sun's heat. By means of a lens, the rays of the sun, distant 90,000,000 of miles, can be concentrated and sufficient heat produced to make a metal glow. This is not the result of conduction or convection, but radiation. In other words, the undulations of the rays of light from the sun produce a synchronous vibration in the metal. These percipient elements of the retina are of so peculiarly sensitive structure that they are almost immediately affected. Yet there may be an almost inappreciable length of time necessary for them to attain this perfect harmony, and it may require this same inappreciable time for them to cease vibrating. By a most delicate apparatus it can be demonstrated that the eye does not perceive a ray of light at the exact instant it strikes the retina, and a very simple experiment will show that retinal images persist after the cessation of light. Whirl a red-hot poker about the eye rapidly in a dark room and there is the appearance of a ring of fire due to the fact that luminous impressions persist after the cessation of light.

A prolonged sound, however musical, becomes positively painful; after a time the ear tires of the prolonged vibration. So with luminous impressions or vibrations, there is a diminution of retinal sensibility from the beginning of visual impressions. If one eye be used exclusively in reading for a little time, the difference in the sensibility of the two retinæ will be very apparent. If a white spot on a black background be gazed at steadily for a moment and then the gaze directed to a white surface, a black spot corresponding to the white one in form and size will be seen. This is due to the fact that that part of the retina on which the white spot impinged becomes less sensitive, or, in other words, tires, and when the direction of the eyes is changed the vibrations cease but those parts of the retina which are exposed to a comparative absence of light are fresher, and when another surface is looked upon they immediately appear brighter, the contrast giving the appearance of an opposite picture from the first. If the eye be fixed too long upon a luminous point, the local diminution of sensibility becomes fatiguing and even permanent injury may result. Gazing at the sun or an arc light sets the molecules into such violent vibration that the percipient elements are for the time being paralyzed. A dark spot will persist for a long time of the exact form of the sun or electric light.

These facts show that, first, it requires an instant for the molecular elements of the eye to vibrate synchronously with the ray of light impinging on them; second, an appreciable time is required for these vibrations to cease, and third, continuous vibrations are fatiguing. If there were not some energy, however slight, being exercised in the retina there would be no fatigue. A mere chemical or thermal process would entail no weariness. It may seem inconceivable that so slight a force as a ray of light, an imponderable thing, can affect so material a thing as the molecules of the granules and rods and cones, yet that it is not an impossibility is proved every day by the wonderful performances of electricity. By wireless telegraphy an imponderable force is sent hundreds of miles, and then exerts an influence on instruments which, compared in size with these molecules, are as grains of sand to mountains.

If the sensation of light is caused by this vibratory action, it follows that the sensation of color is generated in the same way, for white light is but the sum total of all colors. If we interpose a platinum wire in the circuit of an electric current, we place resistance in its path and where there is resistance heat is developed. Before the current is turned on there is but the normal amount of molecular vibration within the platinum; that is, there are no visible rays of light thrown off, or the vibrations are not sufficiently rapid to affect the retina. The wire appears black or gray. As the current begins to generate heat the molecules begin to move more briskly or through wider amplitudes, and as the heat increases and the vibrations also, a point is soon reached when the wire appears red. The molecular motion is now sufficient to generate rays of light of sufficient rapidity to affect the retina. Soon this motion has become such that if the light from this wire be allowed to pass through a prism we shall see an orange color beside the red, and after a time we get a complete spectrum. As each successive color appears, the preceding one becomes more vivid. These colors

must have been produced by reason of the heat, for they were not in the wire or in the electric current.

It is thus evident that there is no difference in the quality of the vibrations of white or colored light. The difference in sensation is only in quantity or rapidity of vibration.

If the rate of vibration of the molecules does not correspond with that of the various colors entering the eye, the sensation at the central organ will not be the same. The molecules of every cone, rod, and granule are set into a corresponding rate of vibration with the color which impinges on them. These vibrations stimulate in some way the filaments of the optic nerve with which they are connected and by them are transmitted to the central organ or visual centers of the brain, where they are correctly interpreted as visions.

The inappreciable time for the eye to perceive correctly is because of the time for this synchronous vibration to be attained. We may have another color before the real sensation is obtained, but so quick is the change that it is not perceptible. As we stand beside a piano and make a musical tone with our voice or a violin, we hear a corresponding tone, for one of the wires is vibrating synchronously. Whether it vibrates at a lower rate before this unison is attained we do not know, so quickly does this unison follow.

The time required for the unfatigued eye to recognize the color red is 1.28 seconds; for green, 1.42 seconds; for violet, 2.32 seconds. Violet has 699 trillion undulations per second, red has 477 trillion, showing that an appreciable time is required for the unison to be attained and for further showing that it takes longer for those colors which have a more rapid vibration to produce this harmonious vibration in the retinal elements than for those of less frequency.

Every color of the spectrum has a definite number of vibrations, never more, never less. The red ray enters the eye at the rate of 477 trillions of undulations per second. The molecules of the granules and rods and cones are immediately set into a corresponding rate of vibration. This produces some kind of a stimulation that is transmitted to the organ of conscious vision where it is transformed to sensations of vision. No color or picture that may appear on the retina is transferred to the consciousness as such: it is a mere interpretation.

The eye as an organ is not commensurate with the entire range of solar radiation. It is not capable of receiving visual impressions from all the rays emitted by the sun. Beyond the violet there are a vast number of rays totally unfitted for our powers of vision; and below the red are others that fail to awaken in our eyes the sensation of color. Beyond these two extremes the eye ceases to be useful as an organ of vision; for though these waves strike the retina with more or less rapid recurrence, they fail to arouse a corresponding vibration and so to awaken the sensation of light. We always think of the form of an object as its distinguishing visual characteristic. If our premises are correct, it follows that color should be its peculiar attribute in this respect. If there were no color there would be no visible form. In a dark room the forms of objects are indistinct because the dim rays of light emitted, or, more correctly, not absorbed, are of so nearly the same length that, striking the retina with nearly the same rate of vibration, they do not give any sensation of contrasting color nor any clear outline of form. The color of distant objects is usually apparent before its form becomes distinguishable. Two differently colored, contiguous objects are made conspicuous by the contrast in color rather than by their form. Hence we are justified in saying that it is color, rather than form that gives us visual sensations. In other words, visual sensations are but color sensations.

That ultra-violet rays are not perceptible to the eye shows that the molecules of the retina are incapable of vibrating beyond a certain rapidity, as there are sounds beyond the capacity of the ear to hear. Color blindness exists in some eyes, because there is a lack of ability of the retinal elements to vibrate in unison with certain colors, as in some ears there is an incapacity to distinguish between certain sounds. Some people have no appreciation of harmony; they cannot sing and may not be able to tell one note from another, and, strange as it may seem, many such do not know of this disability. They can make all kinds of sounds and noises, but they are discordant. This condition corresponds to color blindness and often the same disabilities will be found to exist in the same individual. There are similar defects in the mental sphere. In the case of defective speech, aphasia, there is no fault of the articulation, but the person has lost the power of expressing his thoughts in language, although he may be able to write them. He still has a correct mental vocabulary, for he understands what is said to him, knows when he has spoken wrongly, and has unimpaired reasoning powers. This is true also in amnesia, where the patient has lost the memory of spoken words. Words spoken to him are no longer sounds calling up special groups of ideas, for though he hears, he does not understand. It is a "word deafness." Both these conditions are doubtless due to some disease or defect of the central organ, where certain sounds are incorrectly interpreted or not at all. So with color blindness; the defect may be due to an inability of the molecules to vibrate properly, to some defect in the conducting fibers to rightly convey the stimulus, or to some defect in the brain to interpret preperly the stimulus.

To summarize briefly:

Light is the effect of undulations of the luminiferous ether.

Each color of the spectrum is caused by a definite number of undulations or vibrations per second. It is the normal stimulus to the eye.

The percipient parts of the eye are the retina and the essential elements for vision are in the layer of rods and cones and the outer nuclear layer. These, like all other bodies, contain molecules and are capable of the same molecular motion or vibration.

When they vibrate in unison with certain colors, the sensation of that color is conveyed to the brain where it is properly interpreted.

Visual perceptions are the result of different wave lengths or of diffused colors affecting the granules and the rods and cones and producing more or less rapid vibrations therein.

It is color, rather than form or outline, that enables us to distinguish objects.

And finally, it is color alone that gives us distinct visual impressions.

Royal Slumbers.—It is alleged that the recent operation for the removal of adenoid vegetation of the nasopharynx to which King Alfonso was subjected was instigated primarily by the fact that he snored so loudly as to make sleep difficult in his vicinity. The operation is said to have been effective in rendering the royal bed chamber more quiet.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

OPHTHALMO-REACTION IN TYPHOID FEVER.

AT a meeting of the Paris Academy of Medicine in July, 1907, Chantemesse, as we noted some months ago, reported that a few drops of typhoid toxins dropped onto the conjunctiva of the lower lid caused redness and secretion, a reaction which he believed to be a positive sign of typhoid fever. In a recent article in the *Wiener klinische Wochenschrift* (November 7, 1907), Kraus, Lusenberger, and Russ publish the results which they have obtained by conjunctival instillation of a few drops of typhoid toxins, the latter having been prepared according to the method of Chantemesse. In healthy individuals they observed a slight redness (no secretion) in four out of eleven persons, in from six to twelve hours. In twenty-two typhoid patients with a positive Widal 1:50, they noted a reaction (redness and secretion) in all within six hours after instillation, the symptoms having lasted over twenty-four hours.

This corroborates the work of Chantemesse insofar that the typhoid extract is capable of producing inflammatory appearances in typhoid patients and none in healthy individuals, but it does not prove that the reaction is a positive sign of typhoid fever. Chantemesse claims that his extract caused a reaction in typhoid patients only. Kraus, Lusenberger, and Russ, on the other hand, found that when the reaction was absent in healthy persons and present in those with thyphoid fever the same extract caused redness and secretion in people suffering from other diseases, the intensity and duration of the reaction varying in no way from that in typhoid fever. In twenty-one patients suffering from various diseases a reaction was observed in about one-half, including sufferers from pneumonia, multiple sclerosis, and tuberculosis. In diluted solution the extract gave negative results in both the typhoid patients and those suffering from other diseases. Such findings certainly throw some doubt on the diagnostic value of a positive conjunctival reaction in persons suffering from typhoid fever. These investigators also found that a paratyphoid extract, diluted or concentrated, caused no reaction in healthy individuals, while seven out of thirteen typhoid patients reacted to it from six to eighteen hours. An extract of colon bacillus caused no change in the conjunctiva of healthy persons, but of eleven typhoid patients a reaction occurred in all. So, too, diluted tuberculin, which in healthy individuals caused no reaction, brought about redness and secretion in eleven out of twelve typhoid patients in eighteen hours; this finding thus also argues against the claim of Calmette and others that a conjunctival reaction brought about by tuberculin is a positive sign of tuberculosis, as none of these patients ever showed any signs of this disease.

We thus see that while healthy individuals did not react (or very rarely, and then only slightly) to any of the bacterial toxins used, typhoid patients and those suffering from other diseases reacted to the paratyphoid, colon, tubercle, and typhoid extracts; in other words the conjunctiva of typhoid patients did not react in a specific way to typhoid toxins. Kraus, Lusenberger, and Russ assert that the ophthalmo-reaction is of no use in the diagnosis of typhoid fever. While this is true as far as a positive reaction is concerned, their findings surely show that the absence of the reaction speaks against typhoid fever, and that the conjunctival test is therefore of some value.

KOCH'S ALLEGED DISCOVERIES IN SLEEPING SICKNESS.

RECENT newspaper reports have conveyed the impression that Prof. Koch claims to have discovered that crocodiles are fertile, if not the chief, agencies for disseminating that dreadful African scourge, sleeping sickness. Dr. Koch stated that *Glossina palpalis*, the carrier of the germs of the disease, not only breeds on the banks of the lakes, but likewise along the streams in the interior, right up to the source, and he is said to have ascertained that there is a distinct connection between crocodiles and sleeping sickness. The blood of the crocodiles forms the main nourishment of the glossina which sucks the blood between the plates of the animal's hide. Prof. Koch also asserted that the principal outcome of his investigations was that there is a possibility now of making a certain diagnosis of the disease and of adopting measures to combat it. The eminent German scientist has had undoubtedly ample and favorable opportunities of studying the disease and its means of propagation, for he has been isolated for eighteen months on a desolate island, belonging to the Sesse group in the middle of Lake Victoria Nyanza, where the affection is remarkably prevalent. Despite these facts, presuming that the accounts of the newspaper interviews are authentic, it seems that Koch has hardly given the credit which is due to several other men who have made investigations previously into the problem of sleeping sickness.

For instance, Mr. Sheffield Neave, who was attached to the Gordon Memorial, Khartoum, in the capacity of traveling pathologist and naturalist, in a report published in 1906, and the Acting Commissioner for the British Central Africa Protectorate in his report, made remarks concerning the habits of *Glossina palpalis* very similar to those of Koch. Moreover, Dr. Daniell, the medical officer in charge of the London School of Tropical Medicine, a man who has made careful researches into the whole subject of fly-borne diseases, has referred to Koch's alleged discoveries in a very guarded manner. Speaking to a representative of the Lon-

don *Standard*, he pointed out that, whereas, crocodiles are common all along the banks of the Nile, sleeping sickness is confined to the upper reaches; the animals are plentiful on the Zambesi, on Lake Nyasa, and on the river Shire, localities which up to the present have been free from the malady.

Of course, these circumstances do not absolve the crocodile, but they render it very improbable that he should play a leading rôle in the spread of the infection. Dr. Daniell drew attention to the fact that the possibility of certainty in diagnosis is not owing to Koch's investigations, but rather to those of Dutton and Castellane, and lastly that the so-called remedy, said to have been discovered by the German professor, the subcutaneous injection of arsenic, goes back in principle of practice to the French Jesuits, more than one hundred years ago. In its modern application the discovery originated with the experimental work of the Liverpool School of Tropical Medicine, while it was first put to practical use in 1905 at the London Tropical School of Medicine.

Undoubtedly, sleeping sickness is a veritable pestilence in some parts of Africa. It has been stated authoritatively that unless means can be devised to rid Uganda of this plague it will be impossible as a place of residence, and consequently of no value to white or black man. The Congo district, again, is devastated in parts by the ravages of the disease, and many other localities are in a similar plight. It matters little to the world, even to the African world, who may have discovered the mode of dissemination of sleeping sickness or the most efficient measures to be adopted to extirpate it, or even to check its spread; it concerns us, indeed, not at all, except from a humanitarian and scientific standpoint. Still, "fair play is a jewel," and if the facts narrated by Koch have already been published by other men, there is every reason that to them should be accorded the honor. It may be, and probably is the case, that Koch has confirmed and amplified the discoveries of previous investigators, and for this he deserves his meed of praise. This is, however, not the first time that he has announced as his own the results obtained by the labors of other observers—his theatric announcement of the nonidentity of human and bovine tuberculosis, based upon the work of Theobald Smith and others, which he proclaimed his own, is still remembered. He is a brilliant, patient, and accurate investigator, and in these respects is surpassed by no man, but he does not add to the luster of his great name by appropriating, or rather ignoring, the results of the researches of former investigators.

The Ventilation and Drainage of the "Mauretania."

So much is said in the papers nowadays about each new Atlantic liner, that the public comes to feel a sense of ownership in the vessels, and many persons whose sea voyages never have been or never will be farther than Coney Island become enthusiastic over speed records and are loud in their praises of the new craft. The old traveler who has crossed and recrossed the ocean and in whose mind linger keen recollections of foul or smelly air in bad weather ask if they "have learned how to ventilate her." The *Mauretania* presents some distinct advances in this direction which are described by the Liverpool correspondent of the *Lancet*. He notes that passengers have a propensity to open something in order to get fresh air. "They are so accustomed to open a door or window at home that when they reach a cabin their habit must be gratified or they will insist that they are not getting proper ventilation." The new vessel shows the usual cowls on the uppermost deck, but these ventilate the engine room, and have nothing to do with the cabins and saloons. The new system seems to be independent of the opening and closing of various ventilators within the passengers' reach, and its triumph seems to lie in the fact that he may open what he likes without disarranging the ventilators. All the passenger cabins and saloons and the crew quarters are supplied with compressed air. In other words, the air in every habitable portion of the ship is under greater pressure than the outside atmosphere, except in the lavatories. Thus, if a cabin door opens, the air rushes out of and not into the cabin. In case of the lavatories the process is reversed. The system is known as the thermo-tank system. No less than 65 of these machines, says the *Lancet* correspondent, are placed in different parts of the vessel. They consist of a strong metallic case containing in one part an electric fan of such power that it can pump down into the ship 4,000 cubic feet of air per minute. This means a grand total of 260,000 cubic feet of fresh sea air from the upper deck per minute. With that supply the entire atmosphere within the habitable part of the ship can be changed every four minutes. Within each of these apparatuses are a number of coils that can be filled with steam, and thus the air is warmed before it is pumped into the ship. The ventilation in no wise depends on the weather or the wind, but wholly and solely on the rapidity in the revolutions of the fans. The shafts that communicate with the lavatories do not serve as inlets, but as outlets; the current is, therefore, to the lavatory and out by the shafts and these abut into the outer funnel. Thus, the air from the lavatories is discharged into the open at the top of the funnels with the smoke. The lavatories are flushed from a large tank of seawater on the upper deck. Even in the highest closets, there is a water-head of 55 feet. The flushing is therefore done with great force and thoroughness. For the steerage passengers, many of whom have never seen a modern toilet, all the apparatus is arranged to work automatically, and the whole compartment containing their toilets and bathtubs is tiled and can be washed out with a hose.

The Ophthalmo-Reaction for Tuberculosis.

Shortly after Pirquet last spring showed that in young children cutaneous inoculation with tuberculin was of diagnostic value, Wolf-Eisner, Vallée, and Calmette elaborated a method of applying the same principle by dropping a solution of tuberculin into the conjunctival sac. This procedure possesses a very decided advantage over the former, for practically all adults react to the cutaneous inoculation—owing, Pirquet says, to the fact that most persons have at some time been infected with tubercle bacilli—whereas the ocular reaction is very often absent. The degree of reliance that is to be placed on the result of this test is still undecided, but appears to be not inconsiderable. Different observers, however, do not altogether agree in their conclusions. Thus Cohn states in the *Berliner klinische Wochenschrift*, of November 25, 1907,

that the positive outcome of the ophthalmo-reaction in all probability indicates the existence of tuberculosis, but a negative result does not exclude the disease; while Franke (*Deutsche medizinische Wochenschrift*, November 28, 1907) reports experiences that appear to show that more dependence is to be placed on the negative outcome. For example, in testing twenty-four patients suffering from various ocular disorders a positive reaction was obtained in four persons who gave no other evidence of tuberculosis in the lungs or elsewhere. Cohn found that fifty per cent. of the patients with advanced phthisis do not react, an observation in accordance with what has been noted concerning the ordinary tuberculin test by subcutaneous injection, and also that typhoid fever patients not infrequently give the reaction, especially during convalescence. According to Calmette the reagent is best prepared by precipitating the albuminous bodies in tuberculin by means of seventy-five per cent. alcohol and using a one per cent. watery solution of the dried precipitate. The test is made on one eye, the other serving as a control, and if the result is positive a local inflammatory reaction of more or less severity is caused. This subsides promptly and is not accompanied by constitutional disturbance or followed by any after-effects, though the eye acquires an increased local susceptibility, so that even if the first test was negative a second one made at a later date may prove positive. Most of those who have reported on the method speak well of it and recommend a more extended trial on large numbers of cases so that its value may be definitely ascertained.

The Administration of Chloroform.

One of the difficulties to be contended with in the administration of chloroform as an anesthetic has always been the fact that it so readily undergoes decomposition if exposed to the air and light. This change in composition is attended by the formation of hydrochloric acid, and two ingenious French surgeons have suggested that in order to receive prompt warning of this alteration a small disk of elder pith dyed in a saturated alcoholic solution of Congo red be kept in the bottle of anesthetic. As soon as the chloroform becomes acid the indicator turns blue. The device would seem a good one, except that to profit by it it is necessary to keep the chloroform in a bottle made of clear glass instead of the customary brown. In the *Münchener medizinische Wochenschrift*, November 26, 1907, another suggestion in regard to the use of this anesthetic is made by Haun. He has found that simply warming the bottle from which the agent is being dropped by setting it in water kept at about 100° F. greatly facilitates the induction of narcosis and diminishes the amount of the drug required. The patients also recover consciousness more quickly and suffer less from the ordinary after-effects. This he explains on the assumption that cold chloroform vapor is to a large extent deposited in the nasal and upper air passages without ever reaching the alveoli or being absorbed from these. Instead it is very gradually taken up, often even after the operation is completed, and serves to produce many of the disagreeable sequelæ so frequently observed. The warm vapor, on the other hand, can penetrate readily to the deeper parts of the lung and practically all of it reaches the blood promptly and effectively. This suggestion is hardly new, but is not generally followed, although so simply carried out.

Highland Folk Medicine.

In the *British Medical Journal* of November 2, 1907, are some interesting comments on an article recently published in the *Scotsman* to the effect that "wise women" and "folk doctors" are fast becoming extinct in the Highlands. The diffusion of knowledge is gradually crowding them out. We are told that one of the first things the "doctor" looks for is any peculiar mark upon the body. Thus "the position of moles is supposed to show the patient's temperament; teeth set wide apart indicate that the owner may be expected to make a safe recovery from his illness, while, on the other hand, close-set teeth show the patient to be miserly and melancholic, and more difficult to cure." A special mode of diagnosis is called for in cases of cardiac disease. "The patient is made to kneel on the floor near the fire; a sieve, on which is a large bowl filled with water, is placed on his head. Into this bowl molten lead is poured through iron, as through the finger-hole of a scissor blade, and it is thought that one of the pieces of lead is sure to assume the rough shape of a heart. If this supposed shape has in it a scallop or hole, heart disease is certain, and the lead has to be melted and poured into the water, over and over again, until a neatly-shaped piece bearing some resemblance to a heart is produced, with no hole and no scallop; then the patient is considered cured." All these ideas seem curious to us of the present day, but inquiry among some of the rural inhabitants of our own country will often bring out the same curious results as to belief in disease peculiarities and remedies therefor.

News of the Week.

To Amend Illinois Medical Law.—The Illinois State Board of Health has prepared a bill providing that the board in its discretion may admit to examination any candidate who has completed four annual sessions or terms in a medical college in good standing, and who has passed the examination of said college. Those who pass can obtain temporary licenses good for eighteen months. On completing this period, a regular license may be issued if the applicant presents a diploma from the medical college in which he completed the session of the fourth year and if he otherwise complies with the requirements of the State Board.

Annual Conference of the Committee on Medical Legislation and the National Legislative Council of the American Medical Association.—This conference was held at the Auditorium Hotel, Chicago, December 10, 11, and 12. The Chairman of the Committee on Medical Legislation of the American Medical Association, Dr. Charles A. L. Reed of Cincinnati, presided. Twenty-three States were represented. The Committee on Naval Medical Reorganization made its report, and the following bills were endorsed by the conference and recommended to Congress for passage: (a) A bill reorganizing and increasing the efficiency of the hospital corps of the United States Navy and regulating its pay. (b) A bill authorizing the appointment of dental surgeons in the United State Navy. (c) A bill for the establishment and organization of a corps of trained women nurses in the United States Navy. (d) A bill to equalize and fix the pay of medical officers of the army, navy, marine corps, and revenue cutter service, and for other purposes. Bills providing pensions for the widows of Drs. James Carroll and Jesse W. Lazear were presented to the conference, endorsed, and recom-

mended to Congress for passage. Dr. Wm. H. Sanders, State Health Officer of Alabama, delivered an address on Federal and State Regulation of Public Health. He outlined the system of public health regulation in Alabama, saying that each County Medical Society was likewise a County Board of Health, and that there was also a State Board of Health. Dr. Arthur Dean Bevan, Chairman of the Council on Medical Education of the A. M. A., delivered an address on Medical Education. Dr. Bevan's address was followed by one by Dr. H. C. Sharpe, Chairman of the Committee on Medical Legislation of the State of Indiana. These gentlemen urged a better preliminary education than the average medical student now had. Proposed uniform laws on food and drugs were discussed, and the conference decided to urge federal and State governments to propagate education on sanitation for the prevention of tuberculosis, typhoid fever, and other contagious diseases, and an immediate cleansing of all inland waters from pollution. The Chairman, Dr. Reed, was authorized to organize a council of forty-six members, one from each State, to consider existing laws on labor, taxations, corporations, banking partnerships, insurance, railroads, transportation, commerce, sanitation, quarantine, foods, drugs, traffic, marriage and divorce, reciprocity, and comity, for the purpose of securing uniform legislation on each.

Federation of Hebrew Charities.—Representatives of the following charitable organizations last week met in the Mt. Sinai Hospital and formed "The Council of Jewish Communal Institutions:" The Mount Sinai Hospital, the Hebrew Orphan Asylum, the Montefiore Home, the Educational Alliance, the Hebrew Technical Institute, the Hebrew Sheltering Guardian Society, the Lebanon Hospital, the Hebrew Technical School for Girls, the United Hebrew Charities, and the Beth Israel Hospital. The new council is to consider purely local problems affecting Jewish eleemosynary institutions and aid in their solution; it is to coordinate the work now done independently by the various organizations included in its membership; to work out an economical system of buying by cooperation, and to discourage the multiplication of rival organizations, while at the same time encouraging the foundation of enterprises entering upon new branches of relief work. While Jewish in name, the new council is not primarily sectarian. It is willing to assist any charitable organization whatever, give it advice, lend it cooperation, and help it raise funds. These officers were elected: *President,* Justice Samuel Greenbaum; *Vice-President,* George Blumenthal; *Secretary,* Edgar J. Nathan; *Treasurer,* Louis Stern.

A Post Office Quarantined.—The post office at Augusta, Me., had to be closed for about eighteen hours on December 12 and the delivery of mail matter discontinued owing to the breakage of a culture tube, presumably inoculated with diphtheritic material, which was being mailed to the State laboratory. The Board of Health ordered a disinfection of all the mail matter.

A New School for the Blind.—The new building erected by the New York Association for the Blind at 118 East Fifty-ninth street as a school of instruction for sightless adults was opened on December 16.

Tuberculosis Exhibition.—The traveling tuberculosis exhibit which has been established by the State Charities Aid Association was held this week at Rome, N. Y. During the preceding fortnight it was in Utica, where a committee on the prevention of tuberculosis has been established and a free dispensary started.

Influenza at Smith College.—An epidemic of grip is spreading among the students at Smith College at Northampton, Mass., and over one hundred patients have been ill enough to require to be sent to the college infirmary while many others have been unable to attend recitations.

Opium in the French Navy.—The French naval authorities are attempting, apparently without great success, to restrict the use of opium by the officers and men which is said to be very widespread, and is alleged as the underlying cause of some of the disasters that have recently occurred on the vessels. It was discovered that in Marseilles users of the drug were obtaining it from a number of dealers in Oriental curiosities, and on searching the shops of the latter several thousand dollars' worth of opium was found and confiscated.

Disease on Immigrant Ship.—Two hundred of the eight hundred steerage passengers arriving last week on the Russian steamer *Kherson* from Libau were quarantined on account of smallpox, scarlet fever, measles, and diphtheria, cases of all of which occurred on the vessel during the voyage.

Alcohol and Marksmanship.—The Bavarian War Ministry has just issued a preliminary report on tests made to determine the effect of the use of alcoholic beverages on marksmanship. Squads of men are alternately kept abstinent for a week and during the next week allowed definite amounts of alcohol. Already over 10,000 shots have been made under these conditions with the result that the drinking men made better scores while firing singly than did those belonging to the squad which had been kept abstinent. In field and volley firing by companies, however, the sections which had been entirely abstemious attained slightly better results than their stimulated comrades. These results are somewhat at variance with those obtained some time ago in the Swiss Army, which we believe demonstrated that the nonalcoholic soldiers were more reliable shots than the drinkers.

Cuban Quarantine Raised.—The United States Marine Hospital Service has decided that the quarantine against the Island of Cuba is no longer necessary and has ordered it to be discontinued.

Women Nurses for the Navy.—On the recommendation of Secretary of the Navy Metcalf and Surgeon-General Rixey, a bill is to be introduced in Congress providing for the establishment of a corps of women nurses for the navy. They will be stationed at the various hospitals at naval stations and are intended to form the nucleus of a female nurse corps for service on hospital and ambulance ships in time of war.

Carnegie Research Fund Increased.—At the dinner of the Board of Trustees of the Carnegie Institution held in Washington on December 10, the announcement was made that Mr. Carnegie was about to increase the $10,000,000 endowment fund by a further gift of $2,000,000.

Vermont State Tuberculosis Hospital.—The Vermont State tuberculosis hospital built at Pittsford with the $100,000 gift of Senator Redfield Proctor was opened on December 10. Accommodations are provided for thirty-five patients.

Waterbury Physicians Decline Lodge Practice.—At a meeting of the Waterbury (Conn.) Medical

Association held on December 9, it was unanimously voted not to make any contracts with fraternal organizations to attend their members for less than the regular rates.

Typhoid Fever in Trenton.—Owing to the prevalence of typhoid fever in Trenton, N. J., where fifty-five cases of the disease have been reported this month, an entire change in the water supply is being planned. Either a complete filtration plant will be installed or a new acqueduct will be built to bring water from Sorrell Mountain.

Benefit Entertainment for Chicago Hospital.—An entertainment was recently given, which netted $1,000, for the hospital fund of the North American Union. This is a fraternal insurance order with about twelve thousand members in Cook County, Ill. It is the plan of the society to give every member free medical attendance, and when necessary to send the patient to a sanatorium maintained by the order.

Treatment of the Criminal and Other Social Parasites.—A symposium on this subject was held at a joint meeting of the Physicians' Club of Chicago and the Chicago Law Club December 13. In the course of the evening these two theories were advanced: Elimination of criminal children by sterilization. Treatment of criminals over thirty years old as habitual, and either sending them to penal institutions for life or putting them away in some other manner, possibly by the cemetery route. Dr. Wm. T. Belfield is said to have advocated the sterilization idea. He took up the biological aspect of the criminal, and after tracing the development of the individual to the point where he became a danger to society, made a plea for race suicide. For the mature criminal he advocated permanent segregation either by the penal colony or the cemetery. The indeterminate sentence with the parole was a radical error for the criminal over thirty. Dr. John N. Hurty, Secretary of the Indiana State Board of Health, spoke of the Indiana movement, which consists in educating the prisoners in the Indiana Reformatory to allow themselves to be sterilized. More than 300 of them have submitted to this operation so far. The criminals are told who they are and why they are, and after an examination is made of the mental status of the criminal to determine what his chances of improvement are, the operation is performed.

For a Central Ambulance System.—At a meeting of the Municipal Hospital Commission last week a conference was held with a delegation of hospital physicians and superintendents for the purpose of discussing modifications in the present ambulance system. The plan, tentatively submitted by the commission, provides for a central ambulance station, corresponding with fire headquarters, to which all ambulance calls should come and through which they could be assigned to the various hospitals. Such a station, it was thought, would do away with a certain amount of confusion in the ambulance service. It was also suggested that emergency stations be established in the more congested parts of the city for the purpose of dealing with accident cases.

The Hygienic and Moral Education Society.—A society with this name has been formed in London for the purpose of educating the young in regard to sexual matters and to arouse public interest in regard to the medical examination of those contemplating marriage. There are to be lectures, school instruction, and the dissemination of suitable printed matter.

International Tuberculosis Congress.—The following additional members of the committee of arrangements for this congress have been appointed: John Barrett, the director of the Bureau of American Republics; Dr. William A. White of Washington, superintendent of the Government Hospital for the Insane; Dr. C. H. Mayo of Minnesota, and Dr. Henry M. Bracken, secretary of the State Board of Health of Minnesota.

Penobscot County (Me.) Medical Association.—Officers as follows were elected at the meeting of this organization held in Bangor on November 27: *President*, Dr. Harry Butler; *Vice-Presidents*, Dr. S. E. Phelps of North Sullivan and Dr. W. P. McNally; *Secretary*, Dr. B. L. Bryant of Bangor; *Treasurer*, Dr. H. H. Crane of Bangor.

Chattahoochee Valley Medical and Surgical Association.—The next annual meeting of this organization is to be held in Columbus, Ga., January 14, 1908. The association, which is entering on the second year of its existence, has for its object the bringing together of the members of the medical profession of Alabama, Georgia, and Florida. At this meeting the association will be the guest of the Muscogee County (Ga.) Medical Society. The president of the association is Dr. J. A. Goggans of Alexander City, Ala., and the secretary is Dr. W. J. Love of Opelika, Ala.

Middle Tennessee Medical Association.—At its recent meeting held in Nashville this organization elected the following officers: *President*, Dr. E. H. Jones of Murphysboro; *Vice-President*, Dr. W. Litterer; *Secretary and Treasurer*, Dr. R. M. Jones.

Chicago Suburban Health League.—This league was recently organized as a permanent society to look after the health of Chicago and surrounding territory. The territory extends north to Kenosha, Wis.; west to Aurora and Elgin; and south to Whiting, Ind., and Chicago Heights. The following are the officers: *President*, Dr. Wm. R. Parkes, Evanston; *Vice-President*, Dr. Albert F. Stork, Oak Park; *Secretary-Treasurer*, Dr. Heman Spalding, Chicago; *Executive Committee*, Health Commissioner Evans, Chicago; S. G. MacCracken, Winnetka; Aaron G. Lauer, Whiting, Ind.; Clarence W. Geyer, Aurora, and Albert F. Stork, Oak Park.

Centenarians.—Meyer Shanholz, a seventy-year-old resident of New Brunswick, N. J., has been notified that his father, aged one hundred and seventeen years, has died in Warsaw. He had sixteen children, of whom one is living in Warsaw at the age of eighty-five years. Mrs. Margaret Carpenter of Brooklyn died on December 11 at the age of one hundred and two years. She had been blind for twenty-seven years owing to cataract, but up to two years ago was able to walk with a cane.

Death of Professor Moritz Schmidt.—Professor Moritz Schmidt of Frankfort-on-the-Main, one of Germany's foremost laryngologists, died on December 9. He was well known throughout Europe, and several years ago removed a polypus from the throat of the German Emperor. For this service he received the title of Excellency.

Société Universelle d'Etudes Psychiques.—The following were elected as officers of this association at its meeting held in Paris on November 16: *President*, Dr. P. Joire; *Vice-President*, Dr. Le Morrant des Chesnais, Dr. E. Allain, and Dr. Demonchez; *General Secretary*, M. de Vesme, Editor of the *Annales des Sciences Psychiques; Assistant Secretary*, M. Dhuigue; *Treasurer*, M. P. Donchez.

The Late Dr. George F. Shrady.—At a meeting held December 10, 1907, the Medical Board of the Willard Parker and Riverside Hospitals, having learned with profound regret of the death on November 29, 1907, of Dr. George F. Shrady, Consulting Physician to the hospitals of the Department of Health, it was unanimously

Resolved, That this board mourns the death of Dr. Shrady, an eminent member of the medical profession of this country. It recalls with pride his magnificent record as a physician, his pioneer work in medical journalism as editor of the MEDICAL RECORD, his civic patriotism which placed him always in the foremost ranks of those who sought the welfare of the community, his wisdom as a counselor in former years to the health authorities of this city, as well as those of the State and country.

Resolved, That the members of this medical board individually regret the loss to themselves of a charming, genial, loyal, broadminded, and cultured colleague whose mental and social attributes endeared him to those whose privilege it was to be closely associated with him.

Resolved, That the medical board remembers with especial satisfaction the unselfish heroism which prompted him when in the height of his surgical reputation to respond to the call for the performance of major surgical work upon persons suffering in the hospitals of the Health Department from contagious diseases.

Resolved, That the medical board extends to the widow and family of Dr. Shrady its esteem and deep sympathy in this affliction, and the assurance that it shares with them the sense of loss suffered in the death of one of whose character, work, and life they are so justly proud.

Resolved, That these resolutions be spread in full upon the minutes of this board and that they be transmitted to the family of Dr. Shrady, and appropriate publicity be given them in the medical journals of the city.

For the medical board, John W. Brannan, M.D., William H. Park, M.D., Louis Fischer, M.D., S. A. Knopf, M.D., Henry W. Berg, M.D.

Obituary Notes.—Dr. EVELYN J. WATSON died at Chester, Pa., on December 8. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1902.

Dr. HENRY D. RENNER, one of the oldest practitioners in the city of Philadelphia, died on December 9 at the age of seventy-four years. He was graduated from the medical department of the University of Pennsylvania in the class of 1854.

Dr. A. M. CARPENTER of St. Louis died on December 3 of an intestinal disorder after an illness of several weeks. Dr. Carpenter was born in Lincoln Co., Ky., in 1834 and was educated at Centre College near Danville. He was for a time connected with the Keokuk Medical College, and came to St. Louis twenty-four years ago. He was one of the founders of the Marion Sims-Beaumont Medical College, and at the time of his death was vice-president of Barnes Medical College.

Dr. FREDERICK ROBERTS of Nashville, Tenn., son of Dr. Deering J. Roberts of that city, died of tuberculosis on December 9 at the age of twenty-two years. He was graduated last spring from the medical department of the University of Tennessee.

Dr. E. E. WINN died at Port Lavaca, Tex., of carcinoma on December 3 at the age of seventy-seven years. He was a native of Georgia and had served as surgeon in the Confederate army.

Dr. OTTO QUITMEYER of Parkers Prairie, Minn., died of pneumonia on December 6 at the age of thirty-one years. He was graduated from the medical department of Hamline University in 1902.

Dr. O. H. DOGGE of San Francisco died suddenly of heart disease on November 30 at the age of sixty years. He was born in Germany, but had practised in Butte, Mont., from 1889 to 1900, when he removed to San Francisco.

Dr. LUTHER S. ARNOLD of Londonderry, Vt., died on December 1 at the age of seventy-three years. He had practised in Londonderry since 1865 and in 1889 represented the town in the State legislature. Two years ago he gave up active work.

Dr. W. J. O'NEIL of New London, Conn., died of tuberculosis in Elmira, N. Y., on November 21 at the age of forty years. He had practised in New London for about fourteen years, but last summer was obliged to give up active work owing to his illness.

Obituary.

WILLIAM H. S. WOOD.

NEW YORK.

MR. WILLIAM H. S. WOOD, senior member of the firm of William Wood and Company, died at his home in this city on December 11, 1907. Mr. Wood was born in New York in 1840, the son of William Wood and the grandson of Samuel Wood, the founder of the publishing house. He was graduated from Haverford College in 1863, and two years later was taken into partnership by his father, the firm name of William Wood and Company being then adopted. His father had paid particular attention to the publication of medical works and the son advocated further specialization in this direction. In 1865 he conceived the idea of the publication of a journal to be conducted in the best interests of the medical profession of the country, and the following year he founded the MEDICAL RECORD, requesting Dr. Shrady to become its editor. A few years later he purchased the *American Journal of Obstetrics,* edited until 1891 by the late Dr. Paul F. Mundé, and since that time by Dr. Brooks H. Wells. For several years the house also published the *American Druggist.* Mr. Wood remained the active head of the house to the time of his death, but for the last four years had devoted his chief energies to the conduct of the Bowery Savings Bank, of which he had been a trustee since 1872, and to the presidency of which he was elected in 1903. Under his guiding hand the influence and prestige of the bank continued to increase until, in July of this year, its deposits reached the sum of over $100,000,000.

Mr. Wood was an active member of many public societies. He was a director of the Young Men's Christian Association for seven years, and a manager of the American Bible Society for twelve years. He was a life member of the New York Historical Society, the American Pomological Society, and the New York Horticultural Society; fellow of the American Geographical Society; benefactor of the New York Academy of Medicine; member of the St. Nicholas Society, of the New York Society for the Suppression of Vice, the Chamber of Commerce, the New York Academy of Sciences, the New York Zoological Society, the Clinton Hall Association, and the Orthodox Society of Friends; incorporator of the New York Botanical Society; and member of the Union League, Grolier, Seawanhaka Yacht, and Indian Harbor Yacht Clubs. His special hobby

was horticulture, and he wrote several volumes on pomology and other horticultural subjects.

In 1865 Mr. Wood married Miss Emma Congdon of Providence, R. I., who died in 1896. In January, 1907, he married Mrs. Cornelia Elliot of Baltimore. He is survived by the widow, three sons, and a daughter.

Mr. Wood was a man of strong personality and indomitable determination, uncompromising in the essential duties of life, and never swerving from the course which he had set for himself when convinced it was right. His many friends were bound to him by cords of steel; antagonists he met as force always must; but indifference toward him none could feel. His heart was tender toward those in moral distress or physical want, and many whom he had secretly helped by brotherly counsel or by material assistance remain to bless his memory.

Correspondence.

REMOVAL OF BILE FOR EXAMINATION.

To the Editor of the Medical Record:

Sir:—I beg to make the following preliminary report of two new methods of removing bile from the body for examination.

In the first the intrahepatic method, a fine needle attached to an organometer is forced through the abdominal wall into the parenchyma of the liver and a twenty-eight inch vacuum applied until the required amount of material to be examined has been drawn into the instrument. The bile acids, etc., are then separated by a process to be described in a future communication.

The second method consists in forcing a very fine, specially devised needle through the abdominal wall into the fundus of the gall-bladder, and a fifteen-inch vacuum applied until a sufficient quantity of bile for examination has been removed. The needle is then disconnected, but not withdrawn, and a quantity of sterile saturated boracic acid solution equal to one-half the amount of bile withdrawn is injected at a temperature of 115° F. and under not more than 30 mm. pressure.

With one exception, all of the experiments have been performed on dogs, cats, rabbits, and guinea-pigs. It is comparatively easy to locate the lobes of the liver in these animals, and one seldom fails to find a desirable point in a lobe for the needle, but the locating of the fundus of the gall-bladder is quite difficult unless one follows a set of anatomical landmarks. A triangle with its apex represented by the junction of the ensiform appendix and the ninth costal cartilage, its base by a horizontal line drawn from the tip of the ensiform appendix to the external border of the ninth costal cartilage, its left side by the right border of the ensiform appendix, and its right side by the internal border of the ninth costal cartilage has been of inestimable value in my attempt to perfect this method. The apex of the triangle is the point of election. With the animal rolled slightly to the right the needle should be held in a vertical position and forced directly downward through the abdominal wall and diaphragm through the apex of the triangle. It is then very slowly withdrawn about one-quarter of an inch and a rest taken for one-half minute. If the puncture has been successful the bile will flow into the organometer during this time; if unsuccessful, the needle is withdrawn another inch and another half minute is allowed for the bile to make its way to the surface. If after this wait there is still an absence of bile in the receptacle, the needle is gently withdrawn from the body and the same procedure is repeated midway between the apex and the base line on the left or sternal side of the triangle. At this point in the triangle the needle should be held so that the point will be directly a little to the left. Should this second attempt prove ineffectual a third and last puncture is made at a point on the base line one-half inch to the left of the sternal side of the triangle. The point of the instrument is directed downward and backward. If the result of this last attempt is negative one may be reasonably sure that the gall-bladder is either empty or the bile is too heavy to flow through the needle.

My records show four hundred and thirty-three failures in three thousand attempts. The failures on guinea-pigs amounted to 96 per cent., on rabbits 85 per cent., on cats 52 per cent., and on dogs 12½ per cent. Dogs represented 91 per cent. of the material used in the work, and of this 91 per cent. 52 per cent. was done on dead animals. After removing the bile from 225 dogs, and immediately injecting it into the peritoneal cavity without a single fatality or even a significant rise of temperature, I removed 2 c.c. of my own bile through the following described triangle which I had previously worked out on the human cadaver. A line is first dropped from the ensiform appendix (*a*) to the umbilicus (*b*), another horizontally from the right costal arch on a level with the lower border of the ninth rib (*c*), to the xiphoid-umbilical line (*d*); a cross at *e* is made on the line (*c d*) 11/16 of the distance externally from the point *d*. A line is drawn from point *c* to point *f* on the internal border of the right costal arch opposite the lower border of the seventh rib. Eleven-sixteenths of the distance from point *c* to point *f* is then measured off (*g*), and a line is dropped from *g* to *e*, another line is drawn from *f* to a point *h*, 5/16 of the distance from point *d* to point *c*, and after measuring off 8/16 of the distance from *h* to *f* (*i*) a horizontal line is drawn across *g e*. The center of the gall-bladder lies directly under the point where these lines cross at *j*. My temperature, appetite, pulse, etc., remained, as in the animals, perfectly normal after the experiment. After the needle had passed through the skin I suffered only the slightest pain.

I made cultures from the bile of 127 live animals and got growth in 21 per cent. The fact that bile from a much larger number, two hundred and twenty-five, was injected into the peritoneal cavity without deleterious results, suggests a powerful inhibitory action of bile over bacteria, when the former is acting on microorganisms in its normal environment. Small doses of bile bacteria were not pathogenic for white mice, but large doses killed in from eighteen to thirty-six hours. There was a small leakage of bile after puncture in 7 per cent. of one hundred and ten cases, the remaining 93 per cent. withstood 100 mm. air pressure without leakage.

Three c.c. of a 3½ per cent. morphine solution was always given to dogs one hour before experiment; the smaller animals were given ether. The technique on the animal is sufficiently perfected to be of practical value in laboratory work, but under no circumstances should an attempt be made to do this work on the human subject until the technique is absolutely perfect. Drawings, photographs, and technical detail will appear in a complete communication. I hope eventually to be able to treat diseases of the human gall-bladder and bile-ducts locally by going directly to the seat of the disease. It is possible to force drugs directly into the intestinal tract by way of the gall-bladder, thus avoiding the necessity of having the material intended for the intestines pass through the acid medium of the stomach. To have the drugs reach the intestines in pure form it is necessary first to flush the gall-bladder with a physiological salt solution at 100 mm. pressure.

I wish to thank Dr. H. K. Miller, proprietor of the New York Canine Infirmary for the vast amount of material placed at my disposal during these investigations.

W. Byron Coakley, M.D.

72 Riverside Drive, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

TUBERCULOSIS, AVIAN AND HUMAN—EFFECT OF HIGH ALTITUDES ON BODY AND MIND—TRAVELER'S OPINIONS ON MEDICINE, ETC.—FIRES IN HOSPITALS—A STUDENTS' ESCAPADE—OBITUARY.

London, November 29, 1907.

The relationship between human and avian tuberculosis is the subject of an important contribution to the Pathological Section of the Royal Society of Medicine by Drs. Shattock, Seligman, Dudgeon, and Panton. Their researches were carried out in the laboratories of St. Thomas' Hospital and are naturally exciting a good deal of interest, as birds form an extensive part of human food. A typical case of tuberculosis in birds is one in which it is found in the spleen and liver, the lungs not being involved and the intestine may or may not be ulcerated. Such (as the usual fatal form in birds) furnished the avian material of the experimenters; that of human tuberculosis was from pulmonary cases and contained numerous bacilli. Pigeons were the birds employed. It would appear from feeding experiments that the avian bacillus is markedly pathogenic for birds, but not, or very slightly, for the guinea-pig or the monkey—a decided contrast with the human bacillus. Further, the human bacillus was not converted into the avian by "passage" through birds, and therefore as far as these experiments go the two organisms are not identical. But this inference is not quite on all fours, I think, with the experi-

ments on "passage" of the Royal Commission, in which a series of animals were employed.

The conclusions submitted to the Section by the authors of the contribution under notice are: 1. That the human bacillus is pathogenic to the pigeon in a very limited degree only. It sets up no disease of the intestine or abdominal viscera by feeding on sputum. By injection into muscles or subcutaneous tissues from infected organs of guinea-pigs it sets up a local and glandular disease only, and such local disease retrogresses instead of progressing. 2. Avian bacillus is pathogenic to the guinea-pig in a slight degree. 3. Human bacillus is not convertible into avian. Salt suspensions of infected spleen of birds in every instance produced not merely a local lesion in the guinea-pig, but a general tuberculosis. The human bacillus, after a sojourn of as long as eight weeks in the spleen, produced the glandular and visceral disease in guinea-pigs as though it had been transferred directly from human sputum. It did not produce merely a local or local with glandular disease, such as it should have done had it acquired the characters of the true avian bacillus.

The authors do not attach much importance to the opsonic test, which shows that either bacillus will extract the opsonin from tuberculous serum, for some of their experiments prove that the opsonin may be extracted from serum by saturating it with a thick emulsion of melanin, showing that the removal is not indicative of specificity but is largely mechanical.

The effects of high altitudes were illustrated in an interesting paper read at the Geographical Society on Monday by Dr. Workman, who has spent five seasons in Himalayan exploration. He, with Mrs. Workman, stayed one night alone at a camp 21,300 feet above sea level. They could not sleep as on previous occasions in similar circumstances. The absolute silence that reigned during the night proved almost as nerve-wearing as excessive noise. He spoke of a feeling of having completely lost touch with the material world. The imagination, he said, uncontrolled by the suggestions of ordinary sound, will run riot among fancies and possibilities—neither pleasing nor reassuring. At this altitude, the highest at which mountaineers have passed a night, there were nine Europeans in the camp and only one suffered from mountain sickness. At the previous camp (20,632 feet), though this man complained of some headache and weakness, he started forward with a light load of instruments, but he could not keep up with the rest. Before reaching 21,000 feet, though naturally strong and healthy, he collapsed. He had loss of sensation in his hands and where his woolen mittens were drawn off the fingers were stiff and white and on the point of becoming frost-bitten. Vigorous friction restored the circulation and he was sent back to the next camp. None of the other members of the party were incapacitated, but everyone felt the effect on the respiration, some more than others. As usual, there was dyspnea and panting on slight exertion. When resting in the erect position it was not very noticeable, but on movement it was marked. At night on lying down it became urgent and was accompanied by a feeling of oppression, rendering deep inspirations necessary, and these wearied the respiratory muscles to a degree amounting to pain. This constant gasping for breath interfered with sleep, no matter how tired one might be. If after long wakefulness one dozed a moment, one immediately started up with frantic efforts to get oxygen enough to stay the stifling sensation. In the highest camp for five nights no one got more than a few snatches of sleep, and four, of whom the doctor was one, practically none at all. Those nights will not be easily forgotten, lying sleepless in the snow, in the cold, in the silence, and darkness, struggling for breath and counting the hours with a feeling that the strain could not last until daylight. The strongest could not hold out long against the insomnia and lowering of vital energy due to the scarcity of oxygen. All felt loss of strength, and after six days of work and five sleepless nights longed to descend to a lower level. The effect on the mind must also be mentioned. Irresolution and disinclination to effort made the simplest action seem formidable. Photography, easy enough lower down, became a bugbear and the ascent of a peak an impossible proposal. It was necessary, indeed, to force oneself to carry out what was proposed by exerting the will power to the very uttermost.

Another intrepid traveler, Mr. H. Savage Landor, has published the story of his last feat in a couple of bulky volumes entitled "Across Widest Africa." The march took him twelve months and he traveled without white companions. Though he passed through fever-infected districts, he rejected the precautions usually adopted and speaks of them with contempt. His specific for fever is castor oil, which, with abstemious habits and abstinence from alcohol, served him so well that he was never delayed long by fever and he was able to push ahead in long marches better than his native followers. He has no confidence in quinine, and as to mosquitos he goes so far as to declare that instead of bringing they "rather took away fever." In this, as in his other travels, Mr. Landor's endurance shows that he has an enviable constitution and is endowed with remarkable resistance to bodily disease. But he does not seem immune from that mental weakness which is often met with in great travelers and displayed in an attitude of superciliousness sometimes amounting to disdain or contempt for the opinions and experience of the untraveled world.

The symptoms in his case are not confined to medical matters, for, having been hospitably entertained by Belgian officials and having listened to their views as to the government of the Congo, he pooh-poohs the story of atrocities he did not witness, apparently unconscious that the experience of a passing traveler can only weigh as the "small dust of the balance" against the evidence of numbers of men and women who have lived for years in the devastated regions.

The danger of fire in hospitals has lately received rather unpleasant illustrations. The Prince of Wales, as president of the King's Hospital Fund, last February asked Sir E. Shaw and Captain Wells to draw up recommendations as to the best methods of securing protection from fire in the London hospitals. These gentlemen have now submitted a report embodying the result of their deliberations. Valuable suggestions are made as to sites and architectural considerations which could be influenced by the fund in the future. The existing buildings have been erected without any system and as to fire appointments without any forethought, and in some of the smaller hospitals, not built for the purpose, no suggestions seem possible except cleanliness, prevention of dust, unfailing watchfulness for the first sign of danger, and immediate notice to all concerned inside and outside the premises. Hospital committees should make regulations as to the duties of the officials when an alarm is given and each should instantly take his appointed place. Fire drill should not be neglected. Simple appliances should be at hand, but their use should not delay the summoning of the fire brigade, when officials could give attention to allaying panic and removing patients to a safe place.

A few medical students planned a silly trip to Battersea to deface the memorial to a dog erected by the anti-vivisectionists. They regarded the inscription on it as a slander on their college. Five were arrested and fined £5 each, though no damage was done. The magistrate told them the erection was legitimate. Perhaps he meant legal or not illegal. Further, he threatened imprisonment in case of a repetition. His severity rather contrasts with the trifling fine inflicted on many a man for violence to another man or even woman. In a day or two thirteen students started from their college on a little march to protest against the heavy fines. As they walked along the pavement a couple of police warned them and as they continued their parade reinforcements were obtained and a posse of constables led by two mounted officers dispersed the students. Think of it! mounted men against thirteen juvenile students! The yellow press got hysterical over the matter and the virtue of the antis. But the sensational paragraphing failed to stir the public. The funny thing about it is that the same papers chronicled a march of hundreds of workingmen whose procession was "escorted by the police." People are saying these men were voters and the Government dared not risk offending them and so losing their votes!

Dr. Montague Murray died on Monday, aged 52. He was a University College student and graduated at the London University, taking the M.D. in 1884, when he also became member of the College of Physicians, of which he was elected Fellow in 1893. He was long connected with Charing Cross Hospital, where he filled numerous offices, including those of Medical Registrar, Assistant Physician, Lecturer on Pathology, Dean of the School, and eventually Senior Physician and Lecturer on Medicine. On the last subject he had been examiner at the University and at the Conjoint Board. He edited the third edition of Quain's Dictionary (1902) and the eighth and ninth editions of Green's Pathology. He contributed to the journals and societies various articles.

Dr. Rob John Paton, surgeon to the Newport and Monmouthshire Hospital, died on the 16th at the age of 45 from septic poisoning following a slight prick of his finger during an operation. He was M.D. (Ed.) and a licentiate of the two Edinburgh Royal Colleges, as well as of the Glasgow faculty. His untimely death is deeply lamented throughout the district, where he had worked for some sixteen years and attained a great reputation as a skillful surgeon.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CEREBRAL EXPLORATION—JACKSONIAN EPILEPSY—TUMORS OF THE SPINAL CORD—MILK SUPPLIES—SURGICAL TREATMENT OF EMPHYSEMA—SPINAL ANESTHESIA—INOPERABLE CARCINOMA OF THE UTERUS—NURSING BOTTLES—AUTOTOXIC ECZEMA—TYPHOID BACILLI CARRIERS.

BERLIN, October 15, 1907.

DURING the months in which the medical societies are taking a well-earned rest a large number of congresses hold their sessions. The Association of German Men of Science and Physicians has recently absorbed four special societies on laryngology, psychiatry, pediatrics, and pathology, and a few of the subjects that were discussed will be referred to briefly.

At the first annual meeting of the Association of German Neurologists, held in Dresden, Neisser of Stettin spoke on cerebral exploration by means of an electrical drill. This was to be used without anesthesia in cases of hematoma, abscess, tumor, and exudate into the ventricles. As the procedure was attended by but little danger, it might be repeated as often as necessary for diagnostic purposes. Krause of Berlin reported good results in the operative treatment of Jacksonian epilepsy. The operation scars themselves, as opposed to those of inflammatory nature, never give rise to epileptic manifestations. In most of the cases of Jacksonian epilepsy the forearm center is involved; the next in frequency is the one for the face, and finally those for the lower extremities. The surgical treatment of tumors of the spinal cord was discussed by Bruns of Hanover. He said that the differential diagnosis was very difficult only in cases of localized serous meningitis. It was impossible to determine the level of the lowest segments involved in the new growth. If antisyphilitic treatment was ineffectual exploratory puncture should be resorted to. Cassierer of Berlin read a paper on tumors of the cauda equina. In twenty-four cases of this sort that had come to operation two cures had been obtained. The operative prognosis was less favorable than in dealing with the spinal cord, as the growths were usually very large and malignant. Exact localization was usually impossible.

In the general session of the Association of Men of Science and Physicians an important contribution was read by Hempel on the subject of milk supplies. He stated that nineteen milliards of liters of milk, having a value of $400,000,000, were produced annually in Germany. Examination of the milk of healthy cows had shown such great fluctuations in its composition that by the use of set formulas for general employment different results would be obtained, and mixtures so calculated might be unsuitable for infant feeding. Boiling milk sterilized it, but also destroyed its bactericidal ferments. For the transportation of milk the American refrigerator cars were very desirable and should be introduced into Germany. On standing, milk soon separated into layers of different composition, so that the receptacles should be provided with devices for insuring thorough mixing before the removal of each portion.

In the surgical section Burker of Rostock recommended the complete excision of the area involved in all cases of thrombosis in varicose veins after a preliminary ligation of the occluded venous trunk. Trendelenburg of Leipsic described a syringe for removing clots from the heart, which had been successfully used on sheep. Hoennicke of Dresden described experiments on animals in which he had in forty-six cases produced monstrosities by the administration of thyroid extract, ammonium sulphate, ether, and alcohol before and during pregnancy. Paessler and Stieda demonstrated some interesting cases illustrating the surgical treatment of emphysema. In the case of a woman of fifty-one years portions of the second and third ribs 2 to 3 cm. in length were removed, with the result that the mobility of the upper portion of the thorax was greatly increased and the aeration of the lung was much improved.

In the section on obstetrics and gynecology Krönig of Freiburg spoke on a series of one thousand spinal anesthesias. He had found that this method could be employed successfully in laparotomies only when combined with scopolamine narcosis, but in this form it was likely to prove a serious competitor of inhalation anesthesia. In regard to the question of whether the scopolamine-morphine procedure should be included in the methods employed in private practice, Steffen of Dresden said that he was inclined to take the negative view on account of the uncertainty of the method, its possible complications, and the protracted presence of the physician which it made necessary. Gellhorn recommended acetone as a local application in cases of inoperable carcinoma of the uterus. Under anesthesia the growth was thoroughly curetted and cleaned and then one to two tablespoonfuls of acetone were poured into the cavity. The patient was kept with the pelvis elevated for fifteen minutes to half an hour, and after the fifth day the remedy was reapplied through a speculum at intervals of three or four days. The effect was to check the hemorrhage and suppuration, the walls of the diseased cavity became smooth and dry, and the general condition improved. Brüning of Rostock read a paper on the history of nursing bottles. In the days of the Greeks and Romans vessels of various sorts were in use from which the contents could be poured out drop by drop. Since the thirteenth century bottles provided with some equivalent for a nipple had come into use. In the fifteenth, sixteenth, and seventeenth centuries nursing bottles were of wood, and in the seventeenth, eighteenth, and nineteenth centuries metal bottles were in use. Glass nursing bottles were first mentioned in 1769.

An unusual type of disseminated dermatosis was described by Leiner of Vienna as occurring in infants during the first or second months. The lesion consisted of erythematous patches on the trunk or seborrheal lesions on the head, which soon spread over the entire body. At the height of the disease the head was covered with crusts and scales and the skin of the rest of the body was red and scaly. In one-third of the cases death occurred with fatty degeneration of the heart and liver and intestinal catarrh. The condition appeared to be a form of autotoxic eczema.

In the section for internal medicine, Chiari of Strassburg discussed the relation of typhoid and paratyphoid fevers to the gall passages. In typhoid fever the bacilli were nearly always to be found in the biliary passages and multiplied in that situation. They might remain in the gall-bladder for a long time, even fourteen years, and might induce choleliathiasis. In eight cases of typhoid examined in one year Chiari had found typhoid bacilli in the gall passages of seven of the patients. The bacilli reached the gall-bladder through the blood. Förster of Strassburg pointed out that the bacilli might appear in the blood during the period of incubation, but in the excretions only after first and second weeks. The antibodies also appeared in the blood sooner than the bacilli in the feces. Among the bacilli carriers three groups might be distinguished—those in whom the organisms persisted for weeks, months, or years. An interesting fact was that, just as in the case of gallstone disease, 80 per cent. of the bacilli carriers were women. Cholecystectomy was indicated in bacilli carriers who suffered from gallstones. For others the administration of bile and biliary acids was advisable for the purpose of cleansing the gall-bladder, and bactericidal substances might be added to these agents.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PHILIPPINES MEDICAL SCHOOL—FILIPINA TRAINED NURSES—PURE MILK FOR INFANTS—BAGUIO, THE SUMMER CAPITAL—ANTHRAX IN HONG KONG—PERIODICITY OF THE PLAGUE—PERSONAL.

MANILA, P. I., November 8, 1907.

THE cause of medical education and that of public health, sanitation, and hygiene have received considerable impetus since the arrival of the Secretary of War, William H. Taft, in the Philippine Islands. He has taken a deep interest in the work which has been accomplished here since his last visit and has made it a point to stimulate by his presence the efforts of those engaged in this work. He visited the Philippines Medical School and after inspecting the institution and learning more of the details of the nature of the work which is being accomplished, he expressed his hearty approval and future support.

He also visited the Girls' Dormitory of the Philippine Normal School, where sixteen Filipina women are undergoing a preliminary course of instruction in the art of nursing. He was much gratified that this work has been undertaken, because it is the first time that efforts in this direction have met with any success whatsoever, as the women of the better class among the Filipinos do not take kindly to this form of work, because, in Spanish times, it was considered more or less degrading for a woman to engage in any form of manual labor. In addition, it is distinctly contrary to the customs of the country that a woman should, at any time, be alone in a place like the male ward of a hospital. Much patience and perseverance have been and will be required to overcome these preconceived notions and to introduce American customs in the islands with regard to nursing.

Mr. Taft also visited the "Gota de Leche," which is a

charitable institution modeled after those of France, which has for its object the distribution of wholesome milk to the infants of the city of Manila, with a view to reducing the infant mortality which plays such an important rôle in the mortality statistics of the islands. This movement is receiving the active support of the Filipinos, and bids fair to be as successful as a similar movement which did so much for Japan.

He also visited the summer capital at Baguio, which is the health resort of the Philippines, and expressed himself as being pleased with the practical results which have been obtained in the way of restoring the health of those who went there during the past years. He will recommend to Congress that the present army post at Baguio be enlarged to a brigade post and that the tour of duty in the Philippines be increased at least another year, with the understanding that the troops in the Philippines shall be given at least six months' stay in Baguio, thus giving them all the advantages of a visit to a temperate climate.

Mr. Taft also visited the site of the new reservoir, and the dam, situated about twenty miles from Manila, from which the new water supply for the city is to be piped from an uninhabited watershed, this project alone involving an expenditure of more than two million dollars to carry it into effect.

Last week there arrived in Manila a shipment of cattle from Hong Kong, among which were found some that were afflicted with anthrax. The entire cargo of cattle were refused admittance to the islands, and the importation of cattle from Hong Kong has been temporarily suspended. Dr. Musgrave has been sent by the Philippine Government to Hong Kong to make a thorough investigation as to whether these shipments could be resumed with safety.

Owing to the disappearance of plague, in and about Amoy and vicinity, the quarantine of seven days which has been imposed upon vessels from that port during the past six months has been removed, and from now on vessels from Amoy will only be required to undergo disinfection at one of the quarantine stations of the Philippines before being granted pratique to the islands. The seasonal prevalence of plague, which is indicated by the above order, is most remarkable for its regularity, as is shown by the time of imposition and lifting of the quarantine against that port during the past seven years. The number of plague cases gradually increases about the month of March, reaches its fastigium during April or May, and then gradually declines until October, when the disease disappears completely.

Assistant Surgeon Joseph H. Ford, United States Army, who has been experimenting with antimalarial serum, having completed his tour of duty in the Philippines, has been ordered to return to the United States upon the transport which sails from here about November 15 next.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 5, 1907.

Nocturnal Paralysis.—After a reference to a previously reported personal case and to recent literature on the subject, I. H. Coriat reports four additional cases from the neurological clinic of the Boston City Hospital. Case I. is entitled psychasthenia with peculiar crises and nocturnal palsy; Case II., neurasthenia with rather protracted attacks of nocturnal palsy; Case III., hysteria with narcoleptic attacks and nocturnal palsy; Case IV., neurasthenia with nocturnal palsy. The author states that on clinical evidence at least nocturnal palsy seems to possess the following characteristics: (1) It appears only in the hypnagogic state and runs parallel with it. (2) When it occurs in normal individuals it is a transitory and rare phenomenon. (3) Sometimes it follows a strong emotional shock and assumes the characteristics of a recurrent mental state, as in the case published in my first paper. (4) The symptom-complex may occur in hysteria, neurasthenia, or psychasthenia. In neurasthenia it appears to be merely symptomatic of the underlying neurosis with its concomitant sense of exhaustion. In hysteria and psychasthenia it is an equivalent disorder in the sense of replacing the narcoleptic attacks in the former disease or the peculiar crises of anxiety in the latter. (5) This nocturnal palsy has a varying duration, from a few seconds in normal individuals to several minutes, or even a quarter of an hour in pathological cases. (6) The entire symptom-complex is a mental dissociation reacting most strongly on the motor mechanism, and as a purely functional disorder it is distinctly amenable to psychotherapeutic treatment.

New York Medical Journal, December 7, 1907.

Diseases of the Liver Amenable to Surgical Treatment.—Under this heading C. A. McWilliams mentions cirrhosis, abscess, malignant disease, and prolapse. He refers to Kocher's statement that it should be the rule in all liver diseases accompanied by persistent jaundice, in which the latter is clearly not due to an inoperable condition such as advanced liver and pancreatic cancer, to perform an exploratory laparotomy. Reference is made to various authorities in this department of surgery, and the author presents statistics from the records of the Presbyterian (N. Y.) Hospital. Of four cases of operation for ascites, all have done well. The statistical list includes 16 cases of abscess, but the ultimate results are not given. Six patients had more than one abscess, and of these four died. Ten patients had single abscesses, and of these three died. The list of malignant cases comprises twenty-five. In seven of these erroneous diagnoses were made before operation (cancer of the colon, biliary calculi, gastric cancer (2), abscess of the liver (3). He refers to Keen's collection of seventy-six cases of resection of hepatic tumors, sixty-three of which recovered. When the tumor is exposed resection should be undertaken only when the tumor is primary and solitary, when its margins are clearly defined, when it is quite certain that the whole of the neoplasm can be removed, and in malignant cases, that such a margin can also be cut away, so as to make it probable that recurrence will be prevented or long postponed.

Infections Within the Thorax.—J. H. Musser finds, in going over the histories of 12,892 cases of pneumonia, that 2.1 per cent. had empyema. He does not believe that the latter disease is ever idiopathic. The pneumonia is almost always attended by a serous pleurisy, and this frequently becomes purulent. The exciting organisms are in their order of frequency, the pneumococcus, streptococcus, and the tubercle bacillus. Typhoid and scarlet fever are frequently followed by empyema, which also supervenes in disease of the ribs, subpectoral tissues, esophagus, and subdiaphragmatic lesions. In making a diagnosis we must look out for the evidences of pus (chill, fever, sweating, etc.), occurring coincidently with the crisis of the original pneumonia. A leucocytosis after the crisis associated with the general features of an infection is of great significance. Steady, persisting pain in certain localities is always suspicious, as is also localized tenderness. Of suggestive physical signs, special mention is made of localized friction sounds, which are very good guides as to the position of the abscess when it is between the lobes or under the diaphragm. When between the lobes the frictions are along the septa. Musser has found them in the anterior axillary line, either on the left side or right, when the abscess may be two or three inches above or between the septa, and practically almost always near to the root of the lung. Concerning percussion, he says that first the note is overresonant. After three or four days the quality of the resonance changes to impaired and then dullness, depending upon the rapidity with which the abscess increases in size. It is surprising how long the abscess may remain localized and of moderately small area. By this time the voice sounds are not usually different from those we find in the occurrence of small effusion. The *x*-ray is of some value in the recognition of the presence of an abscess. When small abscesses are present one is only able to see that a well defined shadow is present. We cannot, of course, make a diagnosis of abscess within the pleura, and can only state that there is a consolidation or effusion by the difference in the density. If the physician is reasonably certain of his diagnosis he should lose no time in calling on the surgeon to make an exploratory puncture.

Some Things Not Generally Known About Syphilis.—The points emphasized by J. A. Hawkins are the following: (1) that all diseases due to nontraumatic arteritis, as paresis, tabes, true angina pectoris, aneurysm, etc., are due to syphilis. (2) That they are parasyphilitic or quaternary manifestations and are seldom amenable to treatment as usually exhibited. (3) That the iodides are of little value in the class of cases just mentioned, and if any benefit is expected, it must be obtained through the use of mercury, preferably administered in the form of hypodermatic injections of biniodide of mercury. (4) That no other disease is more often maltreated than syphilis. (5) That secondary syphilis, if energetically and intelligently treated, is positively curable. (6) That mercury, and not iodide, is the drug to use in the early stage, and is often the drug for the later stages. But to get the effect, it must be given in increasing doses until the point of tolerance, and then continued in tonic doses intermit-

tently, at least two years. In the early stage, deep intramuscular injections are most effective, the salicylate of mercury being preferred. (7) That two years of active intermittent treatment, after disappearance of the secondary syphilides, will assure a cure, as proved by a number of women and their offspring in his own practice. (8) That syphilis is far more prevalent than the majority of physicians suppose, and is frequently overlooked by the family physician through his lack of familiarity with its various phases, with consequent disastrous results to the patient or his progeny.

Animal Therapy in Tuberculosis.—G. B. Sweeny refers to certain observations made by him on the theory that the immunity conferred upon cattle by the inoculations of Behring (method described) was dependent on the lymphocyte. He therefore conceived the idea of utilizing the lymph collected from the thoracic duct of the immunized animal in the treatment of tuberculous patients. The results of such injections are herewith summarized: (1) Following injection into the healthy organism no febrile reaction is observed to follow the administration of the lymph, and no special influence is exerted, excepting that which follows the administration of a simple cell tonic. (2) Following injection into the tuberculous patient, at first there is a period of intoxication, characterized by a lowering of the antibacterial power of the blood cell. This negative phase is more or less marked and prolonged, according to the dose of lymph injected. If the dose is large, the negative phase may be revealed by a rise of temperature and a reaction of the organism. If the dose is small, the negative phase may be accompanied by no clinical signs whatever. After the negative phase there comes a positive phase, which is characterized by an increase of the antibacterial power of the blood. This phase represents an increase of resistance against intoxication. The curve, which represents the variation in the opsonic influence on the blood, often rises suddenly and descends at first quite rapidly and later more slowly. The patient experiences a feeling of well being and of physical vigor at the time when the positive phase reaches its apogee. These "negative and positive phases" of opsonic influence may be aptly called the ebb and flow of the tide of immunity. When immunity seems to have been acquired, the "negative phase" entirely disappears, and the results following injection are identical with those observed in (1). (3) A decided tendency to approach and maintain a normal temperature is noted, whether this has been conspicuously above or below normal. (4) Night sweats, which had previously accompanied fever, are absent or materially modified. (5) Marked stimulation of the secretions, as manifested by facilitating expectoration, where this is scanty and tenacious. Consequent amelioration of cough. The alvine and urinary discharges display a like stimulation. (6) Where hemorrhages have occurred from lungs, previous to administration of lymph or where cavities are present, cicatrization is encouraged by a process of lymphocytosis (?) directed toward the seat of the lesion. Concomitant with this condition is an increase in weight and bodily vigor.

Journal of the American Medical Association, December 14, 1907.

Experimental Lymphatic Spirillosis.—W. C. White and F. Proescher include under this head the following diseases: Acute lymphatic leukemia, chronic lymphatic leukemia, pseudoleukemia or Hodgkin's disease, chronic benign lymphomatosis and lymphosarcomatosis (chloroma myeloma.) In all these diseases they have found spirochetes in enormous numbers in sections from the glands. Portions from the glands were injected subcutaneously into a guinea-pig, and it was then examined for tuberculosis which was not found. The animal, however, developed an ulcer at the site of the operation and enlarged glands in the groin. In the fluid aspirated from these, the same form of spirochete was found as that in the original glands. The same infection was transferred from this guinea-pig to three other healthy ones, a hard indurated edged ulcer appeared on the eighth day, with enlarged glands in the groin. Microscopically the sections of the glands stained with hematoxylin and eosin gave the picture of hyperplasia of the lymph gland with patches of sarcomatosis.

Anorectal Malformations.—S. W. Kelley reports three cases of imperforate anus. In one there was a depression bridged by a tail-like process from the coccygeal region to the scrotal raphe. The rectum was reached by a quarter-inch dissection and permanent good result obtained. The other cases were of more serious malformations, and both patients succumbed. In commenting on these cases, Kelley thinks that they show the necessity of early discovery of the condition and prompt operation. They also illustrate the impossibility, before operation, of ascertaining the degree of development of the rectum or the position of the enteron. In the first of the two, the pouch was situated on the right side in the cecum, in the other on the left. He thinks that if a patient with imperforate anus or malformed rectum, without a previous sinus, were to come before him now in a fit condition for operation, he would persist in the perineal, coccygeal, or even sacral route, separate and drag down the pouch if possible and stitch it to the skin margin. Of course, this would have to be done in time, while the patient was fit for such an operation.

Urinary Infection in Children.—I. A. Abt describes the bladder and kidney infections in children which are almost always of bacterial origin. He states that the infection is most frequently an ascending one, though congenital malformations predispose to it. During the past few years 22 cases of cystopyelitis have come under his observation, mostly in infants under eighteen months and nearly all in private practice and in families in comfortable circumstances. The trouble usually began suddenly with restlessness and fever, anorexia, and sometimes persistent vomiting. Local pain seems to be sometimes present. In several of these cases casts were found in considerable quantities. The urine is usually cloudy and of low specific gravity. If the colon bacillus or that of tuberculosis is the cause the urine is usually acid; staphylococci and streptococci generally occur with alkaline urine. The blood shows a marked leucocytosis. Twenty of his patients recovered. In one of the fatal cases there was a malformation of the kidney. The other child died of a protracted and neglected cystopyelitis. The prognosis, if early recognized and properly treated, is favorable. The diagnosis can only be made by an examination of the urine, and it cannot be too strongly emphasized that infants with a persistent irregular fever for a succession of days should have the benefit of both a chemical and microscopical urinary examination. Pus in an acid urine with epithelial cells and occasional casts and colon bacilli is proof positive of a cystitis or pyelitis or both. As a prophylactic all who have the care of very young children should be instructed as to the importance of thorough cleanliness of the buttocks and genitalia. The treatment depends on the cause; if it is a stone or foreign body, surgery is indicated, but if an infection, the free administration of fluids, especially water, is advised. Medicinally hexamethylenamin (urotropin) is the most valuable remedy. To infants one to two years of age it may be given in one-grain doses four times a day and increased, if it is well borne. Salol may be given either alone or in combination with urotropin to children of this age. In one rebellious case he found one-drop doses of guaiacol of advantage. During fever the nourishment should be largely liquid and nonirritating. Irrigations are not usually necessary, except in the severe forms of streptococcic or staphylococcic infection. In other respects, the treatment is expectant and symptomatic.

Surgical Relations of the Temporal Bone.—G. E. Shambaugh describes and illustrates some of the more important structural variations that may complicate the mastoid operations. The first of these is the occasional encroachment of the sigmoid sinus on the posterior wall of the meatus so that the usual space is lacking for the opening into the antrum. In such case the first stroke of the chisel in opening the shell of the mastoid could easily open into the sinus. Hence the necessity of caution when the sinus is close to the surface of the bone, as we have no means of ascertaining the exact location of the sinus beforehand. The most important structure to be considered, especially when performing the complete tympano-mastoid exenteration, is the facial nerve. If the bony shell between it and the tympanic cavity is lacking, as sometimes happens, it may easily be injured in curetting. Its relation to the posterior wall of the meatus is such that any attempt to remove completely the posterior wall toward the floor of the tympanum would certainly result in a severance of the facial nerve. Another point of surgical interest is that from the point just back of the oval window where the nerve curves downward, its course lies further and further away from the posterior wall of the meatus, thus allowing a considerable wedge of bone to separate the nerve from the meatus as the floor of the latter is approached. The bony covering of the lateral or horizontal semicircular canal forms a smooth, ivory-like, rounded prominence in the floor of the an-

trum tympanicum, just where this cavity opens with the tympanum, and a false stroke with the chisel after the antrum has been entered could result in opening this semicircular canal. In curetting and cleaning out the tympanic cavity one must bear in mind the relations of the carotid artery, and the fact that at the tympanic orifice of the tuba auditiva it is separated from the tube by only a thin shell of bone which can easily be penetrated by the curette. Frequently it forms a very thin-walled prominence in the tube. The bulb of the jugular also, while usually separated by at least a quarter of an inch from the tympanum, may sometimes be separated from it by only a thin bony wall, and even this may sometimes be wanting, leaving the bulb of the jugular unprotected and liable to injury.

Cystocele Operation.—D. T. Gilliam describes a simplified operation for cystocele. An oval denudation is done, as in the old method, and a flap is dissected from the vaginal wall on either side of the denuded area; these flaps are then drawn over and sutured to it and to each other from below upward. The technique is described in detail and illustrated. He claims that this operation effaces the cystocele and strengthens the site with the additional layers of fascia. It is adapted especially to cases uncomplicated by prolapse of the uterus. For extensive cystocele with uterine prolapse he can conceive of nothing better than the operations of Goffe and Watkins.

Essential Insufficiency of the Heart in Childhood.—A. W. Fairbanks calls attention to a condition he has frequently observed in the routine examination of children, but which appears to be neglected in medical literature. He regards it as a muscular deficiency of the heart comparable to muscular deficiency elsewhere in the body and due to irregular development. The symptoms are inconspicuous, the more prominent are pain in the chest and shortness of breath on moderate exertion, cyanosis under similar conditions, and sometimes persisting after the exertion for a short time, seen especially in the lips, face and fingers, and cold hands and feet. A more remote effect and less constant but more striking is the backward physical development of these children, most noticeable between the eleventh and thirteenth years. Some of these children show a discrepancy of several years between their actual and apparent ages. They are notably deficient in the usual activities of childhood. In its ultimate results muscular insufficiency of the cardiac muscle is much more serious than the same condition elsewhere in the body, tending to an actual organic deficiency in time. Fairbanks does not, however, consider such defect absolutely essential for the production of all the secondary symptoms of deficient heart, or of the remote results of such deficiency, when long persistent, on the growing body. These cases are generally overlooked by the family physician, who finds no organic disease, and the symptoms observed are credited to some error of hygiene or diet or to something the child is expected to outgrow. He does not venture to say just what etiological factor is directly to blame for this insufficient cardiac development, but believes that every infection or toxemia affects the cardiac muscular and nervous structure to a certain degree, and advises giving more attention to the slight ailments and greater care during the convalescence from the ordinary infections in this stage of life. The treatment advocated is the same as that for cardiac incompetency from demonstrable organic disease—rest, absolute at first, combined with massage and warm carbonated saline baths and, in the case of older children, resisted movements, and, at a later period, graduated physical exercises under control of a physician or nurse.

The Lancet, November 30, 1907.

A Very Successful Method of Treating Acute and Chronic Suppurative Otitis Media and Other Forms of Otorrhea.—The method described by A. F. Blagdon Richards consists in the use of the following combination for ear drops after the usual cleansing: boric acid 1 dram, rectified spirits 2 to 3 drams, and glycerin to make 1 ounce. He uses boric acid one dram to the pint for cleansing purposes. He employs the same combination in acute as well as chronic cases, and says that he cannot recall a single case in which the acute has merged into the chronic condition in which he has had the opportunity of treating the case from the outset. A series of illustrative cases is appended.

The Value of Blood Pressure Determination in the Diagnosis of Aneurysm of the Aorta.—O. K. Williamson presents the following conclusions: (1) The arterial blood pressure in most cases of aneurysm of the thoracic aorta or innominate is either normal or slightly above normal. It is, as a rule, however, much higher in cases of mere dilatation of the aorta, and this fact is of some value in the differential diagnosis of these two conditions. (2) A distinct difference (at least five millimeters) between the arterial blood pressures in the two arms is the rule in the majority, and in about the same proportion of cases, on the one hand, of both aneurysm of the arch or ascending portion of the aorta and aneurysm of the innominate and, on the other, of dilatation of the aorta; and a marked difference (at least ten millimeters) is equally common in both. Such differences are therefore of no value in the differential diagnosis between these conditions. A great difference (at least twenty millimeters) seems to be likewise about equally common in these two classes of cases, but a difference of upwards of thirty millimeters speaks strongly in favor of aneurysm as against mere dilatation of the aorta. (3) While distinct (at least five millimeters) or marked (at least ten millimeters) differences are the rule in a far larger proportion of cases of aneurysm of the arch or ascending portion of the aorta or innominate than in cases, on the other hand, of arteriosclerosis or mediastinal tumor, yet such differences are sufficiently frequent in the latter conditions to lead to the conclusion that their presence in a particular case affords but little help in the differential diagnosis between these conditions on the one hand and aneurysm of the arch or ascending portion of the aorta or innominate on the other. Differences of pressure between the two sides greater than twenty millimeters afford, however, strong evidence in favor of aneurysm of the arch or ascending portion of the aorta as against the two other conditions. (4) A distinct difference between the pressures on the two sides is the exception in cases where none of the above pathological conditions are present. (5) Digital examination of the pulses in cases of aortic aneurysm is a far less sensitive method than instrumental, frequently gives results directly at variance with those obtained by the latter means, and hence is of much less value in diagnosis. Elaborate tables are appended, detailing the clinical observations on which the above conclusions are based.

On Change of Type in Leukemia and Its Significance.—S. G. Scott refers to five cases of this nature reported by various authorities during the last few years. He offers the following summary as to the cytology of the disease: (1) The large lymphocyte is present in the blood in all leukemia. The large mononuclears and lymphocytes are frequently increased in myeloid leukemia. Myelocytes are usually present in lymphadenoid leukemia. (2) Between the extreme types ordinary myeloid and ordinary small-celled lymphadenoid (chronic lymphatic) on the one hand, and the undifferentiated, usually acute, large lymphocytic leukemia on the other hand, all gradations have been found. (3) Both myeloid and lymphadenoid leukemia may become large lymphocytic. (4) Simultaneous myeloid and lymphadenoid leukemia is not known. He adds one personal case, that of a boy fourteen years old, who had complained one month before admission to hospital of fatigue and drowsiness. Spleen was enlarged and he had some fever. The heart was a little dilated, and a faint systolic bruit was heard over the pulmonary area. The lungs were normal. The liver dullness was slightly increased downwards, and the spleen reached below the umbilicus and to the right of the middle line. The urine was free from albumin and sugar. The blood examination showed the features of myeloid leukemia, and the rather high proportion of large lymphocytes justified a diagnosis of atypical myeloid leukemia. Arsenic treatment was adopted and continued until vomiting set in. Later *x*-ray treatment was begun, five minutes' exposure of the spleen and each knee-joint daily being prescribed. As the patient was getting worse rapidly and the *x*-rays caused some discomfort, the treatment was discontinued. Later the glands in the neck, axilla, and groins were noticed to be slightly enlarged. Later some pale retinal hemorrhages with marked neuroretinitis and pallor of the optic disk were noticed. There was also some diplopia. He again became drowsy. Three days later there were several attacks of severe paroxysmal precordial pain. During the stay in hospital there was fever for most of the time. In the first fortnight after admission the weight increased by fourteen pounds and after that remained roughly constant. Death occurred after an entire illness of about ten weeks.

British Medical Journal, November 30, 1907.

Rigor Mortis in a Stillborn Child.—D. W. Whitfield reports attending a woman, thin, active, but poorly nourished, aged twenty-two years, in her third confinement, one month before the expected time. She had felt the child moving vigorously about eight hours before its

birth. She had an easy and straightforward time, and was in labor about four hours. The child, a female, when born was dead and in a state of well-marked rigor mortis, the legs and arms were flexed and quite rigid, the child seemed to be well nourished, and did not appear to be of more than eight months' development. Her first child was born alive. The second was born dead. Her husband is a weakly man, with synovitis, probably gonorrheal, of his knee-joint.

Hysterectomy and Appendicectomy in a Patient Aged 74; Recovery.—The patient of J. D. Malcolm was a healthy, well-nourished woman, and the operation was done at a time of election. The condition determining the operation was the existence of a well-marked flatulent enlargement of the abdomen and a tumor continuous with the uterus, and apparently within the right broad ligament. It was rounded in shape, not tender, large enough nearly to fill the pelvis, and firmly fixed, but he thought that the fixity was in part due to its size and position. It seemed to be a soft, solid, or a thick-walled cystic growth. There was no history of any serious illness, and the other organs were healthy, with the exception that there was a trace of albumin in the urine, the specific gravity of which was 1,014 to 1,016, and its quantity was normal. Menstruation was regular and free, but not excessive at any time, and its cessation, at the age of fifty-three, was not accompanied by noticeable symptoms. Operation was without incident. Sutures were removed on the eighth day, but during the following night part of the incision gave way, and when the patient was being put under an anesthetic with a view to inserting fresh sutures the whole wound broke down. The exposed coils of intestine showed no sign of inflammation or tendency to form adhesions, and the wound, after being reunited, healed throughout without suppuration, all the sutures being left in position fourteen days, and some sixteen days. Except for a slight bronchitis and a painless swelling of one leg of about three days' duration, there was little further trouble, and the patient recovered her strength in a very satisfactory way. It was noted, however, that as she moved about and took nourishment more freely, the amount of albumin in the urine increased, but not to any great extent. The patient left the hospital five weeks after the first operation, and some months later was to all appearances well.

The Correlation of the Ovarian and Uterine Functions.—The experiments on rabbits of E. S. Carmichael and F. H. A. Marshall lead them to the following conclusions: (1) The removal of the ovaries in young animals (rodents) prevents the development of the uterus and Fallopian tubes. These remain in an infantile condition. The subsequent growth and general nutrition of the animals seem to be unaffected. (2) The removal of the ovaries in adult animals (rodents) leads to fibrous degeneration of the uterus and Fallopian tubes (most marked in the mucous membrane). The animals' subsequent health and nutrition remain good. These observations, for the most part, support the evidence obtained clinically in the human subject after surgical operation. (3) The removal of the uterus in a young animal has no influence in preventing the further development of the ovaries. These are capable of ovulating and forming corpora lutea after adult life has been reached. (4) The removal of the uterus in an adult animal does not give rise to any degenerative change in the ovaries if the vascular connections of the latter remain intact. These latter observations do not support the contentions of those surgeons who advocate subtotal hysterectomy, believing that the functional activity of the ovary is in some way dependent on the presence of the uterus.

Movable Kidney from a Surgical Standpoint.—W. Billington discusses the morbid anatomy of this condition and then speaks of treatment by belts and by operation. He describes his operative procedure (diagrams given) and passes on to the results of the operation. These he has found to be in the highest degree satisfactory. All but one of his seventy cases did well. The exception was a man who, on the fourth day after operation, went into sudden collapse and died without any apparent reason. Autopsy revealed nothing abnormal. Billington notes that there are several reasons why it has been found difficult to fix movable kidneys successfully and permanently. The renal parenchyma is soft, and sutures passed through it tear out easily, so that the capsule alone can be utilized for purposes of support. The muscles of the back are too yielding, and will not withstand the drag of a kidney fixed to them; further, by their own contraction, they tend to push the kidney away from them, and so strain the supporting stitches. The strain thrown upon the supporting sutures during the retching that is so common after operation is enormous, and is, the author believes, the cause of so many kidneys being found loose again as soon as the patient assumes the erect position. He is firmly convinced that no method by which the kidney is sutured to the muscles of the back will give satisfactory results. Another difficulty has been experienced in connection with buried sutures; these, such as catgut, which are absorbed in the tissues, are apt to soften and yield too soon, while the permanent suture materials, such as silk, frequently give rise to troublesome sinuses. To avoid these troubles, the kidney capsule itself has been cut into strips which have been made to serve as sutures, and some of the tendons of the back muscles have been utilized for the same purpose. The results, however, have not been altogether satisfactory.

Berliner klinische Wochenschrift, November 25, 1907.

The Forensic Application of the Method of Fixation of the Complement.—Bruck finds that by this method it is possible to identify albuminous bodies in much more diluted form than by the older precipitin test, but he considers that the latter should still be employed in forensic work for the purpose of distinguishing between albuminous bodies of human and those of animal origin. The fixation method should, however, be also employed as a control in every case, but its great sensitiveness makes it advisable to work with serums whose potency is not too high and requires a considerable degree of experience on the part of the worker to avoid error. By using a weaker serum it is possible by the fixation of the complement not only to make the diagnosis as to the nature of the animal from which a given albuminous fluid has emanated, but also to differentiate between different body fluids, such as blood, pus, semen, etc. The reactions for these are sufficiently characteristic to render the method practically useful for forensic purposes.

Münchener medizinische Wochenschrift, November 25, 1907.

The Transplantation of Epithelial New Growths.—Reinke succeeded in inducing epithelial new growths in the lens of the eye of the salamander by means of injections of 4 per cent. ether. The lens containing the colonies of proliferated cells was excised and reduced to fragments in physiological salt solution. This was then injected into the abdominal cavity of other animals. At the expiration of sixty days the parietal peritoneum contained nodules of the size of the head of a pin, which on microscopical examination were found to consist of the transplanted epithelial cells, together with new formed blood-vessels and connective tissue. The treatment with ether, and also possibly the transplantation, appeared to have altered the specific character of the lenticular cells, so that in addition to their increased proliferative capacity they had lost the ability to form lens fibers and prevent the penetration of blood-vessels and connective tissue. The structures so formed possessed resemblance to true carcinoma.

The Treatment of Gastrointestinal Disorders with Bolus.—Gorner discusses the application to internal treatment of bolus alba—powdered clay—originally suggested by Stumpf as a local application in granulating wounds and then as a remedy in cholera. Gorner has found that it is of value in the treatment of gastrointestinal disorders of bacterial origin, probably because of the inhibiting effect on the growth of microorganisms which the substance seems to possess. It is tasteless, and can be given to adults in doses of 50-100 g. in about a quarter liter of water. Infants may take 10-30 g. It is best administered with the stomach empty, and it is preferable to avoid the addition of any other substances such as sugar or milk. The method is particularly effective in the treatment of acute gastroenteritis, the vomiting and diarrhea promptly subsiding. The remedy did not prove particularly satisfactory in the treatment of typhoid fever, though the author suggests that it might be of value as a prophylactic, and he concurs with Stumpf in recommending it in the treatment of cholera.

Deutsche medizinische Wochenschrift, November 14, 21, and 28, 1907.

The German Sleeping Sickness Expedition.—Koch contributes a long final report embodying the results of the work of the expedition that has been studying sleeping sickness in Eastern Africa. The following measures are recommended for combating the disease: Permanent camps should be established under the charge of a medical director with several white assistants. These camps should be sufficiently numerous to accommodate all the patients in a district and should be, if possible, in spots that are not infested by the glossina. In addition to receiving patients that apply for treatment, active search for infected individuals is necessary and blood ex-

aminations of such persons are essential, as the absence of lymphatic enlargements does not preclude the existence of the disease. As an example, Koch cites the results of the examination of fifty-two young boatmen who were considered perfectly well and had just finished a journey during which they had rowed for over twelve hours almost without interruption. Eleven of these had enlarged lymphatic glands, seven had trypanosomes in the blood, forty-seven had the *Filaria perstans*, twenty-six had malaria organisms, and two the spirilla of relapsing fever. Patients in the camps should be treated for at least four months with atoxyl and must be kept under observation until their own blood is free from trypanosomes, and it may be assumed that the glossinas in their dwelling places are also free from infection. Quarantine regulations are necessary to prevent the transmission of infection from one district to another and it may be necessary to remove small communities to other regions free from the glossina. The attempt to reduce the numbers of the glossina should be made by clearing woodland and endeavoring to exterminate the crocodiles on whose blood the insects largely subsist. Details regarding the atoxyl treatment, the geographical distribution of the disease, etc., are given at length.

Lymphocytosis of the Cerebrospinal Fluid in Hereditary Syphilis.—Kretschmer says that it has already been shown that lymphocytosis of the cerebrospinal fluid occurs in the hereditary syphilis of infants, and that it is desirable to ascertain whether or not the same condition obtains in regard to the later manifestations of the hereditary disease. He reports four cases of patients from ten to nineteen years suffering from eye conditions and in one case from broken-down gumma of the palate, in two of which there was a very pronounced lymphocytosis of the cerebrospinal fluid. He therefore concludes that lymphocytosis is not an exclusive manifestation of hereditary syphilis in infants, although the question requires further investigation on large numbers of patients. The effect of treatment on the lymphocytosis should also be investigated.

Obesity Diets.—Sternberg says that in carrying out courses of treatment for obesity the patients often suffer severely from hunger, and that the feeling of satiety after eating is essential to the sense of well being and capacity for work. It is desirable to add to the dietary something which will contribute to the feeling of repletion after eating without itself being digestible or nourishing. Such a substance is to be found in the ligamentum nuchæ. It is possible to prepare this in such a way as to be appetizing and applicable to many different culinary uses. The ligament is boiled until it has become perfectly soft, which requires a long time, and it is then passed several times through a chopping machine until it has been reduced to very fine particles. The material may be used to make croquettes, forcemeat for soups, and as a substitute for flour in many different egg dishes. One of the recipes recommended by the author is as follows: The chopped ligament as above is stirred with whipped cream and put into a buttered ramekin; a raw egg is added and the whole is baked in a dish containing hot water. Before serving, cheese is sprinkled over the top. Several other methods of using the material are given by the author, who says that it may also be advantageously employed in preparing starch-free dishes for diabetics.

The Association of Tabes Dorsalis and Cardiovascular Disease.—Strümpell contributes a long article on this subject and summarizes his conclusions as follows: In patients exhibiting aortic insufficiency, sclerosis of the aorta, and aortic aneurysm, careful search not rarely reveals evidences of coincident tabetic disease, such as reflex pupillary rigidity, absence of tendon reflexes, lightning pains, etc. On the other hand, pronounced tabes dorsalis is comparatively often associated with insufficiency of the aortic valves and aortic sclerosis. This combination of the two diseases is due to the fact that they have a common origin, both are consequences of a previous syphilitic infection. The presence of tabetic symptoms, particularly of reflex pupillary rigidity, may in general be regarded as proof of a syphilitic taint and therefore has especial diagnostic significance.

Acute Leukemia and Streptococcus Sepsis.—Eppenstein's patient was a man of twenty-one who died after an illness of about eight weeks of what the blood examination showed to be acute lymphatic leukemia and streptococcus septicemia. The streptococci were obtained from the blood during life and after death were found in the spleen, lymph glands, and bone marrow. The leucocytes and the bone marrow in this case did not manifest any ability to digest gelatine or blood serum, and as the large lymphocytes comprised more than half of the total number of white cells the author considers that this fact affords evidence against the view that has been advanced to the effect that in acute leukemia the large lymphocytes serve as carriers of a proteolytic ferment. He considers that in cases such as this the bacterial infection is secondary, and is not, as some have suggested, the cause of the blood disease. It is more likely that, owing to the presence of the latter, the powers of resistance are weakened, and therefore infection results more readily.

Lime, Phosphorus, and Nitrogen in the Child's Brain.—Cohn describes a method of analysis to be used for determining these constituents quantitatively and discusses the results obtained from a series of thirteen analyses made on brains, of which the youngest came from a fetus of 25 cm. and the oldest from an individual of twenty years. He concludes that after the first year growth of the brain is accomplished through the accretion of nonnitrogenous substances rather than through increase in nitrogenous bodies. The total phosphorus in the child's brain shows a slight relative decrease during the period of growth, but the phosphorus of the extractives rises slightly during the first years. Lime decreases considerably in amount as the brain develops and grows, this being most pronounced during the last of the fetal period and the first six months of the first year. This depends on the increase in the development of the medullary substance. Two of the brains were from infants suffering from tetany and dying of glottic spasm; these showed a slight increase in water, a normal nitrogen content, a slight increase in phosphorus, particularly of phosphorus containing extractives, and normal amounts of calcium. While the theory that tetany in infants depends on anomalies of calcium metabolism cannot be absolutely contravened, it has as yet not received satisfactory demonstration.

French and Italian Journals.

Pathogenesis and Treatment of Arteriosclerosis.—Ch. Colombo believes that arteriosclerosis is not a result of hyperemia of the vessels, but rather of a toxemia which causes eventually degeneration of the vessel walls. The dilatation of the vessels which at first occurs is only a symptom of the poisoning. As long as the kidneys and other excretory organs are in good condition this poison is eliminated and does no harm, but when these structures fail poisoning occurs, which causes a degeneration of the vessel walls. Treatment should be in the direction of favoring elimination by the skin, intestines, and lungs. The diet should consist of milk and vegetables, and meat and liquors should be denied to the patient. Hot baths are of value to relieve cerebral symptoms.—*Lyons Médical*, September 15, 1907.

Passive Hyperemia in the Treatment of Sluggish Ulcers.—Walfredo Chiodi finds that passive hyperemia accomplished by the use of cupping glasses is of the greatest value in the treatment of sluggish ulcers and fistulæ. It produces engorgement of the granulations and a fresh supply of blood to the surface of the ulceration, which results in speedy healing. The granulations become capable of reaction against the bacteria and an energetic effort to remove them goes on. The circulation is stimulated. Curetting of the ulcer and fistulæ is avoided. The author applies the cups for three or four successive days for a half hour at a time. He records five cases treated by this method with success.—*Giornale Internazionale delle Scienze Mediche*, August 31, 1907.

A Frequent Lesion of the Liver in Cases of Eclampsia.—Michel de Kervily describes the lesion which he has observed most frequently in examination of the liver after death from eclampsia as a fatty degeneration of the stellate cells, the hepatic cells themselves not being involved. He made examination of seventeen cases of death during pregnancy or the puerperal state. Of these autopsies six were on cases of death from eclampsia. The special lesions described were not found in those who died from other causes. He concludes that this is a frequent and characteristic lesion of the liver in eclampsia. It may constitute the only recognizable lesion of the liver.—*Bulletin de la Société d'Obstetrique de Paris*, July, 1907.

Acute Dilatation of the Stomach.—R. Morichau-Beauchant says that acute dilatation of the stomach is not rare. It may be primary, but in general is secondary to other digestive troubles. The symptoms are abundant and persistent vomiting, of a brown color and fetid odor. The stomach is found to be so dilated as to occupy the greater part of the abdomen. Temperature is normal, and the abdomen soft and painless. Treatment consists of evacuation of the stomach contents. Some relief may be obtained by the ventral posture in bed. The pathology of the diseases shows an acute paralysis of the stomach.—*Gazette des Hôpitaux*, August 22, 1907.

Book Reviews.

Surgical Anatomy of the Temporal Bone. By Arthur H. Cheatle, F.R.C.P., Aural Surgeon to King's College Hospital, etc. London: J. and A. Churchill, 1907.

This volume is made up of the Hunterian Lectures delivered in 1906 at the Royal College of Surgeons, and accompanied by the exhibition of some five hundred operations. The titles and sub-titles of the various chapters are: The Temporal Bone at Birth, Surgical Anatomy of the Labyrinth, Superficial Changes in the Bone During Growth, Relations of Lateral Sinus to the Surface, Consistence of the Outer Antral Wall and Mastoid Process, Variations in the Antrum and Middle Ear, Surgical Importance of the Antrum, etc., etc. One hundred and twelve figures illustrate the text. The type is large and clear, and the make-up of the book unusually attractive. Cheatle devotes special attention to operations on the labyrinth. He finds a possible explanation of the Menière symptom-complex in increased tension from increase in the peri- or endolymph or from some obstruction in their circulation. These Hunterian Lectures were warmly welcomed at the time of their delivery and have already passed into the classic literature of otology.

Heart and Blood Pressure. A Practical Consideration of Theory and Treatment. By Louis Faugères Bishop, A.M., M.D., Clinical Professor of Heart and Circulatory Diseases, Fordham University, School of Medicine, New York City; Physician to the Lincoln Hospital; Late Chairman of the Section on Medicine of the New York Academy of Medicine; Member of the New York Pathological Society, the Neurological Society, Alumni Association of St. Luke's Hospital, etc. Second Edition. New York: E B. Treat & Company, 1907.

This most useful little book calls attention to a steadily increasing class of diseases due to modern life and intense nervous concentration. Some of the notes with regard to the therapy of high pressure diseases of the circulation, while not especially new, confirm more exactly the observation of other trained observers. To the busy practitioner who is called upon at times to diagnose a case, baffling because of lack of definite symptoms, we feel this treatise will undoubtedly prove of value.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia, assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital, September 1, 1907. Philadelphia and New York: Lea Brothers & Company, 1907.

The present number of *Progressive Medicine* contains contributions by W. Ewart on diseases of the thorax and its viscera, including the heart, lungs, and blood-vessels; by W. S. Gottheil on dermatology and syphilis; by E. P. Davis on obstetrics, and by W. G. Spiller on diseases of the nervous system. The general plan and the high order of merit of this publication are now so well known that any detailed mention of its contents is unnecessary. The present installment contains much that is new; but of even greater value are the critical comments of the editors of the various sections.

A Manual of Clinical Diagnosis, by Means of Microscopic and Chemical Methods. For Students, Hospital Physicians, and Practitioners. By Charles E. Simon, B.A., M.D., Formerly of the President's Staff of the Johns Hopkins Hospital; Professor of Clinical Pathology at the Baltimore Medical College; Clinical Microscopist to the Union Protestant Infirmary. Sixth Edition, Thoroughly Revised. Illustrated with 177 Engravings and 24 Plates in Colors. Philadelphia and New York: Lea Brothers & Company, 1907.

Professor Simon's work on clinical diagnosis is so well known that it is hardly necessary to do more than call attention to the appearance of this new edition, the sixth within ten years. All the merits of its predecessors have been preserved, while the revision has been exceedingly thorough, and much new matter, notably an entire chapter on opsonins and opsonic technique, has been added. Changes and additions are also conspicuous in the chapters on the blood. Few criticisms occur to the reviewer; an occasional typographical error is still to be found, the ammonia method given as Folin's on page 417 does not represent that ingenious but mutatory analyst's latest technique, and the section describing the staining of spirochetes is hardly full enough to be of service to the beginner, but these are insignificant blemishes in an exceedingly valuable and trustworthy guide that continues to occupy a leading place in the literature of the subject.

The Physiology of Alimentation. By Dr. Martin H. Fischer, Professor of Pathology in the Oakland College of Medicine. First Edition, First Thousand. New York: John Wiley & Sons, 1907.

The author states that this volume is the first of a series of monographs which are to deal with the various phases of physiology. There is abundant room and need for such a series, and we recognize in the present work a very valuable addition to our text-books on the subject. The physiology of the digestive tract is here dealt with in an authoritative and also in an attractive style. The views expressed are up-to-date without being too speculative or theoretical, and the book will be welcomed by both students and practitioners.

Obstetrics. A Text-book for the Use of Students and Practitioners. By J. Whitridge Williams, Professor of Obstetrics, Johns Hopkins University; Obstetrician-in-Chief to the Johns Hopkins Hospital; Gynecologist to the Union Protestant Infirmary, Baltimore, Md. Second Enlarged and Revised Edition. With Sixteen Plates and Six Hundred and Sixty-six Illustrations in the Text. New York and London: D. Appleton & Company, 1908.

On its first appearance only a few years ago this was speedily recognized as one of the most scholarly, and what for lack of a better word we are accustomed to call scientific, works on obstetrics in the English language. It is characterized by unusual breadth of outlook in correlating the literature of the subject, and while founded throughout on practical experience of the most thorough and extensive sort represents the highest type of theoretical reasoning as applied to midwifery in all its aspects. Pathological histology receives a large share of attention both in the text and the figures, and the chapter on development, which has been rewritten for the present edition, is a model both in exposition and illustration. The author's well-known views on the subject of the toxemias of pregnancy cause one to turn with interest to the chapter on this subject, which also has been completely rewritten. Contrary to several recent writers, Williams is inclined to draw sharp distinctions between the members of the triad, pernicious vomiting, yellow atrophy of the liver, and eclampsia, and, in his discussion of the metabolic disturbances accompanying these conditions he supports this thesis with very appealing logic. The section on the nitrogen partition in the disorders of pregnancy is also one to be read with the greatest profit by every practitioner. Sections have been added on the following subjects: The metabolism of normal pregnancy, vaginal cesarean section, contractions of the pelvic outlet, and pubiotomy. The latter operation has been performed eight times in the author's clinic and he says of it that "we may look forward to pubiotomy practically displacing cesarean section in the so-called 'border-line' cases," and also expresses the opinion that possibly it may still further narrow the field for the induction of premature labor, resort to high forceps, version, or craniotomy in moderate degrees of contracted pelvis when the mother is in good condition. In every way the book is a satisfactory one and may earnestly be commended to the attention of students and practitioners.

Practical Diagnosis. The Use of Symptoms and Physical Signs in the Diagnosis of Disease. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; One Time Clinical Professor of Diseases of Children in the University of Pennsylvania; Laureate of the Medical Society of London, of the Royal Academy of Medicine in Belgium; Author of a Text-book of Practical Therapeutics and a Text-book of the Practice of Medicine. Sixth Edition, Revised and Enlarged. Illustrated with 203 Engravings and 16 Plates. Philadelphia and New York: Lea Brothers & Co., 1907.

This book treats of the diagnosis of disease by means of the symptoms presented by the patient, and takes up laboratory methods only in those cases in which they are essential to arriving at correct results. The author emphasizes the necessity for cultivating the senses of touch, hearing, and sight; for, after all, these are the means by which we generally arrive at a correct diagnosis. As a rule the book is written for the general practitioner, and nothing is described that cannot be undertaken by him. The descriptions are generally adequate; as an exception may be mentioned the too meager account of the method of staining the gonococci and the diagnosis of gonorrhea. That the book has been found useful in the past is evidenced by the appearance of a sixth edition; and this is, perhaps, the very best recommendation that it can have

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 26, 1907.

DR. HOWARD C. TAYLOR IN THE CHAIR.

Ectopic Pregnancy Illustrating Almost Fatal Hemorrhage through the Ostium Abdominale without Perforation.—Dr. PHILANDER A. HARRIS of Paterson, N. J., related the history of a patient who had last menstruated on February 12, 1907. From March 17 to April 2 a small amount of blood appeared almost daily. On April 21 she felt somewhat ill and had pain in the hypogastric region, the pain being more severe than during menstruation, when she usually had very severe pains. On April 23 the pain become more severe in the hypogastrium and was accompanied by pain in the right shoulder, from which point the pain ran all the way down to the iliac region. This was the first pain that was referred to one side of the pelvis. On April 25 she became very ill; she vomited and experienced pain in the epigastric region. No pulsation was perceptible at either wrist. There was extreme pallor and thirst, but she did not exhibit the extreme restlessness often seen at this stage of the disease. She was removed to the hospital. Three pints of normal salt solution were infused into the veins of the arm and pulsation was perceptible within five minutes. The abdomen was opened and from one to two quarts of dark fluid blood was removed. Large clots were taken from the cul-de-sac of Douglas and the pelvis and a distended right tube measuring two inches in diameter and apparently still enveloping the fetal products was tied off and removed. The patient was sent to her room with a pulse of 130 and respirations of 40. When the abdomen was first opened blood was seen escaping from the ostium abdominale. The particular interest in this case attached to the fact that so large a quantity, two to three quarts, enough probably to have produced death had the patient not been saved by operation, had entirely escaped from the ostium abdominale and without discoverable rupture of the tubal wall or effort at tubal abortion. This pregnancy, as was evident from the specimen presented, had probably progressed for ten or eleven weeks. Although he had operated upon a large number of cases of tubal pregnancy, this was the only instance in his experience in which the patient had closely approached death from simple bleeding at the ostium abdominale except in cases of tubal abortion. The specimen showed the last inch of the fimbriated extremity of the tube, which showed no tendency to dilate or allow the fetal products to escape. The tube wall enveloping the fetus was perfectly intact, presenting no evidence of perforation at any point.

Advanced Broad-Ligament Pregnancy.—Dr. RALPH WALDO LOBENSTINE reported this case, of which the complete report appeared in the Lying-in Hospital *Bulletin*. He said that rupture of the ectopic gestation sac into the space between the layers of the broad ligament was unusual, and but few cases had been reported up to the present time. Cragin, who had reported several advanced cases of extrauterine pregnancy, had but one true broad ligament pregnancy at or near term. In that case the child was extracted alive. According to Williams, this condition occurred but once in fifty specimens of extrauterine pregnancy. It only occurred four times out of 276 cases collected from the articles of Mandl, Schmidt, Küstner and Fehling. De Snoo in Kouwer's clinic at Utrecht reported but two out of 51 cases of ectopic gestation. One of these was an advanced case with the child living. Whiteford reported a case with the child alive at the fifth month. In the typical case the peritoneal leaves were stripped back in such a manner as to give a sessile tumor. This stripping back of the peritoneal leaves might be very extensive as pregnancy advanced. In the less typical cases the growth of the ovum caused a more or less pedunculated tumor. In either case there might or might not be a typical amniotic sac present. The placenta might occupy any portion of the wall of the gestation sac. The extraperitoneal gestation sac might rupture into the peritoneal cavity at any time, thus becoming a case of "secondary abdominal pregnancy." As was pointed out by H. Rödiger and others, cases of abdominal pregnancy in which the posterior sheath of the broad ligament formed one wall of the gestation sac and peritoneal adhesions the rest of the sac wall were at times easily confused with cases of true broad ligament pregnancy. In the last 30 cases of ectopic gestation at the Lying-in Hospital this condition of broad ligament pregnancy was found three times, while the present case was the only one of advanced broad ligament pregnancy. The patient reported was aged 32, primipara, who entered the hospital April 16, 1907. She had been treated as a case of intrauterine pregnancy. There had been amenorrhea for eight and one-half months. The patient had had more than the usual amount of abdominal pain during the later months, and there had existed an irregularity of the expansion of the two sides of the abdomen. The fetal heart was said to have been heard to within two weeks of admission to the hospital. The woman had lost flesh steadily and during this two weeks her physician became aware that she was going down hill rapidly. There was vomiting, diarrhea, and rapid loss of flesh. On admission she was practically moribund. Stimulation and an intravenous infusion were given. A distinct fluid wave could be made out over the lower part of the abdomen. There was a flat percussion note over this same area. There was a brownish discharge from the uterus; the urine showed a trace of albumin, no acetone, no excess of indican, and no casts. Red cells were 1,600,000, hemoglobin 27 per cent. On the following day they decided to operate and made a median incision five inches long just above the pubis. After opening the peritoneum, separating the delicate adhesions, and walling off with abdominal pads, a large trocar was plunged into the cystic mass and ten quarts of bloody fluid removed. The opening in the wall was then enlarged and a child was extracted. The posterior layer of the left broad ligament had been stripped backwards and upwards, giving an immense cavity, the site of a true broad ligament pregnancy. Both leaves of the broad ligament were greatly thickened. The bleeding was not great, as the patient had bled herself out before admission to the hospital into the broad ligament. The child was dead. The placenta was found to lie in the bottom of the cavity, posterior to the uterus, but partially attached. It was rapidly removed and the cavity packed with plain sterile gauze. The patient was too sick to survive the operation more than a few hours. The packing was removed after death and the fact verified that there had been no more bleeding after operation and that the layers of the broad ligament formed the boundaries of the gestation sac. There was moderate peritonitis. The child weighed 2,100 grams and had been dead for about one week. The case was interesting from the large amount of blood in the sac, the hemorrhage being due to premature separation of the placenta. This accident caused the death of the fetus.

DR. BROOKS H. WELLS said that Dr. Harris' specimen was apparently unruptured, but he asked if it were not possible that one might have such a hemorrhage from an ectopic tube of that size. The parts were badly eroded and the blood could ooze through the peritoneal surfaces. When a certain period had been reached, usually when the tube was smaller than the one presented, it might sweat blood without there being any visible rupture. If sections could be made of Dr. Harris' specimen he had but

little doubt that they would find numerous places in the outer wall penetrated by capillaries, passing through and disappearing.

Dr. H. N. Vineberg corroborated what had been said about hemorrhage ocurring from the walls of a pregnant tube without leaving perceptible openings. The tendency at present was to wait until the patient rallied before operating. In three or four weeks the patients gained strength and it had been shown that they did not die during this waiting period. If one were not experienced or did not have the equipment, it was better to wait, as it required considerable experience to operate successfully. He had had over 80 cases and among them were 16 with profuse internal bleeding, the patients being pulseless. They recovered after the abdomen was opened and saline solution injected. He considered the second case very interesting and wished to emphasize the fact that they found a uterus the size of a three months pregnant uterus. Where one was suspicious of a full-term pregnancy outside the uterus this organ would be the size of a three months pregnant uterus and yet be empty. He had had one such case where the woman recovered.

Dr. J. Riddle Goffe corroborated the statement in regard to hemorrhage where the source could be found only by very careful examination. The walls of the tube eroded until it reached through to the peritoneal covering. He believed the only treatment in these cases was immediate operation. By waiting until reaction set in it had been found that hemorrhage had ceased. There was no doubt but that thousands of cases of ectopic gestation recovered spontaneously. Many believed that it was better to wait until reaction had set in and they could operate with greater safety, and he thought that in cases like that of Dr. Harris it was better to wait until after shock had disappeared.

Dr. James N. West said this subject was an important one. The tendency of the men who had discussed the paper seemed to indicate that these cases did not bleed to death, but recovered naturally after being placed under proper conditions. He thought this was a grave mistake, as many of these cases did bleed to death. The failure of a man who was an expert to move rapidly was a great error. In his opinion, the first thing to do with a patient who gave evidence of exsanguination and shock from a ruptured ectopic was to start intravenous infusion and administer digitalis and whiskey and normal saline per rectum. If the patient responded to these measures the operation could then be performed. He related the case of a woman who gave evidences of a ruptured ectopic at 9 P.M. At 1 A.M. he found the woman presenting the picture of one dying. He immediately opened the abdomen and found an interstitial pregnancy, with a large fetus and an abdomen distended with blood and the wound still bleeding. That woman was going to bleed to death, and she did before he could operate. In another case of the same nature in which he proceeded along similar lines he operated and the patient made a good recovery. There was certainly a number of cases that would die if not interfered with, but perhaps they were right in that the operation should not be undertaken by one who was not an expert.

Dr. William S. Stone said that every now and then patients would die if not operated upon. He cited the case of a woman whom he had curetted and then packed the uterus. At the operation he had noted a mass behind the uterus, but neither he nor Dr. Taylor thought it was an extrauterine pregnancy. The following evening the gauze was removed and the patient went to sleep. At 5 A.M. the nurse thought the patient was breathing differently from what she should and sent for him. He found her dead. The abdomen was filled with blood from a secondary rupture from an ectopic gestation which had ruptured before she had been operated upon and again that night.

Dr. Brooks H. Wells said he had seen a patient of Dr. Mundé die from internal hemorrhage, and autopsy revealed ectopic pregnancy. A year afterward he had exactly the same experience.

Dr. Philander A. Harris of Paterson said that he spoke of tubal pregnancies where the tube still enveloped the fetal products. Of course there was a rupture inside the tube. He thought two or three quarts of blood came from the rupture. The patient was taken to a nearby hospital in an ambulance and not subjected to such exertion as was intimated. He had had a large number of tubal pregnancies which showed blood being forced out when the specimen was in a solution of formalin, the formalin causing the tube to contract and blood oozed out, making it look like a tree. As to whether they should operate upon those cases which were in a tragic state he had tried both ways. During the past ten or eleven years, with a patient with no pulse and on the operating table intravenous infusion was given when the ether was commenced. He cautioned against giving too much saline solution because it would go out through the veins.

Uterovesical Fistulæ.—Dr. W. H. W. Knipe reported the case of a primipara, 21 years of age, having a simple flat pelvis, with an external conjugate of 18 cm. and a true conjugate of 9.50 to 10 cm., who after a prolonged labor and delivery by forceps began a few hours after delivery to void urine through the vagina. Upon digital examination the finger could be passed through the anterior uterine wall into the bladder, through which fistula the urine flowed continuously. The site of the tear was at the internal os of the uterus, extending toward the fundus for a distance of over two inches. The tear in the bladder corresponded in size and position to that in the uterus. Immediate operation was decided upon. Interrupted sutures united the torn edges of the bladder wound, avoiding the mucous membrane of the viscus; one continuous suture was used for the uterine wound, with the closure of the original incision in front of the cervix, leaving a small gauze strip drain to the bladder wound. Continuous drainage of the bladder was obtained by retaining a catheter for three days. The patient's bladder function had remained normal since the operation. In regard to the cause of the vesicouterine fistula, he said one was apt to attribute it to the forceps, but he knew that the physician who had applied the forceps was an expert, and it might have been caused by pressure of the fetal head against the symphysis, or it might have been due to pressure too long continued. The literature on this subject was rather scant. Lengebauer published a résumé of the cases reported up to 1889, and they were 165 in number. In 1901 Sarrabezolles published an account of 36 additional cases. His remarks were confined only to cases occurring as the result of labor. More than two-thirds of the reported cases occurred in multiparas, a contracted pelvis and prolonged labor being the usual accompaniments. The unskilful use of forceps was not nearly so frequently the cause of these injuries as was generally supposed. Version with retention of the after-coming head had been the cause in some cases. Most of these vesicouterine fistulæ were small in size, ranging from the diameter of a catheter to that of a finger, and fistulæ the size of the one reported were very rare. The lower half of the cervix was the favorite site of these fistulæ, either in front or laterally, though there were occasional cases reported where the fistula had been in the posterior lip of the cervix in combination with the general variety. In only one case out of the 165 was the fistula above the internal os. In unusual cases the anterior wall of the bladder, as well as the posterior, might slough away. The peritoneum was sometimes involved. While these fistulæ were of rare occurrence, it was probable that the accident occurred oftener than was reported because of the case with which the urinary discharge from the vagina could be overlooked and because of the great tendency of

these fistulæ to heal spontaneously, especially the smaller ones. Since a better knowledge of obstetric conditions had prevailed generally, and major operative work had taken the place of craniotomy, and since the indications for forceps interference were better understood, vesicouterine fistulæ had become less frequent than formerly. The diagnosis of this condition was generally easy, the patient complaining of passing urine by way of the vagina, though in some cases the urine might pass both ways. The urinary discharge might be continuous or intermittent, depending upon posture. The onset might be immediately after labor or several days later. In some cases the symptoms did not appear until nearly a month after labor. The introduction of the finger within the cervix revealed the opening through uterus and bladder, although if the fistula was small it might pass unnoticed. The passage of a sound in bladder and uterus would often make the diagnosis and the injection of colored fluids into bladder, the same being passed through the vagina, would confirm the diagnosis. The majority of small vesicouterine fistulæ would heal spontaneously; the larger ones required operation. Small fistulæ should be treated by simple cleanliness, vaginal douches, and continuous drainage of the bladder by a retained catheter. After complete involution of the uterus some local treatment was necessary if the fistula persisted. Caustics, such as nitrate of silver stick, applied to the fistula would often cause healing by granulation. If the fistula lay high up in the cervix a recourse had to be had to suture. In most cases it was better to have the fistula cured at one sitting by suture rather than to submit the patient to repeated treatments by caustics. Large fistulæ always required operation. In 1886 Follet devised the operation used in the case above reported. That was incision transversely in front of the cervix, separation of bladder and uterus by means of gauze and sponge, denudation of the edges of the wound in both bladder and uterus, separate suture of the bladder and uterus, and closure of the original incision in vaginal fornix. Ten-day chromic catgut suture was probably the best suture for this operation. The best results were obtained by operating before inflammatory complications had involved the adjoining tissues.

Dr. H. N. Vineberg said that an interesting point in the success of the operation was the mode of causation. He related the case of a patient whom he was called in to see three days after she had been delivered by forceps. From the history he feared there was a tear in the broad ligament and peritoneum. The patient was examined under an anesthetic, and in passing his fingers to the side of the uterus and cervix he entered a cavity containing foul-smelling fluid which proved to be decomposed urine. In the use of forceps the broad ligament and ureter had been slightly torn and there was a leakage of urine. The patient died from the peritonitis. This showed that injury could be done by the direct application of the forceps.

Eleven Cases of Cesarean Section.—Dr. John O. Polak reported these cases. Seven of these operations were done for contracted pelves, three of which might be classed as relative contractures. Two were made necessary by dystocia resulting from the ventrofixation of the uterus, and two for dystocia resulting from incarceration of a pelvic tumor in the pelvis in advance of the head. In all the cases the incision was made to the right of the median line, with the umbilicus as its central point. This brought the uterine incision in the upper thickened portion of the uterus. A longitudinal incision of the uterus was made in all the cases except in the two instances of ventrofixation when the uterine wound was made in the posterior face of the organ. In all instances the uterus was eventrated by an assistant as the child was withdrawn. This permitted the work to be done through a short abdominal incision. A tourniquet for the control of hemorrhage was only necessary in one case. In the last ten of these cases digital compression of the broad ligaments was made by an assistant. The two sides of the uterine incision were held parallel in suturing and everted by an assistant and long straight Keith needles armed with No. 2 two-day chromic catgut were passed at half-inch intervals at once through both sides, skipping the mucosa. These were tied from above downward and buried by a fold of peritoneum brought over with a continuous catgut suture. A gauze drain was twice used. In these instances it was necessary to tampon the uterus for hemorrhage before the sutures were tied. An end of the gauze drain was carried through the cervix to the vagina and withdrawn after twelve hours. The pelvis was always mopped dry and the omentum placed over the intestines and behind the uterus before the abdomen was closed. Chloroform-oxygen was given with an open Esmarch mask. The oxygen tube was run into it. The narcosis was begun as the final scrubbing of the abdomen was begun. This he thought diminished the degree of fatal asphyxia. Ergot was given just as the anesthetic was started and the dose was repeated when the suture of the uterus was begun. The smoothness of the convalescence in these cases was of special note.

Classical Cesarean Section.—Dr. W. Wyllis Bandler reported this case. The patient was 26 years old and in her first pregnancy. Eighty hours before he saw her the membranes had ruptured, and she had been in labor seventy-two hours, the pains at first being strong, but diminishing in intensity and then ceasing. Four attempts at extraction were made with forceps and, four hours after, he saw her. She was then in good condition, with pulse and temperature normal. The uterus, however, was firmly contracted and no fetal heart sounds could be heard. The cervix was dilated and the head at the brim, held by the contracted uterus but not molded. The vagina was swollen and edematous, as well as the perineum and vulva. Owing to the diagnosis of justominor pelvis, and the disproportion between the pelvis and fetus, the choice lay between cesarean section and craniotomy. The fetus was dead, and craniotomy should have been indicated, but owing to the condition of the vagina and vulva, the size of the pelvis, the absence of temperature, and the splendid condition of the woman, he advised cesarean section, which he performed. Recovery followed with no unusual manifestations.

Vaginal Cesarean Section.—Dr. W. Wyllis Bandler reported this case. The patient was 27 years old, married six years, two children with normal labors. She had had three abortions. During the first six and a half months of this pregnancy she was constantly nauseated, dizzy, and vomited. During the next four weeks these symptoms became more marked. Sixteen days before the operation there was a slight general jaundice. She vomited practically day and night and lost much in weight. Her temperature was 101.5° and pulse from 110 to 130. The urine contained albumin and casts. Dr. Bandler made the diagnosis of pyelitis and pernicious vomiting of pregnancy. Because of the jaundice, immediate removal of the fetus was advised and a vaginal cesarean section was done. The patient made an uneventful recovery. In this case the continued vomiting and the jaundice made hurry the essential factor.

Dr. J. Riddle Goffe reported a case of vaginal cesarean section in a patient who had advanced to the sixth month and with a dead fetus. The cervix was contracted and about one and a half inches in length, and without any dilatation.

The Clinical Conditions and Post-Mortem Findings in an Irregular Case.—Dr. Margaret Cleaves reported this case. (See page 1010.)

Dr. Healy discussed the case.

Delayed Labor.—Dr. Walter B. Jennings said that while the length of normal labor varied greatly it averaged

eight hours in multiparæ and in primiparæ it was usually double that time or longer. By delayed labor he meant one in which the frequency, strength, duration, and expulsive character of the uterine pains had been so changed as to prolong the second stage of labor so that either the life of the mother or the child was endangered. Delayed labor might be caused by a rigid os due to old inflammation, malignant disease or cicatrix, but in the sense in which he took the expression "delayed labor" the many forms of pelvic deformity were excluded. Multiple pregnancy which caused a loss of tonicity, uterine tumors, excess of liquor amnii were some of the local causes, as were also an overdistended bladder or rectum. Occasionally a soft sagging uterus, together with a pendulous abdomen, would interfere with the action of the uterus. Among the general causes were lowering of the general condition, rapid child bearing, anemia, wasting diseases, psychical and emotional disturbances, fatty changes and atrophy of the abdominal muscles, or separation of the recti. Uterine inertia sufficient to cause delayed labor was of comparative frequency. Acconci, who studied 2,000 cases, said it occurred in 6 per cent. There was no standard by which the character of labor pains could be measured, but clinically the efficacy of uterine contractions might be measured by their effect upon the progress of labor. Many cases of delayed labor were attributed to the undilated cervix, when, as a matter of fact, they were due to faulty uterine contractions. The majority of cases were due to faulty uterine contraction and not to resistance of the soft parts. Primiparæ over thirty-five were an exception to this statement. Delayed labor was of little importance if the membranes had not ruptured, but during the second stage the life of the child was endangered, and, if it was toward the termination of labor, there was danger of post-partum hemorrhage. Dr. Jennings, in a series of forty-five selected cases of primiparæ, twenty of which were instrumental, found that fourteen were in labor from twenty-four to forty-eight hours, and in one case labor was induced. Of the remaining cases, one was in labor eighteen hours, five fifteen hours, four thirteen hours, and eleven ten hours or less. Of the fourteen cases that were in labor twenty-four hours or longer, ten were instrumental. The value of manual dilatation of the cervix in cases of uterine inertia had been disputed. Pressure on the fundus of the uterus was of benefit in some cases. In the second stage, after full dilatation, and the head in the pelvis, forceps should be applied. He believed in the early application of forceps in the second stage of labor. Every woman had the right to demand every alleviation from suffering that medical aid could provide, such as anesthesia, asepsis, and rapid delivery. It was his rule to use forceps when no progress had been made for two hours. The idea that one should wait until there were signs of danger to mother or child was decidedly erroneous.

Dr. James N. West called attention to the fact that Emmett many years ago brought this matter before the profession. When the head was neither rotating nor descending, with intermittent pains, forceps should be applied. When the head became blocked in the pelvis we should not wait because of danger to the soft tissues.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held October 15, 1907.

Dr. Glentworth R. Butler in the Chair.

The Dietetic Treatment of Nephritis.—Dr. Leon Louria of Brooklyn read this paper. He said that inasmuch as there were no drugs that could directly benefit an inflamed kidney it was necessary to direct the treatment mainly through dietetic and hygienic measures. In spite of the practice sanctioned by tradition of restricting victims of acute and chronic nephritis for long periods to an exclusive milk diet, there were no clinical experiments, and no laboratory proofs, that milk was the ideal food for nephritics and that other foodstuffs were to be restricted in or excluded from the diet of these patients. Only within recent years, under the influence of Von Noorden's teachings, had the diet lists been formulated with more liberality. An abundant clinical material and numerous investigations had enabled this observer to set aside old traditions and to throw a new light upon the rational treatment of nephritis. The fundamental principle of the dieting was to spare the diseased kidney tissues by preventing the excretion of irritating metabolic products. The amount of albumin excreted was, excepting possibly in the acute forms of nephritis, no criterion upon which to regulate the diet. Some metabolites were excreted by the kidneys with ease and others with difficulty, the latter at the same time acting as irritants to the diseased tissues, and if retained in large quantities, causing a general toxemia. The former class included uric acid, xanthine bases, aromatic substances, ammonia, amido acids, chlorides, and water, while the latter class comprised urea creatinin, pigments, hippuric acid, phosphates, inorganic sulphates, and water. Creatinin was easily avoided by excluding bouillon, beef-broths, meat extracts, and the like. The urinary pigments were reduced by the avoidance of the ingestion of hemoglobin. The amount of phosphoric acid was markedly increased by an exclusive milk diet. In this respect the exclusive milk diet was not as harmless as had been generally believed. The amount of hippuric acid was kept down by the omission of such foods as contained large amounts of benzoic acid, namely, green vegetables, kernel-bearing fruits, and cranberries. There was no warrant for the exclusion of pears, apples, raspberries, and grapes, which contained only traces of this acid, and which on account of the large content in sugar were of distinct nutritive value. Except as an occasional cardiac stimulant and digestive in acute cases, alcohol was to be entirely withdrawn from the diet. The exclusion of acetic and citric acids was not warranted. On account of the fact that they favor the production of all oxuric bases the following were forbidden: Thymus gland, liver, spleen, kidney, and concentrated meat broths. From the viewpoint of protective therapy, it was desirable to limit as far as possible the ingestion of proteids, whose end product, urea, passed the inflamed kidney with greatest difficulty. A healthy individual could, for a short time at least, and without prejudice to his body, tolerate a daily reduction of proteid to 60 grams, provided that the missing 50 grams were replaced by an amount of carbohydrates or fat yielding an equivalent number of calories. When the nephritic consumed from two to three liters of milk daily, as was often prescribed, he thus acquired from 110 to 120 grams of proteid, which yielded from 30 to 35 grams of urea which the diseased parenchyma of the kidney could not with ease discharge. This led to an undesired irritation of the kidney and to the injurious retention of urea in the blood. These facts furnished a convincing proof that milk, even in cases of acute kidney inflammation, when taken in large quantities, was by no means an ideal nutrient, but could rather become a dangerous one. Von Noorden's dietary for acute nephritis was three pints of milk, together with three-quarters of a pint of cream daily, which mixture contained 55 grams of proteid, 70 grams of milk sugar, and 170 grams of fat, which were equivalent to 2,100 calories, and contained only one-half as much proteid as three quarts of milk. In large and strong individuals it was necessary to amplify the dietary with gruel and puddings, sugar and fruit syrups. In acute nephritis there was considerable resistance to the passage of water, which gave rise to oliguria, hydremia, and edema. The ordering of large quantities of fluids was in evident conflict with the principles of protective therapy. The improvement of the patient was

more rapid when food was totally withheld for a day or two and the patient's thirst quenched only by small pieces of ice. In combating the edema and hydremia the most effective measure was artificial diaphoresis. Physiological chemists had failed to detect an increased cutaneous elimination of urea during diaphoresis, whose therapeutic value consisted merely in relieving the kidney from excreting all the water. Sweat cures, which were prescribed when diuresis had already set in, the powers of the kidneys had improved, and edema had diminished while albuminuria was still present, lacked a physiological basis and were unnecessarily annoying to the patient. Under these conditions it was more advisable to restrict the amount of liquid nourishment until a normal equilibrium had been established. In the chronic form of contracted kidney in which water was eliminated with ease, the prescription of greater quantities served to flush the tissues and to facilitate the elimination of various end products which were excreted by the kidney with difficulty. An excess of water, however, overtaxed the heart and occasioned stenocardiac attacks. It was not wise to wait until symptoms of heart dilatation appeared, and it was desirable to accustom the nephritic to restricted drinking while the heart was still strong. According to von Noorden, in these chronic cases three pints of fluid daily fully answered the requirements of the patient. If there was a retention of nitrogen, the patient was to be advised, for the time being, to drink more. For prophylaxis one day per week was to be set apart as a drinking day, or, instead, a flushing-out cure of several days' duration was to be instituted every two or three months. Alcoholic drinks were to be strictly forbidden. The fundamental principles of the dechloridization cure, first advocated by the French school, headed by Widal, were: First, in chronic nephritis there was a retention of chlorides which was frequently the only symptom of the disease. Second, as a result of this retention, water accumulated in the tissues in order to maintain the osmotic equilibrium between the latter and the blood. Third, it had been found that the reduction of the amount of salt in the diet was a potent means of combating edema. Fourth, it had been demonstrated that chloride retention aggravated in other respects the symptomatology of nephritis, particularly the arterial hypertension. The traditional good effects of the milk diet depended upon the poverty of this substance in salt. The régime formulated by Widal contained even less salt than milk. This régime included meat, bread baked without salt, potatoes, butter, rice, and pastries, provided that no salt was added in their preparation. Widal found that if the patient was allowed as much salt as was excreted in his urine, as indicated by the daily chart, then this quantity of salt produced no baneful results. The advantages of daily weighing all nephritic patients were that diminution of edema at once showed itself in decrease in weight, while an increase of weight was interpreted as the first symptom of beginning edema not yet visible. The speaker's experience with the salt-free diet had been limited to three cases under his care at the Jewish Hospital, and the results seemed to be in accord with those claimed by others, namely, the general improvement of the patient, the diminution of edema, and the loss of weight all seemed to be parallel to one another. No subject in dietetics had aroused such heated controversy as the question of meat in nephritis. It was von Noorden who first combated the orthodox belief that meat was harmful. Offer and Rosenquist had established the fact that the amount of extractives was not constant, and that they were at times present in greater amounts in white meat, poultry, or game than in beef. It was time to abandon the time-worn custom of prohibiting beef. This modern view was of eminent import to the nephritic who, suffering from a protracted disease and condemned for years to a monotonous diet of white meat, finally developed a complete abhorrence for all meats. The nephritic required a daily ration of 100 grams of albumin. Assuming that he took 750 c.c. of milk containing 26 grams of albumin, two eggs with 13 grains of albumin and 20 grams of proteids in other food, as bread, vegetables, etc., there still remained 50 grams of proteid that could be allowed in the form of meat, which amounted to about half or three-quarters of a pound of the latter. In conclusion, the speaker said that he had not attempted to indicate in more than brief outline the principles underlying the modern dietetics of nephritis, a subject pregnant not only with the utmost significance to the progress of clinical medicine, but also to the well-being and comfort of the innumerable victims of one of the most chronic and hopeless diseases of our modern civilization.

The Control of Social Disease.—Dr. NATHANIEL P. RATHBUN of Brooklyn read this paper. He said that venereal diseases had been known and recognized as far back as the history of medicine carried, but it was only within the last thirty or forty years that they had been studied in anything like a scientific manner by a few observers, and only within the last ten or fifteen years that gonorrheal urethritis in the male had received much attention from the general medical profession, and even at the present time there was an appalling apathy on the part of the profession in proportion to the importance of the subject and the far-reaching effect of the disease. It was within the memory of many when the average physician dismissed the gonorrhea patient, with a very cursory examination or no examination at all, and with no warning as to the serious consequences of his disease to himself and to others. There was no disease, not excepting even tuberculosis, which approached in importance gonorrheal urethritis, from an individual, social, or economic standpoint. It was probable that 80 per cent. of all men have or have had gonorrhea. It was, however, the combination of prevalence and malignancy that made it serious. It had been reported by a committee of the American Medical Association that 5 per cent. of all cases of chronic gonorrhea were absolutely incurable. This applied to cases undergoing the best possible treatment, but the percentage was probably larger among the very large majority receiving no or indifferent treatment. Even among the cured patients many were left permanently damaged, impotent, or sterile. Eighteen per cent. of all sterile marriages were due to gonorrhea in the male, and taking account of gonorrhea in the female, then 70 per cent. of all childless marriages in this country could be traced to the gonococcus of Neisser. It was estimated by Williams that 73 per cent. of all abortions were due to endometritis which was chiefly caused by gonorrhea when not caused by sepsis. It was conservatively estimated that two-thirds of all the abdominal operations performed upon women were necessitated by gonorrhea, usually acquired from the husband. Edgar said that 30 per cent. of all blindness in this country could be traced to gonorrhea. The speaker agreed with Janet in stating that gonorrhea was more important than syphilis in the proportion of 100 to 1, despite the opposite view taken by the laity and also by some of the profession. The question arose as to what could be done to mitigate these conditions and limit the spread of these diseases. Isolation and segregation of prostitutes was not capable of doing it, as seen in the failure of these measures in France and other countries. As Morrow had aptly said, "the male factor was the chief malefactor, and he was entirely neglected in this arraignment. Licensing and routine examination of prostitutes was absolutely useless, for even a careful and painstaking examination could not exclude venereal diseases, and the fees usually paid for this kind of work were not enough to command the best ability. Making gonorrhea and syphilis reportable diseases was capable of doing harm, because on account of the publicity men would not submit to

treatment. A physician's certificate as a preliminary to marriage was not practicable. Among the innumerable forces behind the great social evil, the predominating one was ignorance. The only remedy for this was education in its broadest sense. This fell naturally under three headings: education of the medical profession, education of the young American boy and girl, and man and woman, and education of the general public, particularly of those afflicted with some form of social disease. Under the first heading great progress had been made in recent years. It was not enough that every medical college had a special chair in this department. It was necessary that every medical student and medical man should be impressed with the responsibility of treating cases of this kind. It was necessary to explain to the patient the serious nature of his disease and its possible consequences, and the importance of a thorough and radical cure. As family advisors, it was the duty of physicians to tell fathers and mothers of growing sons and daughters some of the essential facts about these conditions, and to have the parents warn their adolescents against the temptations facing them and the evil consequences arising from a succumbing to these temptations. The speaker emphasized the importance of a compulsory course of hygiene in the first year of the high school course, in which sexual hygiene was to have a prominent place. In some of the German cities pamphlets of instruction along the lines of sexual hygiene were issued to all the employees of factories and other industrial institutions. A similar pamphlet might well be placed in the hands of all men in the Army and Navy, particularly the new recruits. Under the third heading, in the education of the great majority, the best work could be done. The average man with chronic gonorrhea disseminated his disease not through wilful viciousness, but because of ignorance. The speaker had been distributing to his patients at the Brooklyn Hospital a little pamphlet, couched in simple language, to impress and perhaps frighten the patient, with a few words of advice. That this had done some good was shown by the fact that patients who would ordinarily have discontinued treatment with the cessation of the discharge had continued under treatment until they were well. It was not thought that education would ever eradicate the plague.

The Value of Sphygmograms and Blood Pressure Estimations in Diagnosis.—Dr. Alfred Stengel of Philadelphia read this paper. He asked the indulgence of the audience for the introduction of elementary points in the physiology of the pulse. The mechanism of the latter included four elements: (1) The systolic expulsive power of the ventricles; (2) the resistance of the peripheral vessels; (3) the resiliency of the arterial walls, particularly that of the aorta; and (4) the degree of viscosity of the blood. Benjamin Rush described nineteen different kinds of pulse. Few clinicians could by means of the finger alone detect the different varieties. We all distinguished in our minds between high-tension and low-tension pulse. It would be a matter of considerable difference of opinion among various observers as to what they felt when they feel the pulse. The usual estimation of the tension of the pulse was that obtained by palpation, but in this the idea of the tension was that conveyed by the impact of the pulse at the apex of the pulse wave, and did not give any knowledge of the average tension of the pulse-wave in its entirety. Thus in aortic regurgitation the sphygmographic tracing shows an average low arterial tension, although the apex of the curve may reach the point of 100. Many years ago the English physician Mahomet had described the so-called sustained pressure of the pulse, and emphasized the importance of recognizing the arterial pressure between the pulses. In estimating the value of sphygmograms it was necessary to understand what led to high systolic pressure. This was due to two elements: (1) Ability of the left ventricle to contract, and (2) dilatability of the peripheral vessels. The speaker discussed the value of the instruments used for determining blood pressure. The educated finger of the physician could detect the sustained pressure of the pulse, but the speaker admitted that his finger had not reached in this respect the degree of accuracy that he could wish. There were considerable portions of the pulse wave which the finger was not capable of distinguishing. The first and simplest instrument for estimating blood pressure was that invented by von Bosch, but this only gave the highest pressure. This was likewise the case with the Riva Rocci apparatus. The Gaertner tonometer was accurate, but recorded only the highest pressure. In this country the instruments in use were the Erlanger, the Janeway, and the Staunton forms of apparatus. These were adapted easily for use in private practice. They gave both the systolic and the diastolic pressures; they indicated the expulsive power of the heart and the resistance in the peripheral vessels. By means of them could be easily detected the sustained pressure of arteriosclerosis and chronic nephritis. In any case of continued high pressure one had to suspect sclerotic vessels. The time element of the pulse is important. The value of the sphygmograph in the study of cardiac irregularity was emphasized by Engelman and Windelbaum in Germany and MacKenzie in England. Jacquet's sphygmochronograph showed the time relations between the beat of the heart and the excursions of the pulse. These instruments were of value in showing the various causes of irregularity of the heart. Irregular pulse occurred in myocarditis, in digitalis poisoning, and in neurasthenia. The time intervals were sometimes longer and sometimes shorter in a neurasthenic individual; they were an indication of a neuromuscular disorder. The study of the irregular pulse was much more significant in elderly people. Too frequently was irregular pulse attributed to the use of tea or coffee. The cause was rather to be found in a true myocarditis. The phenomenon of extrasystoles was due to some ventricular degeneration. The sphygmograph provided two valuable aids to clinical medicine. First, it provided a means of getting an accurate picture of what the pulse is performing. Second, it reflexly trained our fingers, by enabling us to compare the results of their palpation with the results obtained from the apparatus.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held October 14, 1907.

Dr. Leon Louria in the Chair.

A Case of Streptococcus Septicemia.—Dr. S. R. Blatteis of Brooklyn read this paper. It detailed the history of a case occurring in a female child six years of age, whose family history had been negative, who at the age of three years had had chicken-pox, and whooping cough one year later. A few months subsequently the child took suddenly ill, on the second day presented signs of a limited area of pulmonary congestion, and on the third day the urine was smoky and contained one-third by volume of albumin, with red and white blood cells and granular, blood, and pus casts. Blood examination showed a leucocytosis of 33,000, with a polynuclear count of 85 per cent. and lymphocytes 10 per cent. On the fourth day a pericardial friction murmur and a faint aortic murmur were audible. The pericardial sac rapidly filled up with fluid. There was present at the same time a severe enterocolitis with marked tympanites. At the end of the first week a purulent discharge yielding the *Streptococcus pyogenes* occurred from the right ear. During the first week the temperature had been moving from 99.5 to 104.6, at the beginning of the second week it was 99.5 and 101, and at the end of the second week it varied between 98.5 and 99.5. The lesions in the lung never developed to more than a congestion. The urine, which had

varied between 240 c.c. and 480 c.c., increased at the end of the second week to 915 c.c., the 24-hour amount of urea increased from 3.3 gms. to 10.5 gms., and remained below normal for about two months. At the end of the second week the leucocytosis diminished to 9,600, while the red blood cells were 4,620,000. After the absorption of the pericardial effusion a faint systolic murmur was detected at the apex, and the tympanites disappeared. During the third week of convalescence the patient developed measles, which proved to be a severe attack and was complicated with suppuration in the left ear. A year later she had an attack of mucous colitis, following which, after three months, she had a severe attack of tonsillar diphtheria. At the present time the patient was well-developed and in sound health, the only abnormal manifestation being a faint mitral systolic murmur at the apex.

A Case of Rhinoscleroma Treated with the X-Ray.—Dr. Milton J. Ballin of Manhattan read this paper. The patient was a female, of Russian birth, who had had the disease for sixteen years. Medication of all kinds had been tried with no improvement. It was a peculiar circumstance of this case that the larynx was not affected. The nose was of an extraordinarily large size. The *x*-rays had a surprising effect. The rays were allowed to play upon the parts for three to four minutes, three times a week. At the end of five months of treatment the nose was reduced to almost its normal size, the redness disappeared, the tissues became softer and more pliable, and the outline of the nostrils again returned.

Acute Anterior Poliomyelitis, Its Diagnosis and Treatment.—Dr. Henry Dwight Chapin of New York read this paper. It was necessary to distinguish between the endemic and the epidemic forms of the disease. The endemic form, so far as the speaker had observed, was never fatal, but it was never absolutely recovered from. On the other hand, the epidemic form was occasionally fatal, though very rarely, and then only in the early stages of the disease. In this form, also, there was a great variation in the extent of the paralysis; it was sometimes very extensive and sometimes very slight. Besides, in this form there was a certain proportion of complete recoveries. The lesion tended to be more varied and extensive than in the endemic form. Associated with an epidemic form of poliomyelitis there was sometimes a polioencephalitis, sometimes a peripheral neuritis, and occasionally a meningitis. The prevailing idea among recent writers was that the spinal paralysis of children was an infectious disease, and the occasional epidemics confirmed this view. Church and Peterson stated that its infectious nature was indicated by the abrupt onset, the usual febrile movement, the gastric disturbance, the occasional occurrence of convulsions, and, most of all, by epidemic and endemic outbreaks. In some of the outbreaks a considerable variation from the type had been noticed, and some cases presented the symptoms of Landry's paralysis, the infectious nature of which was known. Gower's recent volume, in discussing this subject, state that it was necessary to remember the vascular activity that all functions entailed, and the readiness with which the vasomotor system of children was disturbed. The occurrence of the disease in more than one member of the same family indicated a congenital disposition of the system to react in a similar manner to certain external agencies, while a special feature in the latter probably explained the occasional epidemic character of the disease and furnished grounds for ascribing to it an infective character. Doubtless there was more than one possible cause for poliomyelitis, sometimes of an infective nature, sometimes due to refrigeration, and again to a possible traumatism. An interesting epidemic occurred during the summer of 1899 at Poughkeepsie, N. Y., most of the cases being attacked between the middle of July and the middle of August. The peculiarity of this epidemic appeared to be the existence of severe pain in the parts affected by the paralysis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Board of Health of Missouri.

St. Louis, September 10, 11, and 12, 1907.

ANATOMY.

1. Give landmarks for location of the fissure of Sylvius; (*b*) fissure of Rolando.
2. Give origin, ending, branches, and relation of the brachial artery.
3. Give gross and minute anatomy of the kidney.
4. Describe the diaphragm. Give lines of insertion.
5. Describe the kneejoint.
6. Mention all muscles that flex the leg on the thigh.
7. Describe the os innominatum.
8. Name lobes of brain and their subdivisions.
9. Give all structures divided in amputation of the arm at the middle third.
10. Give gross and minute anatomy of the urinary bladder.

PHYSIOLOGY.

1. What effect would section of the spinal accessory nerve have on the heart's action?
2. Describe in detail the alimentary canal and give function of each section.
3. To what is acidity of the urine due and what kind of food tends to lessen it?
4. Explain theory of color vision.
5. Give organs and tissues in which white blood corpuscles are formed.
6. Describe the liver and give its function.
7. Describe secretion of sweat; upon what does quantity secreted depend?
8. Give the function of the pancreas and name the ferments secreted by it.
9. Give a brief description of the lymphatic circulation.
10. Give the function of the skin.

CHEMISTRY.

1. Give chemical composition of sweet milk.
2. Give two tests (chemical) for sugar in the urine.
3. What is the effect (chemical) of tannic acid with ferruginous preparations?
4. What are the chemical properties of ethyl alcohol?
5. What is the chemical composition of "lime" or "hard" water?

THERAPEUTICS.

Give doses and indications for use of:

1. Arsenic.
2. Ipecac.
3. Tartar emetic.
4. Caffeine.
5. Heroin.
6. Magnesia sulph.
7. Lobelia.
8. Copaiba.
9. Hydrastis.
10. Ergot.

PATHOLOGY.

1. Discuss exudation and transudation.
2. Describe the changes that take place in Peyer's patches in typhoid fever.
3. Discuss hyperplasia.
4. Discuss pseudomembranous formation.
5. What is degeneration? Name the principal forms.

PRACTICE.

1. What is Bell's palsy? Give symptoms and treatment.
2. Give etiology, symptoms, and treatment of cerebral apoplexy.
3. How would you differentiate this condition (cerebral apoplexy) from opium poisoning?
4. What is Romberg's sign; Stellwag's sign; and with what diseases are they associated?
5. Give etiology, symptoms, and treatment of Addison's disease.
6. Give etiology, symptoms, and treatment of leukemia.
7. What is a hemophilia? Give a brief discussion.
8. What is a papilloma?
9. Give symptoms and treatment of sunstroke.
10. Give etiology, symptoms, and treatment of cholera infantum.

OBSTETRICS.

1. Give manner of applying forceps and mechanism of the delivery in R. O. A. position.

2. Give history of fecundated ovum from time it leaves ovary to its normal delivery at full term.
3. Describe tubal pregnancy, giving causes, symptoms, diagnosis, and treatment.
4. Describe varicose veins of pregnancy. Give dangers of same. Give treatment.
5. Differentiate puerperal sepsis from malarial infection. Give symptoms and treatment of puerperal sepsis.
6. Describe Credé's method in delivery of the placenta. Give dangers to be avoided in using the same.
7. Describe asphyxia of the newborn, giving causes, symptoms, and treatment.
8. Describe in full the obstetrical preparation of the patient.
9. What is meant by a dry birth? Give management of rigid os uteri in labor.
10. How would you prevent laceration of the perineum in normal delivery? Describe manner in which the same should be repaired.

GYNECOLOGY.

1. Describe inversion of the uterus, giving symptoms, diagnosis, and treatment.
2. Describe laceration of the cervix, giving causes, symptoms, and technique of repair.
3. Describe vesicovaginal fistula, giving causes, symptoms, prognosis, and treatment.
4. Describe uterine polypus, giving symptoms, diagnosis, and treatment.
5. Differentiate between pyosalpinx and a salpingitis. Give technique of treatment of pyosalpinx.

BACTERIOLOGY.

1. Describe a practical bedside method for demonstrating the plasmodium malariæ.
2. Enumerate the characteristics of the bacillus of diphtheria.
3. Describe in detail a method for demonstrating the existence of tubercle bacilli in the sputum.
4. Describe the steps which you would take to demonstrate by the microscope the existence of gonococci in the vaginal secretion.
5. What is meant by phagocytosis?

JURISPRUDENCE.

1. Give process and length of time, by and in which, a body is converted into adipocere.
2. Define paralytic dementia.
3. Give the post-mortem appearance of vaginal tract of third month of pregnancy.
4. Define illusions, delusions, hallucinations, and lucid intervals.
5. What is infanticide, in both a physiological and a medicolegal sense?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF HEALTH OF MISSOURI.

St. Louis, September 10, 11, and 12, 1907.

ANATOMY.

1. To locate the *fissure of Sylvius*, draw a line from a point one and a quarter inches behind the external angular process of the frontal bone and the same distance above the zygoma, to a point three-quarters of an inch below the most prominent part of the parietal eminence. (a) The main fissure will correspond to the first three-fourths of an inch along this line; (b) the horizontal limb will correspond to the rest of this line; (c) the ascending limb will correspond to a line one inch long, going upward (parallel to the coronal suture) from the junction of (a) and (b).

(b) Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the *fissure of Rolando*.

6. The muscles that flex the leg on the thigh are: Sartorius, Gracilis, Semitendinosus, Semimembranosus, Biceps, Gastrocnemius, Plantaris, Popliteus.

9. The structures divided in amputation of the arm at the middle third are: Skin, fascia, Biceps, Triceps, and Brachialis anticus muscles; brachial, superior profunda, and inferior profunda arteries; brachial, basilic, and cephalic veins; median, ulnar, internal cutaneous, musculospiral, and musculo-cutaneous nerves, and humerus.

PHYSIOLOGY.

1. Section of the spinal accessory nerve would have a tendency to quicken the heart's action.

3. The acidity of the urine is due to acid sodium phosphate; vegetable diet tends to lessen the acidity of the urine.

4. There are two theories of color vision, as follows:

(a) *The Young-Helmholtz theory*, which assumes that there are three fundamental sensory elements in the retina which correspond to and are stimulated primarily by the primary colors—red, green, and violet; also that each color-perceiving element is slightly stimulated by others of the spectral rays. When red rays fall upon the retina they stimulate the red-perceiving elements strongly and the green and violet very feebly. The resulting sensation is that of red. So also is it with green and violet rays. When the retina is stimulated by both red and green rays the two corresponding color-perceiving elements are strongly stimulated. The resulting color perception, however, is a combination of the two sensations and corresponds to some region of the spectrum between the red and green, according to the relative intensity of the two stimuli. When all three color-perceiving elements are stimulated at the same time this theory assumes that white light will be perceived. In a similar manner all the various color sensations are arrived at.

(b) *Hering's theory*, which is based on the assumption that there are chemical substances in the retina, photogenic substances, which are stimulated by the colors of the spectrum. It assumes three photogenic substances which are called the red-green, the yellow-blue, and the white-black substances. By this theory, when the red-green substance is stimulated by red or green light, respectively, the former produces destructive or catabolic changes, the latter constructive or anabolic changes, in the substance. When red light falls upon the retina it produces catabolism in the red-green substance, which in turn develops a nerve impulse that arouses the sensation of red. When green light, on the other hand, stimulates the retina, it produces anabolism of the red-green substance and the sensation of green. The same rule holds with the other two substances. It will be noticed that this theory is based on the complemental colors. (From Kirkes' *Physiology*.)

5. White blood corpuscles are formed in the spleen, lymph glands, and lymphoid tissue; also from other white cells by direct cell-division in the blood stream; the eosinophiles may be derived from the bone marrow.

6. The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

8. The *functions of the pancreas* are: (a) The secretion of the pancreatic juice, which (1) changes proteids into protoses and peptones, and afterwards decomposes them into leucin and tyrosin; (2) converts starch into maltose; (3) emulsifies and saponifies fats; and (4) causes milk to curdle.

(b) The manufacture of an internal secretion.

The *ferments secreted by the pancreas* are: Trypsin, amylopsin, steapsin, and a milk-curdling ferment.

9. The lymphatic circulation is, strictly speaking, not a circulation at all; since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

10. The *functions of the skin* are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

CHEMISTRY.

1. The composition of cow's milk is:

Water	87 per cent.
Solids	13 per cent.
Proteids	4 per cent.
Fats	4 per cent.
Sugar	4 per cent.
Salts	0.7 per cent.

2. The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test*: Place in a test-tube a few c.c. of the

liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presences of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Boettger's test*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthans' *Essentials of Chemistry*.)

3. Black ink is produced when tannic acid is brought into contact with ferruginous preparations.

4. Ethyl alcohol yields on oxidation first an aldehyde, then acetic acid; if the oxidation be very energetic the alcohol burns and is converted into carbon dioxide and water. Alcohol is acted upon by chlorine and bromine, with the production of chloral and bromal. Iodine acts upon alcohol in the presence of an alkali, to produce iodoform. Acids act upon alcohol, with the production of ethers and esters.

5. *Lime* is calcium oxide, CaO.

Lime water is a solution of lime in water, CaH_2O_2.

Hard water is water containing an excess of calcareous salt; *temporary* hardness is due to the bicarbonates of calcium and magnesium; *permanent* hardness is due to the sulphates of these elements.

THERAPEUTICS.

The doses of:

1. Arsenic trioxide, gr. 1/30.
2. Ipecac: As an expectorant, gr. j; as an emetic, gr. xv.
3. Tartar emetic: As an expectorant, gr. 1/10; as an emetic, gr. 1/2.
4. Caffeine, gr. j.
5. Heroin, gr. 1/20 to gr. 1/5.
6. Magnesia sulph., ʒiv.
7. Lobelia, gr. vijss.
8. Copaiba, ɱxv.
9. Hydrastis, gr. xxx.
10. Ergot, gr. xxx.

PATHOLOGY.

2. In the first stage of typhoid fever Peyer's patches become swollen, hyperemic, and reddened; a few days later they appear as whitish or gray elevations, and the hyperemia has disappeared; the surface of the patch is smooth and its edge is sharply defined; after the first week necrosis may occur; the center of the patch becomes softer, more yellow, or sometimes even red from the absorption of blood pigment. The necrotic portion falls off, leaving an irregular ulcer with necrotic and undermined edges. These ulcers are elongated, with the long axis parallel with that of the intestine, and a smooth floor. The ulcers may heal or go on to perforation.

5. Degeneration is a local order of metabolism, in which the protoplasm of the cell is gradually changed into a new material. The principal forms are: Fatty, mucoid, colloid, cloudy, and amyloid.

PRACTICE.

1. Bell's palsy is paralysis of the facial nerve due to inflammation or other lesion of the facial nerve or its nucleus.

Symptoms: "When it is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the Orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." (From Kirkes' *Physiology*.)

Treatment: If possible, remove the cause; potassium iodide, electricity, blistering, massage, local injections of a solution of strychnine have all been recommended.

3. In *cerebral apoplexy*: There are generally paralysis of the head and upper limbs; and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

In *opium poisoning*: The pupils are contracted; there is no sign of paralysis; both respirations and pulse are slow and full.

4. *Romberg's sign* is the inability of a patient to stand with eyes closed and heels together without considerable swaying or even falling. It is found in locomotor ataxia.

Stellwag's sign is a complete, or almost complete, absence of winking as an involuntary act. It is found in exophthalmic goiter.

7. Hemophilia is a hereditary condition characterized by a tendency to bleed on the very slightest provocation. Males are more apt to be affected, but the predisposition is transmitted through the female line. The cause of the condition is unknown; the prognosis is bad.

8. A *papilloma* is a benign tumor composed of connective tissue and covered by one or more layers of epithelial cells.

OBSTETRICS.

5. The following table (from Dorland's *Obstetrics*) differentiates the two conditions; but a careful blood examination, by revealing the presence or absence of the *plasmodium malariæ*, will render the diagnosis certain.

PUERPERAL SEPSIS.	MALARIAL INFECTION.
The chills are irregular in their appearance and are associated with marked alterations in the temperature rate.	The chills occur at regular intervals, and are followed by the usual elevation of temperature and then a sweat.
The constitutional disturbance is profound.	The constitutional depression is moderate, and quite out of proportion to the severity of the paroxysm.
The pulse rate is exceedingly rapid and ominous.	The pulse rate is in proportion to the amount of febrile reaction.
There will be associated uterine subinvolution and tenderness, and probably alteration in the lochia.	There will not be noted any peculiar local pelvic manifestations.
The patient's condition steadily grows worse without appropriate treatment.	Within a few hours there will occur a marked amelioration of the symptoms.

9. A *dry birth* is a labor in which the membranes have ruptured prematurely and the liquor amnii has escaped before the cervix was dilated.

The management of a *rigid os uteri* consists in: The administration of chloral hydrate, gr. xv., three doses being given at intervals of about twenty or thirty minutes; hot vaginal douches directed against the anterior lip of the os; if these methods do not suffice, it may be necessary to give an anesthetic, forcibly dilate the cervix, and deliver by forceps; the cervical laceration, if any, must be repaired.

BACTERIOLOGY.

2. The *characteristics of the bacillus of diphtheria*: The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly, or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

3. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbol-fuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a min-

ute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

4. To demonstrate *gonococci* in the vaginal secretion: On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly-made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

5. Phagocytosis is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria and other foreign matter.

MEDICAL JURISPRUDENCE.

1. *Adipocere formation* only occurs when an animal fat is in contact with nitrogenous material. It is a process of saponification, the result being an ammonium soap, except when the body has been immersed in water containing excess of calcium salts, in which case a calcium soap is formed. The process is hastened by immersion in water, or even by moisture; it commences where fat is most abundant and gradually proceeds through the greater part of the body. It usually takes about three years for a body buried in the earth to be converted into adipocere; but the age and development of the body, as well as the nature of the soil may modify the length of time required.

2. *Paralytic dementia* is a gradually progressive and chronic inflammation and degeneration of the cerebral cortex; it is characterized by failure of memory, changed disposition, delusions of grandeur, and may lead to epilepsy and paralysis.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 7
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 6

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 14, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	360	188
Diphtheria	369	34
Measles	471	20
Scarlet Fever	397	21
Smallpox	4	1
Varicella	160	1
Typhoid Fever	62	21
Whooping Cough	12	2
Cerebrospinal Meningitis	13	10
Malarial Fever	..	..
Totals	1848	298

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending December 13, 1907:

SMALLPOX—UNITED STATES.

SOME UNCLASSIFIED DANGERS IN ANESTHESIA.*

By JOSEPH D. BRYANT, M.D.,

NEW YORK

The sense of appreciation of the dangers arising from constantly threatening things in life is largely comparative and naturally, therefore, the responsibilities relating thereto are quite apt to be similarly adjusted in the minds and by the actions of those closely related to the outcome. That familiarity with dangers of varying degree is apt to lessen correspondingly the sense of danger and accountability belonging to each, is a matter the correctness of which cannot easily be gainsaid. The faithful sentinel who begins his vigil with eager senses and hesitating tread fails in duty when misleading assurance, begotten of familiarity with exacting environment, lessens the acuteness of the situation. Perhaps the idea is better expressed by the well-known Shakespearean thought, "Familiarity breeds contempt." And this not alone in connection with the common amenities of human intercourse, but as well for the punishments related to common human fallacies in the sterner affairs of life.

Formerly, the casual examination of a hospital report showing an unprecedented death-rate from tuberculosis, for instance, would not cause on the part of many familiar with its devastations hardly more than passing notice, such as a sigh of regret by means of which one might express the fact that the measure of human sympathy is not yet exhausted. For so many years had the human ear been familiar with the verdict in this affliction, that the utterances of the human tongue, in many instances, were but of languid regretful import when illustrations of this disease fatality came to hand. Since little rational heed had been given to a danger which was not understood, personal and public responsibility had not sufficient foothold, in this instance, for a firm abiding place, until after the announcements of Koch. And even then the appetite for contention against it awaited on delayed digestion and assimilation of facts of almost self-evident meaning.

Less than twenty years ago but two of twenty-five of the leading physicians of this city were willing unequivocally to vote in writing the affirmation that tuberculosis should be declared by the Health Department a communicable disease and, correspondingly, be reported. And at about this time notions of prevention of common character, now household measures, were targets for the ridicule of the thoughtless, vainglorious, and assumptive persons—medical and lay—who obstinately denied their understandings of the benefits of the aid of their own special senses, and of the profound scientific deductions of others, in this matter. To-day the multitude are striving to lessen the burden of the affliction and wonder why so much delay is taking place; in fact, a grievous need has blossomed into a glorious fad.

It may seem quite strange that the reader should thus open a consideration of some of the dangers and responsibilities of anesthesia with a prelude of this tenor, but it appears to be not unfitting, at least in the sense of emphasis, from the standpoint of the antecedent proposition—that familiarity breeds contempt, or in this instance, at least complaisance, in the presence of danger, especially when the presence is long continued, and also, that under these conditions the body politic likewise sustains a loss of feeling—sort of a pseudo-anesthesia—which hinders, if it does not directly oppose remedial action.

The brief consideration of anesthesia at this time is prompted by the desire to offer something amenable to general discussion with the hope of extracting much of practical importance from the experience and observation of those whose opportunities are measured by abundant and fruitful examples.

The notion that past experience in the use of anesthesia, with relatively crude means of procedure, was commonly attended with great discomfort and a fatality from which the modern means and methods supply comfort and security, is entitled to experienced expression, and from those who were not born yesterday, and whose observation and experience in the two eras of anesthesia it may not be amiss to know something about.

The dangers and the responsibilities of anesthesia should be regarded as correlative, and the realization of the presence of a danger should promptly suggest the means of relief. It is in instances of this kind that trained and experienced attention under any executive equipment, lightens the burden of responsibility and correspondingly contributes to operative satisfaction and lessens the weight of unfavorable outcome. The anticipation in anesthesia of an awkward complication or of a significant consequence bids, on the one hand, a complete preparation therefor, or perhaps on the other, warns against exposure to prospective danger. It naturally follows, therefore, that those who administer anesthetics should be, as far as practicable, fully conversant with the present and prospective demands of rational anesthesia in all instances. The physiology of anesthesia and the therapeutics of its ill effects should be well understood.

The comparatively recent though limited introduction of skilled anesthetists into the professional activities of this country has established a desideratum of most satisfactory and beneficent nature, to all immediately concerned in operative practice.

Of course, competent, responsible forethought and able, painstaking supervision in all operative

*Read at a stated meeting of the Practitioners' Society of New York, December 6, 1907.

work should ever be at hand, therefore the incoming of skilled anesthesia in all the term implies is a blessing which none more than those in command can comprehend. Those of us who have experienced the comforting assurances dependent on the participation and the expressions of a trusty anesthetist in operative practice, as compared with the infrequent feelings of this sort, of past experience, enjoy an association which makes appreciation and gratitude the proxies of anxiety and danger.

It may not be amiss at this time, and in this connection, to register an unpleasant fact which is being forced upon me by observation and experience, viz., that not all those who regard themselves as fitted by modern means to administer anesthetics quite meet the expectation with which they might be regarded, were they less inclined to be original in their methods of practice. To err is human, and much of which error is born of striving to be original, or quite superhuman.

The induction of new notions in anesthesia for the sake of originality is often more pernicious than beneficial, both to the patient and the cause in question. The use of novel mechanism, and the novel administration of a potent remedy to meet special indications which often cause only temporary discomfort, at the risk of the patient's life, are measures to be deplored. The collated experience of dispassionate reviewers, of such false attainments, pronounce against the practice in decided tone, sustained by an increased death-rate from heart failure—with anesthesia. Not so very many months ago, in a place not a thousand miles from here, a friend of mine had occasion to examine the records of an operator who had just then lost a case from heart failure with anesthesia, and found that the last was not the first in order from the same cause—at least with the same verdict. And the time of completion of the record seems altogether too short when compared to ordinary practice, to be regarded as an earnest of the employment of ameliorating measures in anesthesia, or of a judicious practice in the use of drugs.

On infrequent occasions I have been impressed with the notion that unripe anesthetists and even those of maturer growth too often are more inclined to repose trust in anesthesia in the mechanical action of the apparatus, or in therapeutic modifying measures than in the accumulated knowledge of sentient beings. After all is said and done, ordinary prudence and common knowledge decree that favorable outcome in anesthesia, as in other things, can be assured only through wise forethought and vigilant execution. And, too, in anesthesia as in other measures devoted to human relief, final safety is best attained by the use of the means upon which the well-grounded experience of the profession and that of the anesthetist is based. And this latter proposition is incomplete, indeed, unless supported by a familiar knowledge of the use of more than one form of apparatus, supplemented by a reasonable amount of experience in the employment of each under circumstances which test the physiological and otherwise resourceful wisdom of the anesthetist. I, myself, would prefer to receive anesthesia through the agency of the crudest means by skilled hands than from the wisest fashioned mechanism managed on lines of inexperience and theory. I am satisfied that greater security is gained by experience in the giving, than by the use of ingenious mechanism, and that in the presence of inexperience or careless method both are alike objectionable. If these premises be correct, then how important it is that education should be given in the extremes of methods of administration—the classic and the crude as well.

The common plan of to-day in hospitals and in medical institutions inculcates mechanical idealism in anesthesia, and, possibly, through the operation of certain expensive and more or less fickle mechanisms of not yet fully established utility. At the same time ought not instruction be given in the making and in the use of the common means of giving anesthesia, in order that emergencies can be met under all circumstances and in out-of-the-way places? The assimilation of knowledge and of its advantages is not entirely unlike the assimilation of the uncivilized and its disadvantages, *i.e.* "benevolent" or necessitous assimilation as the case may be.

Specialization in the giving of anesthetics is a beneficent proposition so far as the patients open to its influence are concerned, but these latter will make up a small proportion indeed of those who now and will, for a long time to come, be thus favored. Therefore, in hospitals and in medical institutions amplified means of administration should be taught, but not so much from an automatic mechanical standpoint as from an established physiological comprehension of the effects of anesthetics so that its significant phenomena may be promptly interpreted and fittingly estimated under every circumstance. But, in all instances, a knowledge of the use and a working knowledge of the means, and the physiological effects of anesthesia should be well in hand whenever and wherever human affliction requires abatement by this means.

The fact that one of the dangers in anesthesia rests on an inadequate knowledge of the means of administration prompted the saying at this time of much already stated. The stereotyped dangers of anesthesia are numerous and well emphasized, but not enough emphasis is laid, as it seems to me, on the need of inculcating greater versatility in the use of the different means of the giving, and of the differing effects of anesthetics on the human economy. One who controls the influence of potent forces in the other affairs of life, such as of steam, electricity, etc., commonly limits his knowledge to some special mechanism relating thereto and never indiscriminately operates different mechanisms without requisite preparation, for the obvious reason that he ought not to do so, supplemented by the strenuous fact that conservative requirement exacts a better service. If now the dangers relating to anesthesia have a good foundation, then indeed should discreet surveillance be forced through the edict of responsibility as judged by law, if in no other way. Nothing more startling and pathetic can happen in the cause of human endeavor than the sudden and unanticipated death of one who trustingly, or with dread, consigns himself to the care of human agents in matters of this kind. The effect of dire results is broad and far-reaching, never forgotten, rarely overlooked, and contributes often to unjust censure and abiding self-recrimination. And the inhibiting influence thus exercised on those whose duty to themselves and to dependents is obstinate and serious contributes not a little to the burden of unwelcome results.

Nothing has been said in this connection about the dose of anesthesia, or the need on the part of the givers to estimate the comparative effects of dosage. These often discussed and important features can now go without the saying, and, more-

over, to consider them at this time would be foreign to the purposes of this paper, and, besides, might transcend the patience of the listeners. However, briefly, as bearing on the importance of the dose, I will quote from the recent volume (1907) on "Anesthetics and Their Administration, by that master of anesthesia, Frederick W. Hewitt, M.V.O., M.A., M.D., Contab., of London. He says: "When an anesthetic gas or vapor is progressively given by the valvular system until a point is reached at which the phenomena of full anesthesia appear, it is, of course, possible to ascertain the quantity of the anesthetic which has been used. But this quantity does not indicate the dose absorbed; for not only is the greater part of it dissipated in the patient's expiration, but at the termination of the administration there is still a portion of it within the respiratory passages. Although statements have been made by various observers as to the doses of anesthetic which produce the different degrees of anesthesia, our knowledge is not sufficient to warrant any very definite pronouncement upon this point."

If this statement regarding valvular control in administration be apparent, then, indeed, how much more uncertain this feature of safety is in administration by the nonvalvular or cruder means of practice. In any circumstance no one unfamiliar with the effects of the drug on the human body in health and in disease should assume the rôle of an anesthetist. Hence, it follows that instruction related chiefly to the operation of the apparatus should not be regarded as a full meal, but rather as a relish promoting the digestion and assimilation of more substantial aliment. One who is versed in the various effects of anesthetics can be trusted with the use of any form of apparatus whose mechanism can be intelligently operated. I am, therefore, impressed with the notion that there are anesthetists who would insure against accidents in anesthesia by use of modern apparatus—perhaps their own—with a degree of confidence like that which prompts the use of lightning rods on human habitations irrespective of important modifying conditions.

It is not needful that the writer should go far to the lee of passing events to recall in his own experience an instance not entirely foreign to this line of thought. A truly worthy young man beset with anesthetic aspirations of commendable proportions, vouched for to the writer, by a personal friend already delightfully imbued with his anesthetic skill, was invited to anesthetize a patient whose fear of anesthesia was painfully apparent. The young man in question, on entering the operating room with the unconscious patient, was personally equipped in a manner strikingly significant of the many-sided tokens of the anesthetic branch of operative aid. A measured tread and confident mien characterized the worthy young man in question at this time. With the patient on the table and the anesthesia going on in charge as before, my gaze was directed for the instant to the appearance of the patient. She was dusky, with superficial and irregular breathing, pulseless at the wrist, and at the verge of destruction, a condition which was not appreciated by the anesthetist, and even when pointed out did not arouse a spirit of conception of danger in any degree commensurate with the situation. In reference to a query regarding the cause of the condition of the patient, an answer was hesitatingly vouchsafed which conveyed no intelligent appreciation of the cause. The tenor of the remarks relating to the idea of the cause and the concomitant circumstances as stated, did not impress me with a feeling which suggested that the anesthetist had a safe working knowledge of the art of anesthesia. With some difficulty the patient was resuscitated, the anesthetic continued, and the operation successfully terminated.

During an active association with the use of anesthetics, under crude and advanced means of giving, beginning as a hospital interne in 1869, I have witnessed but one death from their use, and this followed twenty-four hours after persistent and ineffectual efforts, under ether anesthesia, to reduce a dislocation at the hip joint; the ether on this occasion was given by myself while a junior. Suppression of urine was the active cause of death. I recall, however, four distinct instances in my personal experience, scattered through later years of surgical activity, in which patients were rescued from ether or chloroform poisoning, only after decided effort. One from chloroform in private practice, two from ether in Bellevue Hospital, and the fourth in Bellevue from ether plus morphine injected for quieting recovery purposes after operation. The amount of morphine injected could not be determined because of thoughtlessness exercised in the giving. The distress in the first three of the list was because the givers of the anesthetic paid greater attention to the technique of the operation than to that of the anesthesia.

As a matter of fact, in each of the first three instances I was made aware of the presence of impending danger by the change in the character of the blood incident to the operation.

I consider the foregoing illustrations as being indubitable evidence that familiarity with anesthetic dangers breeds a disregard for them which good fortune and resourceful nature may frequently, indeed, render innocuous, or if otherwise, heart failure is the verdict. And, moreover, that the introduction of potent drug ameliorating measures for the purposes of lessening or obviating anesthetic consequences of no vital significance is not justifiable except when specifically indicated. The rate of mortality in anesthesia thus supplemented appears to be much greater in some instances than before, and the anticipated advantages of supplemental therapeutic measures are not by any means constantly realized, leading in fact to their rejection as a common plan of practice on the part of those who suffer from disappointed expectancy.

A fertility of resource from the physiological and mechanical standpoints is very essential in order that the necessitous contingencies aroused by the administration and the need for anesthetics, under all circumstances, can be rationally fulfilled. As it seems to me, there are dangers, or objections if you will, in the use of anesthesia which yet are unclassified, at least to the extent which should place them in the long list of accredited dangers as commonly exploited in the use of anesthetics.

Women Doctors to Go.—Five years ago the problem of saving money induced the County Asylum authorities at Fulbourn, near Cambridge, England, to appoint a woman physician. Since then the female staff has been allowed to increase. Now appointments to it are to be terminated on the ground of "physical unsuitability," at least, such is the term used in the report of the committee, the main objection alleged being that women physicians cannot be asked to substitute in emergencies on the male side of the asylum.

ENVIRONMENT AND PERSONAL HYGIENE AS CAUSES OF CONSUMPTION.*

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

"Without hygiene climate is as sounding brass or a tinkling cymbal."—*Solly.*

Of absorbing interest to all students of the history of tuberculosis in America is the consideration of its relations to the colored race. From an inconsiderable factor in their mortality rates the disease has now become so formidable amongst them that it seems to be settling the negro question in this country for all time. In the same way certain tribes of the North American Indians will be in a few score years, unless the ravages of tuberculosis be arrested, as nearly extinct as the buffalo. It is seldom that anything more graphic has appeared in health literature than an account of the spread of consumption amongst the Sioux Indians, by Dr. Robinson, Superintendent and ex-officio Secretary of the South Dakota State Board of Health. He says in part: "In the old wild life, the Sioux were a healthful people. They were probably not wholly free from tuberculosis in some form; if, however, the infection was present, it was not general. In 1863 began the reservation system among the Sioux of the Missouri. There are about 25,000 of them making fine progress in civilization, living in houses, wearing citizen's clothing: the children being educated: the families generally professing Christianity: the able-bodied engaged in some form of manual labor, by which they earn the means of subsistence."

For fifteen years subsequent to 1863, during which time the wild buffalo had been destroyed, and all of the Western Sioux had been brought under agency influence, the annual reports of the several agents were optimistic in relation to the health of their people, reiterating the statement that the Indians were now living under more healthful conditions, coming under civilizing influences, dwelling in better houses, and accepting the attendance of the agency physicians. The first mention of consumption in these reports was in 1878. In 1880 one agency reports that 5.26 per cent. of the deaths resulted from tuberculous troubles. In 1881, consumption is generally mentioned in the reports, and in 1884, it was said, "consumption has a firm hold upon them." Yearly since 1880, the agents' reports have more and more teemed with fearsome tales of the ravages of the scourge. In 1880 there were in four of the leading bands 293 births and 208 deaths. Last year in the same bands the deaths equaled the births. A noticeable feature of the present condition of these unfortunates is the large and increasing percentage of tubercular affections amongst the children. Dr. Robinson says fully 60 per cent. of the younger generation have some form of tubercular affection and that fully 50 per cent. of those over the age of puberty die of tuberculosis.

In a paper read before the Sociological Section of the National Association for the Study and Prevention of Tuberculosis, Dr. Walker of Pine Ridge, South Dakota, says, "There is no inherent peculiarity of the Indian which renders him more liable to infection with tuberculosis than is a white man under like circumstances." Their average strength, endurance, and vitality appear to be about the same as those of the white man, and yet there is a much larger percentage of them affected with tuberculosis. Dr. Walker thinks that tuberculosis had existed among them before they came into contact with the whites, but there were relatively few cases until after they had given up their nomadic life and settled down to life in houses. They were filthy when they lived in tepees, and filthy after they became house dwellers. It was demonstrated by statistics that the most cleanly among them were the most healthful, but it was never shown that the filth in which they lived of itself caused tuberculosis at any time. "In their primitive life, their principal food was flesh. In times of plenty, they would surfeit themselves on raw or poorly cooked meat; at other times they would go hungry. They had no regular meal times. When they began to live in houses the Government supplied them with an abundance of food, and in much greater variety than they had been accustomed to. They were also supplied with cooking stoves and utensils, so that their food was better cooked than when they lived in tepees.

During their savage life the clothing of these Indians was of skins fashioned in a primitive style, the same all the year round, except that in the winter they wore a robe. Their garments were never laundered or changed for reasons of cleanliness. They were often exposed to inclement weather with a scanty amount of clothing and slept sometimes in tepees, sometimes in the open air, with probably little covering. After they had settled down in houses, they were supplied with better clothing in sufficient quantities and with blankets and bedding. They built their houses small and low with tight dirt roof and a ground floor. They daubed every crack and crevice with mud or other material to prevent any ventilation. They imitated their pale-faced brother in their abhorrence of drafts. A heating and a cooking stove were provided for every house, and in cool weather these were both fired at once and the Indians would crowd into these superheated cabins and swelter there. They threw their slops about the door, as they did when living in tepees, but they did not move their cabins every few days as they had moved the tepees, so that the surroundings of the former soon became noisome with filth. They had begun the use of intoxicating liquor before they had adopted our civilization, in its entirety, so that nothing was wanting to induce the scourge and rectifier of outraged nature, tuberculosis, to settle among them. The lesson is but too plain, and he who runs may read it if he will.

The history above detailed is the history of our feeble attempts to civilize the Indian in many parts of the United States. Tuberculosis has been for years prevalent amongst the Indians in Western posts that have been especially salubrious for the whites, as for instance, Surgeons Chase and Barker of the United States Army reported from the Washington Territory, that of 219 cases of sickness occurring in the military post there in the four years 1870-1874, there was only one of phthisis among the white soldiers or their families. Not a case of the disease had originated there. "But two or more cases which were imported had improved rapidly under treatment. Phthisis, however, is very prevalent and very fatal among the Indians." This report was made nearly forty years ago. The Indian was filthy, idle, and intemperate then as he is now, and those in Washington Territory had given up the warpath and their nomadic life long before the Sioux began to adopt our civilization and acquire our diseases. Consequently phthisis had made its

*Read before the American Climatological Association at Washington, D. C., May, 1907

appearance among them before it had been heard of among the Sioux.

A study of the conditions among the negroes in this country shows that phthisis has increased among them in almost the same relentless ratio that it has devastated the Indian reservations. In slavery days, the negro was comparatively free from tuberculosis. He was not, however, immune, as is so often stated, but suffered from the disease only slightly less than the white man. In Charleston, South Carolina, for instance, from 1841 to 1848 the death-rate from tuberculosis of the white and colored people was identical and was 2.8 per 1,000. Since, however, civilization, alleged political freedom, and a chance for education have overtaken the sons of Ham, they have become more and more tuberculous, until in 1900, in Charleston, their mortality from this disease reached the astonishing figure of 7 per 1,000. In other parts of the South, the negro mortality is not so high, and it appears never to have reached a high figure in the rural districts.

As Dr. Jones sententiously remarked, in a paper before the Tuberculosis Congress last year, "No individual or society has yet studied the case of the negro sufficiently to say whether the racial element plays any part as a cause of this disease." The influence of environment is at present so tremendously in favor of tuberculosis among this people that it has been practically impossible to eliminate it sufficiently to discover the racial predisposition, if any exists. To quote Dr. Jones further: "Few of us realize the great difficulties under which this race struggles. A third of it is yet living in one-room cabins. The possible danger of such an existence is indicated by a fact which I discovered last year, in a so-called two-room cabin. Two-thirds of the space in one room was filled by a stove and a table; one-half of the other room was filled by a bed. In this house thirteen children had been born since the war, and twelve of the thirteen had died when they were children. * * * The unusual and heroic struggle for an education under adverse conditions is often a potent cause of consumption among colored students."

It is not only in his liability to consumption that the negro in the United States shows his non-adaptability to his present environment. His death rate is high in almost all diseases, and his general death rate is higher than that of the whites in about the same proportion as is his death rate in tuberculosis. During the War of the Rebellion it was observed that ten per cent. of the negroes who were reported sick from heat stroke died, while of the whites only four per cent. died. This is a good comparison as far as it goes, because the conditions of life were identical at the time for the blacks and the whites, and the former are well known to be less susceptible to heat stroke than the latter. That the colored race has less vitality than the white is unquestionably true, but to assert that negroes so frequently contract tuberculosis by reason of an especial or racial predisposition is to beg the question. Their birth rate has decreased in the last twenty years, a decrease two or three times as great as that of the whites. It is impossible not to observe many analogies between the present condition of the negroes and that of the Indians. Both races have within a comparatively few years entirely altered their manner of living and have evinced conspicuous non-adaptability to their present environment.

And so it is with the Irish race in America. I will not weary you with the figures. Suffice to say that the Irish-American is almost as liable to tuberculosis as the negro, and that the Irishman born in America is twice or three times as liable to die of the disease as the Irish emigrant. "Americanization," we are told on good authority, is beating down the alleged splendid immunity of the Jew to tuberculosis. What does it all mean? Americans themselves are gradually becoming less tuberculous, while the peoples who are trying to live like them and live with them, are becoming more so. The explanation is by no means easy. If so good an observer as Dr. Salmon confesses that the means of arresting the spread of tuberculosis among cattle are not as yet understood, does it seem unreasonable that the problem of handling the disease in the greatly more complicated life of man should be so intricate?

Talcott Williams has said that every case of consumption is a confessed failure of civilization. It is no more so than is a case of drunkenness, of syphilis, or of typhoid fever. Nor is it as much so, because we know the remedy to apply to each of the last named conditions, although for one reason or another its application seems impracticable. But in tuberculosis, we do not really know the remedy, or remedies. We are trying to discover them. It is idle to say that infection is the sole cause of consumption. We are all exposed, and practically all have the disease at some time in our lives, so the pathologists tell us, and yet nine-tenths of us escape without any tangible symptoms.

Why does the submerged tenth suffer? There is no question about the predisposing effect which many occupations have upon the contraction of this disease.

There is no need to remind you that stone cutters, knife grinders, and cigar makers are especially liable to consumption, and that a difference at first blush so slight, as changing the grinding from dry to wet, add years to the grinder's life. The latest statistics from Paris show that the upper tenements in that city have a smaller percentage of tuberculosis than the lower floors in the same buildings, although their inmates are poorer and more crowded together, the first named lodgings being more exposed to the light and air, and being further from the ground. So in New York City it has been demonstrated that there is more sickness from pulmonary and bronchitic disease on the north sides of the street than on the south, where the house gets more sunlight.

In Paris it has been found that fewer illegitimate children die from bronchitis and pneumonia in the first year or two of life than legitimate—the direct opposite from what we should expect. The very fact that they are less carefully tended, and presumably less luxuriously clothed and fed, seems to add distinctly to their power of resistance to pulmonary diseases. Pampered and overfed cattle, like the notorious herd of Jerseys of Queen Victoria, are especially prone to tuberculosis; pampered and overfed children are not so liable now as they were once, since the habit of battening down the windows and piling on the flannels for fear the child might take cold, is not so fashionable as it used to be. Overfeeding would appear to be inimical to the progress of tuberculous disease under some, but not under all conditions

The Actuarial Society of America published an elaborate report in 1903, according to which the $20,000 "risks" had turned out especially badly, only living out, I believe, about half of their "expectation." Here, again, luxury, it seems, is getting

in its perfect work. Heretofore, however, we have not been accustomed to consider it a cause of tuberculosis. Another interesting fact to be learned from the report is that the commercial traveler is an unexpectedly good risk, compared to men of the same age in other occupations. This can be explained only on the hypothesis that travel in itself is wholesome. Man was originally a nomad, hunting about for his food like other wild animals, and, as he developed further, he was a shepherd and led his flock about. The wandering propensity (*Wanderlust*) is still a part of the normal man's disposition, and, like other traits inherent in our nature, should be heeded.

Change of locality is of itself beneficial to the health in many instances. Perhaps the Irish in America illustrate this, the emigrants, as has been said, showing much better life histories, especially as regards consumption, than their children born in this country. No really satisfactory explanation of the great prevalence of phthisis among the Irish-American has been advanced. From considerable study of the problem, the writer believes that the diet of these people has not received sufficient attention as a predisposing factor in the development of tuberculosis. The Irish seem to be intensely carnivorous, eating largely of meat with some of the coarser vegetables, such as potatoes, turnips, and cabbage, none of which afford much energy to the system. They do not seem to eat a due proportion of good carbohydrate food; at all events, their bread all seems to come from the bakeshop, and this is about as nearly without nutriment as bread well can be.

The fine commercial instinct which pervades everything in America has led to the production of baker's loaves of immense size and little substance, conveying to the eye a sense of magnitude, but cheating the stomach by their aerial flimsiness. They are windbags puffed out, it is alleged, by the use of alum or some other chemical. This bread, if soaked in milk or tea, becomes as soft as pap, and can be washed down without chewing. A characteristic American style of eating, by the way.

It states in the life of Count Rumford that this excellent observer and truly scientific man was greatly impressed by the vigorous health of the Bavarian soldiers, who subsisted on food which they bought out of their pay of four cents a day or less, and which consisted largely of soup with such vegetables as beans. The Government, in addition, however, supplied each man with about two pounds of good, rye bread. Such a menu, in fact, affords almost the ideal diet.

The Count seemed to lose sight of the effect upon the nourishment of the body which will follow the consumption of good, substantial bread, requiring much mastication. He was disposed to think that in some way water prepared in soup developed some nutritive qualities. Whether this is so or not, enough is known of dietetics to establish the fact that the consumption of good, hard, bread crusts and drinking plenty of water, either hot or cool, should be the foundation of a normal workingman's diet. I firmly believe that if bread were sold by weight it would do more to arrest tuberculosis in the United States than the strict enforcement of the anti-spitting ordinances, important as I acknowledge these laws to be.

I have seen young Irish-American children come home from school, proceed at once to the cupboard, and abstract therefrom sweet cakes of variegated hues bought at the bakery, and designed to attract the eye and tickle the palate of this class of customers. After eating of these dainties, the future American citizen, with his decayed teeth, so rotten perhaps that he could not chew wholesome food, his neck, probably adorned with scrofulous nodes, and his posterior nares stuffed with adenoids, would, perhaps ignoring entirely the family dinner of corned beef and cabbage and liberal potations of tea, retire to smoke the manly cigarette, spend his evenings on the street corners, or, if a little older, in the saloon, or some more questionable resort, and finally retire to sleep in a small and nonventilated room with an assortment of bed-fellows, relatives, and otherwise, with, however, the never failing precaution that the windows were carefully battened down. The child or young man would probably be muffled in woolen garments, wear heavy woolen underclothes, and perhaps sleep beneath a feather bed, if not in one. In Ireland, poverty had kept the foolish parents from any such indulgence of their offspring, but in this free country, with the greater variety of food, higher wages, and more general education, the children are too much indulged to the injury of their health and their morals.

We are told that wearing the white man's clothes is a principal cause of consumption among the Indians, and that animals and plants will sicken and die when their cutaneous respiration is interfered with. I am anxious to learn more of the truth of this alleged cause of tuberculosis among savages. I can remember distinctly making a campaign during my army life with Indian scouts and some regular troops, in which the Indians coughed almost incessantly. The soldiers and officers had no colds. I was told that the Indians might have contracted theirs from taking sweat-baths, but as they were living under the same conditions as we were, wearing soldier's clothes, and eating soldier's rations, there seemed to be no reason for their greater susceptibility to colds. I was told by experienced officers that the red man is gradually becoming weaker and more prone to sickness. Personally I am disposed to agree with Dr. Page and others who believe that much sickness, and especially consumption, may be caused by covering the body with raiment. So far as can be learned, Indians, negroes, and the South Sea islanders never suffered from consumption to any appreciable extent until they began wearing our clothes. To be sure, they began at the same time to lead more idle and luxurious lives, and to change their diet from simple, coarse food to bakers' bread, impure milk, and more complex viands generally. They now drink more whiskey, use more tobacco, and herd closer together. And they have also begun the interminable struggle for an education, the students, as we have seen, being especially liable to consumption.

I think that enough has been said to show that tuberculosis is a disease following maladaptation to the environment, improper habits, and defiance of Nature's laws. Nothing will stop its ravages entirely except to force every man and woman to live by the physical conscience, and to devote a large share of thought and energy to preventing themselves and their neighbors from contracting the disease and from spreading it. It took, as we have seen, fifteen years of so-called civilizing influences to thoroughly infect the Sioux Indians of the upper Missouri. Bad as those influences are, they would not have taken the same hold on people like the poor Jews of eastern Europe, who have for generations been accustomed to foul, contracted dwell-

ings, modern woolen clothes, overcrowding, overwork, and wretchedness.

The tendency to consumption is born in everyone. Flexner and other good pathologists, as already stated, tell us that at least 90 per cent. of human beings have at some time been infected with the tubercular virus. And we observe constantly that any great change of environment or régime, not by any means invariably to a lower social condition, may result in the development of this disease; so may too much sexual intercourse, whether legitimate or not, an improper diet, the strain of too much study, the use of intoxicants, or the inhalation of smoke and dust. In short, anything that permanently weakens vitality and destroys or impairs the resistance of the body cells is an invitation to the development of consumption in man or animals. And, lastly, want of proper development of the lungs, the muscles, and the vital organs, is an important contributory cause too little thought of.

If dairy cattle were exercised more, and never confined in stables, so that their bodily activity would promote normal metabolism, they would in all probability not suffer from consumption. Just as horses are practically immune, and sheep and goats nearly so. Undoubtedly if negroes and Indians should go back to the life to which centuries of evolution had fitted them, the disease would practically disappear from among them in a generation or two.

They are now paying the penalty of a too sudden change from what was to them a hygienic mode of life to an unhygienic one, and those of them that escape the devastation of the plague will become comparatively immune, able to resist a higher degree of infection, and to remain free from phthisis under conditions which they cannot withstand now.

Infection plays a secondary part in the production of consumption, and so does heredity; the principal causes are a man's life habits and environment. As the Imperial Board of Health of Germany has said, "It is impossible to extirpate all tubercle bacilli, therefore it is indispensable to so strengthen and harden the body that the absorbed germs cannot take hold upon it."

THE BACTERIA AS INCITANTS OF MALIGNANT ENDOCARDITIS.*

By AUGUSTUS WADSWORTH, M.D.,
NEW YORK.

ALONZO CLARK SCHOLAR IN PATHOLOGY; INSTRUCTOR IN BACTERIOLOGY AND HYGIENE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ASSISTANT PHYSICIAN TO THE ROOSEVELT HOSPITAL OUT-PATIENT DEPARTMENT.

(From the Departments of Pathology and Bacteriology, College of Physicians and Surgeons, Columbia University.)

THE clinician at the bedside appreciates fully the practical results attained in the experimental study of diphtheria. But he needs also to know and to recognize that as a result of such study marked precision has been gained in the diagnosis and theoretical conception of bacteriemic disease, even if the methods of serum treatment are unsatisfactory, and that this knowledge has already exercised over modern therapy a judicious control which is of broad scope and of definite practical value. It is in this light chiefly that the study of the bacterial cell as an incitant of malignant endocarditis assumes practical interest.

Inflammatory processes of the endocardium involve, as a rule, the valves of the cardiac orifices. The lesions vary, but usually they are situated in the left heart. In order of frequency the mitral, aortic, tricuspid, and pulmonic valves are involved. The simple verrucose lesions consist of slight infiltration and thickening of the valve. Subsequent contraction of the connective tissue fibers shortens the valve and roughens the endocardium. In the vegetative processes the infiltration is more marked and the hyperplasia is characteristic; in the ulcerative, necrosis defines the type. Thrombi form in all types of lesion. These anatomical distinctions doubtless are necessary and convenient for purposes of description and classification, but at autopsy the lesions often show all degrees of infiltration, hyperplasia, and necrosis.

The etiology of endocardial inflammation has long been the subject of serious study and vague speculation. It is asserted that all acute endocarditis is of infectious origin, and that practically all of the infectious diseases may give rise to endocarditis. Such sweeping assertions, however, do not admit of positive demonstration. Experimentally, tissue reactions of the ulcerative type of lesion have not been induced without the presence of bacteria. Clinically, the signs of acute endocarditis in man are those of infection, and it is just as difficult to define the malignancy of an endocarditis as of a pneumonitis. Anatomically, the lesions accord with those of bacterial origin, but not infrequently at autopsy are found extensive vegetative and ulcerative lesions without bacteria, and exceptionally in the experiments on animals similar lesions have been noted after simple injury. Hence the accepted classification of simple acute, chronic, and malignant mycotic endocarditis is convenient and persists. Nevertheless, the trend of recent study suggests that acute endocarditis, incited under varying conditions by many different species of bacteria, is an infectious disease, symptomatically and anatomically of such wide variation as to render accurate classification difficult. For present purposes, the endocardial affections of active mycotic incitement alone are of interest.

The results of bacterial examination in cases of malignant endocarditis are too well known to the bacteriologist, of too little interest to the clinician, and often too scantily descriptive of the bacteria found, to be cited in detail. Many different species have been reported, among them the colon, Friedländer, typhoid, diphtheria, influenza organisms, the meningococcus, the tubercle bacillus, the *B. pyocyaneus*, unrecognized species; others little known but described as the *B. endocarditis griseus, Micrococcus rugatus, Micrococcus capsulatus* of Weichselbaum, *B. pyogenes fœtidus* (Fasset), *Diplococcus tenuis* (Klemperer), and an organism described recently by Pappenheimer and Satchwell. But usually in characteristic ulcerative lesions the pneumococcus, streptococcus, staphylococcus, or gonococcus is present.

Malignant endocarditis of varied bacteria incitement is similarly variable in its association with other diseases. Rheumatism and chorea, so often precedent to simple acute endocarditis, rarely gives rise to malignant endocarditis. Pneumonia and sepsis, especially the puerperal form, are the most prolific sources of the serious endocardial lesions. Of the exanthemata, scarlet fever, with its streptococcal infections, is most important. But practically all the more common infectious diseases of man may be complicated by endocardial affections. In some, the cardiac lesions may be due to the primary or specific incitants of the disease, as in urethritis;

*Read before the New York Academy of Medicine, November 21, 1907.

in many to the organisms of secondary infection, as in diphtheria. The secondary infections of true diphtheria and the primary infections of pseudo-diphtheria, as Prudden[1] was among the first to distinguish and to demonstrate, are incited by the same bacterial species, the pyogenic cocci. In tuberculosis the endocarditis may be due to the presence of the tubercle bacillus, but this has only exceptionally been demonstrated. In view of the frequent occurrence of tuberculosis and endocarditis, the association of these diseases may be of no etiological significance. Exceptionally, the story and signs of previous infection are lacking, and malignant endocarditis has thus occasionally been considered to be a primary disease.

But, whether the incitants are derived from the main blood stream or are carried in the endocardial blood supply, malignant endocarditis always develops as a secondary localization from bacteriemic or pyemic invasions arising in previous infectious disease. This secondary localization may occur early or more often the signs are obscure or masked and are recognized late. Infectious disease thus acts as a predisponant in the etiology of malignant endocarditis, affords entrance for the germs, and gives rise to the susceptibility of the patient essential to the development of bacteriemias or pyemias. These, however, are frequently noted without endocarditis in both animals and man. Evidently additional conditions of susceptibility or predisposition are necessary for the formation of the characteristic lesions. It has long been noted clinically that the healed or chronic lesions of previous endocarditis often predisposes to the malignant type, affords the essential local conditions. This, however, is capable of far more accurate demonstration by the experimental method.

The endocardium was long thought to be exquisitely sensitive to the slightest injury, but Rosenbach,[2] after passing instruments through the carotid artery and perforating the valves, found that rapid and complete recovery took place. Wyssokowitsch[3] also failed to obtain vegetative or ulcerative lesions in similar experiments, but when he inoculated animals injured in this way the characteristic lesions of ulcerative endocarditis developed. Prudden,[4] in this country, not only corroborated the results of these observers, but found that slight injury secured by nitrate of silver sufficed to determine this localization of the bacteria on the endocardium. Subsequent experimentation has confirmed these results and broadened their significance.

There is thus definite clinical and experimental evidence suggesting that the development of malignant endocarditis in the course of infectious disease is determined by previous lesion of the endocardium. This may be of recent development or long standing. Hence, the occurrence of infectious processes in an individual, with even the simplest of valvular lesions, is of practical interest to both surgeon and physician.

Attempts have been made to distinguish clinical groups of the disease and to classify them according to their etiological or anatomical development, but only two types are generally recognized, the typhoid and the pyemic. The endocarditis of pneumonia, usually of pneumococcal incitement, is said to run a rapidly fatal course, usually without infarction but with metastatic processes in the meninges, peritoneum, pleura, or other parts of the body. In some observations the lesions in the endocarditis of pneumonia were noted in the right heart more frequently than in the left; in others the predominance of lesions of the left ventricle obtains as in other forms of the disease. It is evident that conditions in pneumonia, more than in any other disease, favor the development of the processes in the right heart.* The endocarditis of sepsis is more variable. Usually rapidly fatal with pyemia and infarction, it is nevertheless often of prolonged, subacute type, with occasional recovery, especially in attenuated streptococcal infections, such as follow scarlet fever. The cardiac lesions are left, rarely right. The endocarditis of urethritis, practically of specific gonococcal incitement, is recognized as more uniformly of prolonged subacute type, and, though serious, recovery takes place more frequently than in the pneumococcus, streptococcus, or staphylococcus infections. The right heart is frequently involved. The chief proof of rules such as these is the long list of exceptions which individual cases present.

Variable and subtle in its development and course, malignant endocarditis is recognized with difficulty. Often the diagnosis is made late or at autopsy. The clinical signs nevertheless direct attention to bacterial examination of the blood and determine the significance of the results.

Owing to faulty technique, unreliable results are often obtained in the bacterial examination of the blood. Contaminations occur, and the organisms, especially in the protracted cases, are few in number, or may be so attenuated as to yield little or no growth on artificial media. Considerable quantities of blood are often required, say 5 to 25, or even 30 c.c. In the hands of the expert, broth is an extremely valuable medium for cultivation; but in the hands of the novice often assigned to this work contamination is more apt to occur and is less readily detected than in solid media. Solid media, however, may be enriched by the addition of sera, sugar, or other substances which facilitate growth. As a rule, the best results are secured when the blood is distributed in broth and in plates of solid media. In view of the changes in the number of bacteria in the blood and the technical difficulties of their isolation, failure to find bacteria in a case otherwise showing the signs of the disease should be controlled by repeated examinations. The accurate diagnosis of malignant endocarditis doubtless gives satisfaction and support to the physician at the bedside, but to the patient in bed its practical value is limited owing to the unusually grave prognosis it carries, and the unfortunate inadequacy of specific therapy.

The extremely unfavorable tenor of the prognosis of endocardial infection, as compared with that incited by the same species of bacteria in other parts of the body, is due to the anatomical situation of the lesion. In pneumonia, for example, the pneumococcus infection in the lung, if localized, usually is benign; if generalized, as a bacteriemia, it is serious; but if from the bacteriemia endocarditis develop, it is practically fatal. On the endocardial surface there is no rest, little chance for complete localization, and the ulcerative lesion may discharge directly into the circulating blood. Furthermore, fatal accident by infarction or thrombosis is a constant menace. Bacterial species comparatively benign in other parts of the body thus prove serious or fatal in endocardial lesions; nevertheless, cases do recover.

In the experiments on animals, it may be recalled,

*Among the many conditions which might be suggested in explanation of this the fact that the lymphatic drainage of the pneumonic lesion empties into the jugular vein near the right heart, the frequent occurrence of thrombosis, and the extra work suddenly thrown on the right heart in pneumonia may be seriously considered.

extensive lesions of the endocardium, free from infection, healed rapidly. That the heart of man is similarly recuperative is suggested by the scars of old injuries and the chronic valvular lesions found at autopsy. Once freed of its mycotic nature, the ulcerative lesion of malignant endocarditis tends to heal, and, in view of the difficulties in diagnosis, unrecognized cases doubtless recover. In fact, exceptional though it be, recovery is recorded from endocardial lesions incited by all the more common incitants of the disease, more frequently from the gonococcus than the pneumococcus, streptococcus, or staphylococcus infections. Grave as the anatomical situation of the lesion renders the prognosis in malignant endocarditis, it thus varies to some extent at least in the individual cases, and the mechanism of recovery differs in no essential from that of infection in general.

Infection, considered in terms of its units, the body cell and the bacterial cell, is a series of interdependent adaptations ever varying in balance. Upon the determination of these subtle relations depends all our theoretical conceptions of the disease, its course and prognosis, and all hope of future success in its treatment.

Fortunately, time does not permit discussion in full of the new lore of immunity. Suffice it to glean from this maze of fact and fancy such observations as are practical in their trend. Briefly, then, the body cells, in response to the presence of foreign material, are stimulated to the elaboration of substances which combine with this material to facilitate its assimilation or elimination: noxious substances, if soluble, are neutralized and thereby rendered innocuous; if insoluble, they are disposed of in devious ways; some are stored in harmless places; others undergo dissolution outside the cells, and still others, perhaps the greater number, are taken up by the body cells, the phagocytes, and there digested or cast off. In these reactions the body tissues acquire antitoxic, agglutinative, precipitative, bacteriolytic, chemotactic, and opsonic properties in varying degree active, and doubtless closely related one to the other in this complex mechanism of immunity by which the development of the bacterial cells is controlled or altered in the course of infectious disease.

In recent years attention has been focused on the study of these properties of the body tissues, and wisely and profitably so; but the mechanism of immunity is only part of the mechanism of infection; the susceptibilities and attenuation of the bacterial cell also demand attention if the practical significance of the results of this study of immunity is to be intelligently utilized. In their susceptibilities to the action of these various processes of immunity, as also in their virulence and capacity for adaptation, great variation has been noted in different bacterial species and in different strains of the same species.

The attenuation of bacteria growing in artificial media under various conditions has long been recognized. Frequently organisms recently isolated from disease processes are peculiar in their morphology, staining reactions, and growth, and even in their pathogenicity as tested on different animals. These peculiarities may disappear on cultivation. Among the streptococci and staphylococci, especially in the protracted infections of malignant endocarditis, has this been observed. Definite as is the existence of these slight physiological adaptations within the bacterial cell, they are extremely difficult to study, and our knowledge of them is as yet inchoate.

More marked is the variation found in the susceptibility of the bacterial cell to lysis; some species undergo rapid dissolution; others are insusceptible. The vibrios, cholera, some of the bacilli, typhoid, for example, are in varying degree susceptible. Streptococci and staphylococci are relatively insusceptible. The pneumococcus exhibits in salt solution a susceptibility similar in degree to the cholera vibrio, but in sera differs markedly. In the presence of fresh normal bile, one drop to one cubic centimeter of culture, the pneumococcus undergoes rapid dissolution, whereas the streptococcus remains intact. Similar variations are found in the rapidity with which the phagocytes take up and digest the cells of different bacterial species. As tested *in vitro*, typhoid bacilli are not only taken up immediately by the phagocytes, but they are also as quickly digested; in the test tube mixture all traces of the bacilli often disappear in a few minutes. Staphylococci are as quickly taken into the phagocytes, but there they remain, undergoing slow dissolution, or they grow, destroying the cell. The intracellular distribution of the gonococcus in urethral pus has long been considered characteristic of the organism. Virulent pneumococci and streptococci are comparatively insusceptible to phagocytosis, even after long exposures.

All this susceptibility of the bacterial cell to the mechanism of immunity is a new field of investigation opened up by the newer methods, but these observations suffice to indicate how important it is in our efforts to attain efficient serum therapy, to consider not only the immunity of the body cell, but the susceptibility of the bacterial cell with its capacity for adaptation also. Especially are these considerations important in a disease of so grave a prognosis and of so varied a bacterial incitement, as malignant endocarditis, in which the local lesion bears so unusual and dominant a relation to the bacteriemia.

The adaptation of one cell is thus limited by its susceptibility to the presence of the other. This balance is ever changing, with conditions favoring now one, now the other. These conditions of predisposition have been extensively studied. The effect of exposure to cold, hunger and thirst, fatigue, and many similarly injurious conditions have been the subjects of experimentation, and the results are too well known to warrant further consideration. The effect of fever, however, is so fundamental and broad in its practical significance, and the study of it has apparently yielded such contradictory results, that these may with profit be briefly considered.

Pasteur was among the first to demonstrate the attenuation, loss of virulence, brought about in anthrax by cultivation at elevated temperatures—42° C. Similar results have been obtained with other species of bacteria, notably the pneumococcus; at 41° C., for six days the virulence was lost in Fraenkel's experiments. Pasteur also showed that birds with normal temperatures of 41° C., and insusceptible to anthrax, became susceptible and died of the infection when, by baths or other means, this temperature was lowered. All of Pasteur's observations have been confirmed again and again, but in recent years the results have been attributed to subtle changes other than the lowered body temperature. This is due to seemingly contradictory results obtained in a long list of experiments, in which susceptible animals were rendered more susceptible by exposure to elevated temperatures. Little or no attention, however, was paid to the degree of eleva-

tion attaind by the body tissues during the exposure, nor was account taken of the effect of such temperatures and exposures on the bacteria inoculated.

In Walther's experiments the body temperatures of the animals were carefully determined. Rabbits kept at 41° C. were less susceptible to pneumococcus inoculation, infection usually failed to develop; temporary early incubation, or incubation late after the inoculation increased the susceptibility; the animals died quicker under these conditions. Conditions of experimentation are not exactly those of infectious disease, and to this is doubtless due slight discrepancies in results. But if only certain experiments are to be accepted as significant and the others excluded, there is a large source of error in making the selection; an error often easily avoided if the significance of the results be confined to the scope of the experiments. Thus it is clear that the exposure of animals to a hot atmosphere predisposes, favors, the development of the infection; but it is equally clear that if by that exposure the body temperature of the animal exceeds the thermal limits of growth of the incitant the course of the infection is inhibited.

The thermal limits of growth vary greatly among the different species of bacteria, and for the same species the records of different observers also vary. Tests such as these should be made with standardized thermometers, and the exposures made in water baths kept at constant temperatures. In my experience, the variation of different strains of the same species, under favorable nutrient conditions, is slight, less than the differences in the records of different observers for the same species. Only slight differences, a slightly lower thermal limit, could be detected in organisms recently isolated. These were attributed to the media used; in fact, the thermal limits of a sensitive organism, such as the pneumococcus, varied more in different media than under any other conditions. This suggested the possibility of a similar variation in the thermal limits of the bacteria growing in lesions and subject to the action of the mechanism of immunity. But more accurate determinations are required for so broad a conclusion. Certain it seems, however, that the temperature of fever in some infections at least may limit the development of the bacteria.

It is of practical interest to note that the species commonly found in malignant endocarditis are comparatively susceptible to elevated temperatures. In my experience the pneumococcus develops slowly and only under the most favorable conditions at 40.5° C. to 41° C. Streptococcus growth is inhibited at 41° C. to 41.5° C. The staphylococcus, however, grows well at these temperatures. The early records placed the thermal limits of gonococcus growth at 42° C., but recent observers have all failed to secure growth above 40° C. to 40.5° C., and clinically in the course of urethritis the local inflammatory reactions subside when the temperature of the patient is elevated. These thermal limits of growth may be considered especially significant in view of the fact that the temperature of the blood is 0.5° C. to over 1° C. higher than that of the mucous membranes. The fever in malignant endocarditis may thus be regarded as conservative in its effect on the course of the disease.

Attempts to utilize this knowledge of the conditions underlying infection in the treatment of bacteriemic disease have not given satisfactory results. The administration of serum from immunized animals with a view to supporting the immunity of the patient and of supplying the inadequacies thought to exist have all apparently failed to be of material value. Such methods are now little used or only in an experimental way. Recently the administration of vaccines, an effort to secure a maximum immunity by further stimulation of the body cells, has been revived. In bacteriemic diseases in which the adaptations of the bacterial and the body cells are very equally balanced, disturbance of this equilibrium is a serious menace, especially if the development of immunity be inhibited by the excess of bacterial poison. Wright, the chief advocate of these procedures, guards as he thinks against this by determinations at intervals of the degree of opsonic activity in the blood serum of the patient; but other observers, with few exceptions, have demonstrated in these methods errors which render the results of little or no practical significance. The indications for the use of vaccines, if such exist in the bacteriemic diseases, are thus indeterminate.

In malignant endocarditis such radical procedures, it is evident from the serious nature of the disease, would be more apt to do harm and less apt to do good than in the infections of simple bacteriemia. No reliable specific treatment is yet available, and attempts to formulate general rules or definite measures to be adopted in the treatment of all cases of malignant endocarditis are also open to serious criticism. In the present stage of our knowledge, each case is a problem by itself, and departure from the conservative upbuilding of the patient's natural resources is sanctioned only under the special conditions existing in the individual cases. Our knowledge of infection has thus exercised a judicious control over radical, dangerous procedures of the past in the treatment of malignant endocarditis as of other infectious diseases, and emphasized the importance of a rigid personal or physiological hygiene in the individual case.

SUMMARY AND CONCLUSION.

Malignant endocarditis thus develops on the injured or diseased endocardium as a secondary localization in the bacteriemia or pyemia of infectious disease. It may be incited by many different species of bacteria, but usually the pneumococcus, streptococcus, staphylococcus, or gonococcus is present. It may be associated with any of the infectious diseases of man, but chiefly with pneumonia or some form of sepsis. As a complication of previous disease malignant endocarditis is of so serious a nature and so often outlives or dominates the parent infection that separate consideration of it is justified. The exceptionally grave tenor of the prognosis is due to the anatomical situation of the lesion.

The experimental studies of Rosenbach[2] of Wyssokowitch[3] and of Prudden[4] have demonstrated the importance of previous injury of the endocardium in determining the secondary localization of the infection in the heart, a fact of definite practical significance to both surgeon and physician in the prophylaxis of the disease. This study has also shown that the lesions of the endocardium once freed of their mycotic nature tend to heal, and thus recovery, when it occurs, differs in no essential from that of infection in general, a fact as yet of little practical value owing to the inadequacy of present methods of specific treatment in bacteriemic disease.

Apart from accidents of infarction or thrombosis, the course, the prognosis, and the treatment of malignant endocarditis, as of infection in other parts of the body, depend primarily upon the bal-

ance between the two opposing factors of infection, the body cells and the bacterial cells. In this complex mechanism of infection the different processes of immunity in the body tissues, on the one hand, and on the other the development of the bacteria, their susceptibility, and virulence, vary in their relation one to the other with different bacterial species and under different conditions. Since the control of these subtle conditions is beyond the reach of modern therapy, the manifestations of the disease, even the elevation of temperature, are to be regarded in general as indicative of the effort of the body tissues to maintain a favorable balance. The limitations of rational treatment are thus apparent and departure from a rigid, conservative, personal, or physiological hygiene is sanctioned only under exceptional conditions arising in the individual cases.

SKIAGRAPHY IN ORTHOPEDIC SURGERY.

By FRED. H. ALBEE, M.D.,

NEW YORK.

INSTRUCTOR ORTHOPEDIC SURGERY, POST-GRADUATE MEDICAL SCHOOL; RADIOLOGIST AND CLINICAL ASSISTANT TO HOSPITAL FOR THE RUPTURED AND CRIPPLED.

THE introduction of the Roentgen ray as a diagnostic aid in surgery has led to the establishment of a special branch of study—an art—which may

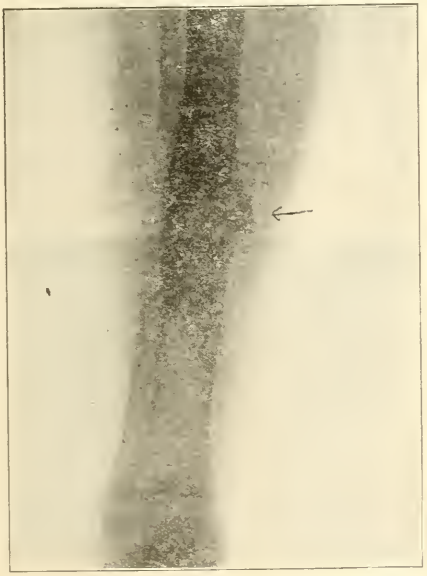

FIG. 1.—A bone furuncle or localized osteomyelitis of the tibia, showing a distinct sequestrum; the leg healed immediately after the removal of the sequestrum.

be termed skiagraphic anatomy and pathology. The intelligent interpretation of the skiagraph requires on the part of the observer an intimate knowledge of the radiographic art, as well as a close acquaintance with the normal and pathological skiagraphic appearances of bones and their various developmental stages (as to time of ossification and union of different bone centers, etc.); just as in the intelligent use of the microscope, a preliminary training in laboratory technique and a definite knowledge of microscopic histology and pathology are required. There are certain rudimentary con-

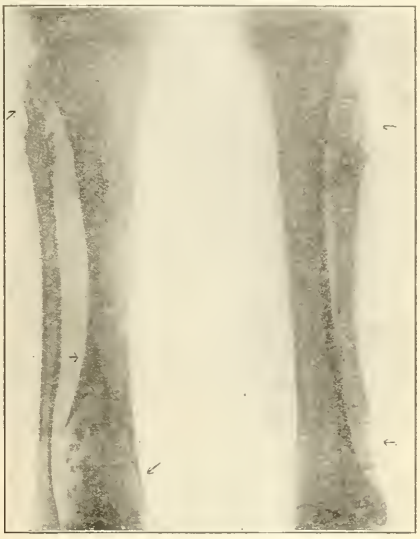

FIG. 2.—A case of congenital syphilis as manifested by the epiphyse a osteochondromata and irregularly thickened cortices of the bones.

ditions which must be complied with if our interpretations are to be of a sufficiently trustworthy character. (1) It is very desirable whenever possible to inspect the plate itself rather than a print; (2) care should be taken that the plate is held at a proper distance from the light and that the light is evenly diffused over it. Both the distance and intensity of light should vary with the depth of development of the plate.

Tuberculosis is the most common bone disease, and of all others the one with which the orthopedic surgeon is most concerned. It is thought by many of our best pathologists to be nearly always primary in the bone. This belief, however, is not, in a large percentage of cases, confirmed by the skiagraphic findings. Although it is not unusual to find a distinct bone focus, it is more common to discover first the thickened capsule with a blurring of the outlines of the bony elements of the joints, later the erosion of the articular surfaces, and finally a real destruction of bone. Another very strong evidence of bone tuberculosis, which is often earlier than any of the above more striking features, is bone atrophy, not only locally but in the neighboring bones. This change can often be detected in the *x*-ray plate, even before atrophy of the soft parts takes place. This bone atrophy presents itself not only as a rarefaction of the bone by a diminution of its salts, but as a lessening of the diameter of the shaft.

The epiphysis, however, is affected differently as to its diameter in the primary tuberculous bone cases, on account of the marked irritation the toxins produce, before actual destruction occurs. This causes an enlargement and a characteristic squaring of this part of the bone. This condition many times cannot be differentiated, without the aid of

the skiagraph, from the marked thickening of the capsule and neighboring soft parts of the purely synovial type of tuberculous joint disease. This differentiation, by the way, is of great importance because of the marked difference in treatment of

Fig. 3.—A case of multiple cysts of the neck of the femur with a spontaneous fracture.

these two varieties, the synovial type being very amenable to operative treatment.

As the process in the osseous type advances, destruction is the most characteristic feature shown in the negative. The bone breaks down, small sequestra are formed, subluxations occur, and detritus is thrown out with or without circumscribed abscess formation. Finally comes bony repair, and the most marked features of the advent of this change are the return of the normal sharp outline of the bony elements of the joint (Freiberg) with new bone formation and ankylosis, or else a practically new joint may form with more or less motion.

As I have mentioned above a very important *x*-ray evidence of joint tuberculosis is the marked thinning of the cortex of the neighboring bones, giving an appearance as if their outlines had been pencilled and a fine line drawn about them. Though this occurs to some extent in other conditions of marked atrophy—as, for example, in anterior poliomyelitis—it is quite diagnostic of tuberculosis.

Köhler describes three types of skiagraph, of as many varieties of this disease, all of which I have confirmed.

Type 1.—There is nothing to be seen in the negative but blurring of the outlines and diffuse atrophy of the highest grade.

Type 2.—Diffuse atrophy of more varying grade, blurring of outlines, and irregular mottling of cancellous bone tissue are to be found.

Type 3.—A still less amount of atrophy is seen. But at some particular point of the bone shadow a circumscribed spot is found with an irregular and indented border. As Freiberg has pointed out, the paramount importance in the study of these negatives is the bone atrophy above referred to. Tuberculosis in bone, as in other tissues, is healed by changes having their initial greatest activity in the periphery of the lesion. Therefore, beginning repair is indicated by a condensation which occurs in the surrounding osteoporotic bone, and a return of sharpness of outline. A reverse sequence of events may occur in the event of an exacerbation during convalescence.

In view of these findings, it will be appreciated that much can be discovered as to the progress of the disease by a repetition of exposures at intervals. Some have found these skiagraphic warnings very reliable and that they occur many times before the advent of disquieting clinical symptoms.

A frequent location for tuberculosis is the phalanges of the fingers, the so-called dactylitis, or spina ventosa. This condition is frequently confused with a similar syphilitic affection, and the skiagraph is of extreme importance in making a diagnosis. The following are the distinguishing features: In the tuberculous variety there is marked atrophy of neighboring bones, a cyst-like condition of the phalanx, usually associated with involvement of neighboring joints. In syphilis there is less atrophy and the articular surfaces are less often involved. There is a new deposit of bone beneath the periosteum and the old line of cortex can usually be seen. If loss of substance occurs the bone ulcer will present clear-cut edges and a punched-out appearance. The tuberculous variety is much the commoner.

In contrasting osteomyelitis with tuberculosis it should be said that while the latter most commonly affects the epiphyses and articular surfaces, the former rarely does so. Osteomyelitis often involves the shaft near the epiphyseal cartilage, but very rarely extends beyond this line because of the marked resistance cartilage bears to infection and the different blood supply of the epiphyses. An important feature is the absence of marked bone atrophy which is so constant an accompaniment of tuberculosis. Moreover, there are to be seen, especially in the more chronic cases, an actual cortical thickening and a ring of bone about the osteomyelitic cavity which is more resistant to the passage of the *x*-ray than the rest of the shaft. The sequestra found are often large and of considerable *x*-ray density.

In the consideration of the *x*-ray evidences of osteomyelitis it seems better to describe types rather than stages, for this is a disease resulting from so

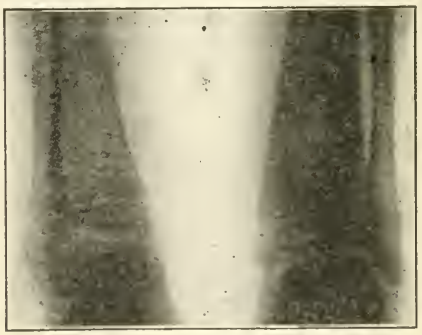

Fig. 4.—A case of bone cyst in the lower end of tibia. Dr H. L. Taylor operated and found this cavity filled with a clear serous fluid. Bone plugging material was used and the wound healed by first intention.

many etiological factors that it presents no typical stages. (1) The first type is that of a circumscribed acute osteomyelitis which it is frequently difficult to differentiate clinically from tubercle. The solution of this diagnosis constitutes one of the most satisfactory skiagraphic triumphs. The diagnosis is

certain and operative treatment is very effective. These lesions are produced by the pyogenic cocci and have been called bone furuncles or abscesses. They are often chronic in character and give little clinical evidence of their presence. Frequently they are located near joints, or even at the epiphyseal

Fig. 5.—Spindle-celled sarcoma, note the marked periosteal proliferation, with the characteristic radiating appearance of sarcoma.

cartilages, and are thus liable to be confused with joint disease. Their thickened walls stand out very distinctly in the radiograph. (2) The second type, a very acute process, is a far more serious condition. It is much more diffuse and extensive, often involving practically the whole shaft, and is immediately evident in the skiagraph. (3) The third type is a chronic process, very extensive generally. The sequestra lie in large bone cavities whose walls are very dense. If the process is of very long duration the periosteum will be much thickened. This type of case may quiet down without an abscess of overlying soft parts being formed.

The bone lesions which occur as a result of syphilitic infection are numerous and varied in their manifestations. Only a few of the most common *x*-ray appearances will be considered here. The hereditary forms are divided into the early and the late types, the former occurring in the early months of a child's life and resembling rickets clinically. It is characterized by a gelatinous deposit beneath the periosteum and at the epiphyseal line, with the resulting *x*-ray shadow. One of the late forms of hereditary syphilis, the juxtaepiphyseal lesion, deserves special mention. This type often manifests itself as a marked tumefaction in the region of the epiphysis. Pathologically these swellings are osteochondromata, which give a peculiar mottled-like *x*-ray appearance. Thickening of the cortex and the deposit of bone beneath the periosteum are the most characteristic evidences of both hereditary and congenital syphilis. In the acquired type the thickening of the cortex is often so marked on one side of a long bone, as the tibia, as to cause it to bend, thus giving rise to the so-called saber-shaped bone. This new-formed bone may be of ivory-like hardness, thus casting a very dense shadow. Frequently along the shaft of this thickened bone small areas of rarefaction appear with a dense shell of bone over them. These have been called, and appropriately, bone blisters by Codman. Typhoid periostitis may simulate these blisters, but there is never the cortical thickening.

Of all bone tumors sarcomata are by far the commonest and the distinguishing characteristics of many of these types can be discovered by the *x*-ray. The myelogenous or medullary giant-cell variety occurs at the rapidly growing ends of long bones and is very prone to develop cysts, while the spindle-celled periosteal type presents itself in the form of dense swellings—with a typical radiating appearance from the superficial part of bone. Generally the old cortical line can be seen beneath. This type most often involves the middle of the shaft and is the most malignant.

I need only state that the skiagraph is absolute in the differentiation of coxa vara, hip disease, and congenital dislocation.

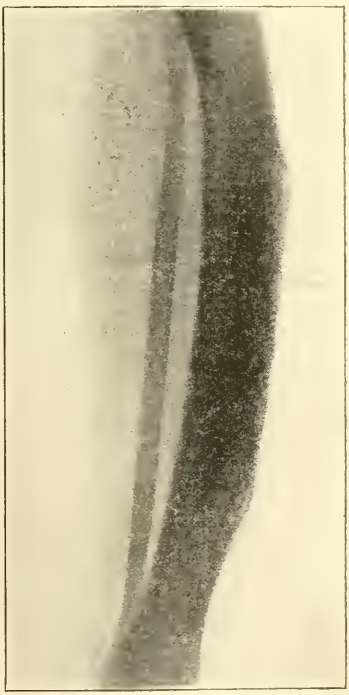

Fig. 6.—From a case of syphilis (acquired), side view of the leg bones; note the tremendously thickened cortex and the antero-posterior turning of the tibia; note also the rarefied areas on the anterior aspect of tibia; these have been called bone blisters by Codman.

Solitary bone cysts usually occur near the end of the diaphysis of long bones. The femur and tibia are the most frequent sites, and if the cysts are near joints they may simulate chronic joint disease. They usually produce pain, tenderness, lameness, and bone enlargement. There has been much dis-

cussion as to their etiology. Many good authorities claim that they originate from a rarefying ostitis or a localized osteomyelitis sometimes called bone furuncle, while other authorities believe that they arise from the softening of enchondromata and giant-celled sarcomata, or they may also be of parasitic origin.

A spontaneous fracture may occur through one or more of these cysts. *X*-ray evidence is absolute in these cases.

Very recently Boehm and others have done some excellent work in the study of the cause of certain cases of scoliosis. They have found many misshapen vertebræ and sacralized lumbar vertebræ which seemed to be etiological factors.

HOT SPRINGS, VIRGINIA.*

By GUY HINSDALE, A.M., M.D.,

HOT SPRINGS, VIRGINIA.

MEMBER OF THE AMERICAN CLIMATOLOGICAL AND AMERICAN NEUROLOGICAL ASSOCIATIONS, FELLOW OF THE AMERICAN ACADEMY OF MEDICINE AND COLLEGE OF PHYSICIANS OF PHILADELPHIA, CORRESPONDING FELLOW OF THE BRITISH BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY, ETC.

An account of the Hot Springs of Virginia was published in 1804 by Rev. Dr. Ashbel Green in the *Philadelphia Medical and Surgical Journal*. Dr. Green says: "These springs are chiefly useful in the cure of rheumatism and gout and other local affections of the nervous system. They are also highly useful in a number of cutaneous eruptions, and are frequently beneficial to persons of a bilious temperament. The cures they have effected in gout and rheumatism are almost incredible." Dr. Green gives the history of two cases which were cured of rheumatism and gout in a few weeks, although the disease had existed in one case for fourteen years. He notes a fact commonly observed at the present day in treating cases at the Hot Springs, viz., that patients experience temporarily, while under treatment, an aggravation of their symptoms. In one of the cases it is stated: "He used the waters . . . and for nearly two weeks he complained that he rather grew worse than better. At length, however, his pains left him so suddenly that he could scarcely believe they were gone. The pains did not return and the patient went away well." This is a common experience of to-day, and it is also remarkable that Dr. Green's record of the "boiler spring" made 107 years ago correspond precisely with the present temperature, 106.5° F.

The present condition of Hot Springs is in strong contrast to that of one hundred years ago. Now the patient is transported in fifteen hours from New York in a through Pullman car directly to the springs. He is provided with quarters in one of the best appointed hotels in the United States. Whether he comes for the "cure" or whether he returns, as many do, for the accessory pleasures of a watering place, he finds much to enjoy. The mountains remain as they were, but the valley is changed. He can travel miles upon the links; he rides over well kept roads; he meets congenial spirits from the centers of fashion all over the world, and, if need be, he can converse with those at home at almost a moment's notice.

It is told of the celebrated Dr. Abernethy that he once insisted that one of his patients, an Englishman, who was a victim of gout brought on by high living, should go to Carlsbad. He described to him the boiling waters, the mud baths, and the rigorous course of self-denial. "Why, sir," exclaimed the sufferer, "it will be like a passage through purgatory." "True enough," replied the doctor, "but it will surely be your escape from hell." However that may have been in Abernethy's time the modern watering place does not impress one as the abode of invalidism or distress. At the Virginia Hot Springs there is an air of gaiety and cheerfulness; the sound of music and the dance dispels the old impress of asceticism, nevertheless, the quiet and seclusion which the invalid desires can be had without imposing any restrictions on those who seek diversion.

While gout and rheumatism are conspicuous among the various ailments treated, there are many nervous affections, especially the so-called functional diseases, that are quite as amenable to treatment. The measures instituted are chiefly corrective and restorative. The sheet anchor of treatment is the full, free, and abundant action of the skin, to which, in general practice, too little attention is paid. The great natural supply of hot water makes it possible to give the bather eight or nine hundred gallons for his bath. The temperature and duration of these baths must be determined by a physician who has knowledge of the physical condition of the patient, and who has frequent opportunities to observe him. In the height of the season there are a sufficient number of bathing attendants to give, if necessary, three hundred baths a day. None are given in the evening. Besides the tub bath, which may have a temperature not exceeding 104° F., there is provided in every bath-room a spout delivering water at 104°, and at a pressure of from 14 to 18 pounds. The effect of this is strongly stimulating, and, in may cases, is employed directly before the full bath. Following this the customary procedure is a hot pack in a hot sheet and flannel blankets, followed by cool sponging or a cold douche and an alcohol rub. The entire process occupies from half an hour to three-quarters, and is succeeded by rest in the recumbent position for half an hour or more. The best time to take these baths is before breakfast or during the forenoon, although many prefer the late afternoon, experience showing that perspiration is then more free. Massage may or may not be added to the treatment. There is usually some massage or manipulation in the flowing water in the tub.

In addition to the type of bath which has been mentioned there are two marble douche tables after designs by Dr. Baruch, which provide douches having a wide range of pressures and temperatures in the various forms of circular, jet, Scotch, rain, and fan douches in conjunction with hot air baths. This form of apparatus has been greatly perfected and makes it possible to give a more tonic method of treatment than the ordinary full tub bath affords. The douche table has come to be an essential feature of large medical institutions in the United States as well as abroad and is invaluable in a wide range of chronic affections. Modern works on hydrotherapy, like those of Matthes, Schweinburg, and Winternitz, as well as the admirable American work of Baruch, reveal a broad field of usefulness such as the ordinary student and practitioner little dreams of. The Germans and Austrians are easily first in their acceptance of these measures. The American practitioner shows a commendable attitude towards physiologic therapeutics and is rapidly following the German lead in that respect.

*Read before the American Climatological Association at Washington, D. C., May, 1907.

Besides the baths there are valuable waters at Hot Springs for internal use. They are all calcareous waters and diuretic in their effects. Their principal constituents are carbonates of calcium and magnesium and are acceptable to the stomach. The abundant use of these waters is decidedly depurative, especially as regards the kidney secretion, and in this way the action of the baths is supplemented.

Accessory measures, such as diet and suitable exercises, are valuable aids in the restoration of health, and it is a matter of common observation that patients realize the need for dietetic regulations and follow prescribed exercises when they have made the journey to a particular health resort with some definite purpose in view. They will more readily cut off their alcohol and check their immoderate eating during the period of probation and generally find that it is better to forego the indulgences that have upset their brains, their stomachs, and livers. So it is that these springs exert a most salutary influence on those who take their treatment seriously and deserve the popularity they have maintained for over a century.

It must be admitted that American spas are not so superbly appointed as are those European spas which are under government ownership or control. The watering places of Europe which have been frequented by royalty and supported and directed by governmental authority, afford luxuries and appointments which we shall probably never see on this side of the Atlantic. Possibly the foreign methods of dealing with patients are best suited to the temperament of the cosmopolitan class that constitutes the patronage. These methods have been developed during ages and are not readily copied, or incorporated into the ways of American communities. In this country we prefer to walk whenever possible rather than to be carried by two men in a Sedan chair. Atlantic City, with its broad walk five miles long, is an ideal place for rolling chairs. These are large enough for one, two, or three persons, and are a necessity for patients who go long distances and need protection from strong sea breezes. The average patient, as I have observed him at Hot Springs, Virginia, dislikes to use even the rolling chair though always accessible; if found to be necessary at first, it is usually soon dispensed with. Perhaps, even in the best resorts of this country, a fair criticism would be that the prime necessity of maintaining the prestige and appointments of the baths and the strictly therapeutic features upon which the reputation of the spa is built tend to be lost sight of by the management. Tournaments and sports of various kinds and the amusements of the well should never be allowed to supersede the provisions made for the treatment and the comfort of the sick.

APPENDICITIS DUE TO THE PRESENCE OF OXYURIS VERMICULARIS.

By M. CLAYTON THRUSH, Ph.M., M.D.,

PHILADELPHIA, PA.

There is no disease that has a more variable and often peculiar etiology than appendicitis. On an examination of any standard work on surgery one will find an array of causes varied in type and character, some being of sufficient rarity to justify their being placed on record. The following case well illustrates this type:

Miss N. D., age 20; occupation, stenographer; family history and previous medical history negative, as patient always enjoyed good health. Six months ago she began to suffer occasional twinges of pain over the region of the appendix, which would come and go at varying periods, sometimes being absent for two or three days, then recurring and later disappearing.

This condition continued without apparently increasing in severity for about four months. During this time an examination of the abdomen was negative as to any localized tenderness over the appendix, although these pains were deep seated. Eating had no bearing on the condition. The patient described the pain as always in the locality of the appendix and rather localized.

Two months ago the pains became more severe in type, but not more frequent in occurrence, and this continued until suddenly the patient was taken with an acute attack of appendicitis, with intense pain and all the usual classical symptoms. Medical treatment was resorted to, with restricted diet, etc., for twenty-four hours, but with no amelioration of the symptoms; so operation was advised and the patient was removed to the Presbyterian Hospital, where the appendix was removed by Dr. H. R. Wharton.

The appendix had all the appearance of an acute infection with marked congestion of the blood-vessels, the only peculiar feature being a bulb-like expansion of the tip into a mass about one inch long and about double the caliber of the remainder of the organ.

On incising the appendix we found that this mass consisted of a thick mucoid substance, with a constriction separating it almost completely from the appendiceal canal, and in this jelly-like substance was a large number of worms of various sizes of development, and moving around freely. Some were quite small, others of full development. Altogether there were about one hundred of these worms. Microscopical examination confirmed the diagnosis of the *Oxyuris vermicularis* as being the variety of worm observed.

Rectal examination of the patient showed, as was expected, an abundance of these worms present. They had spread far up into the colon until they reached the region of the appendix, where some of the ova became imprisoned and developmental changes occurred, causing the attack described above. The patient made an uneventful recovery.

3705 Spring Garden Street.

Aphthous Fever.—Legendre describes the occurrence of a form of severe fever accompanied with vesicles on the lining of the mouth, that break and become confluent, forming ulcers that may be dangerous to life in the very young and weak. The disease has a predilection for young infants, and death may result from weakness and malnutrition. It appears first in the forest animals, and from their saliva is carried to the ruminants. In the human race it comes to infants from drinking raw milk. It may be carried by the unclean hands of the milkers. It will enter abrasions of the skin or mucous membranes. In adults it may come from eating the meat of the diseased cattle. The symptoms are the same in man and animals, fever, malaise, and vesicles in the mouth becoming ulcers. Prevention consists in boiling the milk, and in careful cleanliness of the hands in those employed about the cattle, washing the hands with antiseptic and cauterizing all abrasions. Weak alkaline solutions may be used as mouth washes in man, and vinegar in animals.—*Revue Médicale de Normandie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 28, 1907.

SPEAKER CANNON MUST ACCEPT THE RESPONSIBILITY.

THE bill for the reorganization of the Army Medical Department is once more before Congress, and it is earnestly to be hoped that it may promptly receive the attention it deserves. This bill has had the unqualified endorsement of the American Medical Association and other professional bodies. In a special message regarding this bill President Roosevelt said: "I earnestly recommend its passage by the present Congress. If the Medical Department is left as it is no amount of wisdom or efficiency in its administration would prevent a complete breakdown in the event of a serious war." Secretary Root officially stated of it: "I heartily approve of this bill;" while Secretary Taft in transmitting it to Congress said: "I have the honor to recommend the passage of the bill. * * * * I believe it to be of the utmost importance in securing a proper and efficient Medical Corps." Senator Blackburn, speaking in its behalf in the Senate, said: "It is the best bill the combined effort of the General Staff, the Secretary of War, the Surgeon-General of the Army, and the Military Affairs Committee of the Senate is able to produce."

The bill has twice passed the United States Senate and has twice been favorably reported to the House of Representatives by the House Military Committee. It has not been permitted to come up for action in the House through the unfavorable attitude of Speaker Cannon, although there is every reason to believe that this bill would pass if allowed by him to come up for legislative action. Surely a bill with such a backing is entitled at least to a respectful consideration of its merits by the Representatives.

Speaker Cannon holds a position which gives him the parliamentary power, irrespective of moral right, to disregard the expressed wishes of the Senate, President, authorities at the War Department, and the medical profession of this country. Whether his personal preferences should properly outweigh the combined wisdom of those best qualified to judge in this matter, need not here be considered. The political atmosphere has, however, considerably clarified of late, and opposition to this bill can no longer operate in secret, nor can it becloud the final issue of responsibility. The physicians and citizens of this country ought plainly to understand that if this most necessary measure fails to pass, the responsibility for any medical breakdown in the Army, with the consequent avoidable sickness and suffering of American soldiers and grief in American homes, will rest directly and entirely with the Honorable Joseph G. Cannon, of Illinois, Speaker of the House of Representatives.

TUBERCULOUS MILK.

KOCH'S announcement some years ago, at the London Tuberculosis Congress, that bovine tuberculosis was not transmissible to man through the medium of the milk or flesh of diseased animals afforded immense satisfaction for a few weeks to dairymen and others interested in the milk traffic. Unfortunately the satisfaction so caused was short-lived, and now there are few men entitled to an opinion on the subject who accept this thoroughly disproved assertion of the Berlin bacteriologist. It is, therefore, not without uneasiness that one reads the statement of Dr. Verenus A. Moore, of Cornell University, that 72 per cent. of all the herds of cattle in this State are infected with tuberculosis, and learns further that of 2,753 cattle examined during the year by the State Agricultural Department, 628 responded to the tuberculin test, a percentage of 22.8. It is not stated in how many of these cases the udder was diseased, nor how many of the herds affected contributed to the New York City supply, but it is pretty safe to assume that some of this number were thus locally diseased and again that the milk from some of these found its way to New York. The Health Commissioner of the city is working manfully to keep the milk supply pure, but with the small number of inspectors allowed him each farm can be visited only at rare intervals and a good many cows may become tuberculous in the months that must intervene between these visits.

In order to eradicate tuberculosis from the herds in the State it has been proposed to have a general round-up and kill all the diseased animals as nearly as possible at the same time. It is doubtful whether even such a radical measure as this would bring more than temporary freedom, and the immediate result would certainly be a very serious milk famine. Even then the purity of the milk supply of this city would not be assured, for there would still be tuberculous animals in the adjoining States whence milk is shipped to New York. Inspection is necessary, of course, and all diseased cows whose udders are affected should be slaughtered at once, but real protection from tuberculosis as well as the many other diseases which may be transmitted through milk can be assured only by municipal pasteurization.

It is objected that tubercle bacilli are resistant to the low temperatures at which pasteurization is effected and that boiling, or sterilization as distinguished from pasteurization, is necessary to effect their complete destruction. But this objection is not so serious as the opponents of pasteurization would have it. Even if all the tubercle bacilli are not destroyed at a temperature of 155° to 160° F., the greater number are, and those that are not killed are so attenuated that the healthy organism can be depended upon to dispose of them. Moreover the process does effectually destroy most of the other pathogenic germs commonly found in milk and would, therefore, be necessary even if it did not destroy a single tubercle bacillus.

The opponents of municipal pasteurization, when confronted with this argument, reply that, if pasteurization is necessary, it can be done at home. But any physician who has recommended this to the families under his care knows the result. What housewife or what cook can be depended upon to keep milk for twenty minutes at a temperature within the narrow limits of 155° and 160° Fahrenheit? Nine times out of ten the temperature will be found to be somewhere in the neighborhood of 100° or near the boiling point if not actually at it. Either the temperature will be at a point which favors the multiplication of bacteria or it will be so high as seriously to impair the nutritive qualities of the milk. Pasteurization by dealers may be properly done and it may not; it may be properly done to-day and not to-morrow, and the consumer has no guarantee except the trustworthiness of the dealer; some dealers are trustworthy, some unfortunately are not. The only real security lies in municipal pasteurization. This is practicable, as the experience of Vienna and other cities has demonstrated. The installation of the plants would cost money and so would their maintenance, but the expense would be much less than that of maintaining the immense army of inspectors that would be necessary to assure a pure milk supply to this great city. Pasteurization has its objections, but they are of little weight in comparison with the dangers of a raw milk supply under the very best possible conditions of supervision and inspection of the dairies, and that we are far from a realization of such conditions is notorious.

SCHOOL CLINICS IN POPULOUS DISTRICTS.

Medical inspection of school children is now in force throughout England, and though it will take a considerable time before the system will be working smoothly, it seems that a beginning is being made with a certain degree of enthusiasm. Of course, already the medical and lay journals are full of the views of faddists on the subject. It appears that there are some who believe that the rising generation of England should be fed, treated medically, and educated, wholly at the expense of the ratepayers. Others who do not go quite to these lengths are of the opinion that at least the medical treatment of school children is a duty of the State.

A very interesting address treating of the matter from the point of view of a London County Council medical man was given on November 28 by Dr. A. H. Hogarth before the Childhood Society. The speaker pointed out that it is now universally recognized that medical inspection of schools forms an integral part of every modern system of education. As long as there are in schools children suffering from preventable and remediable diseases of which both the parents and teachers are ignorant, so long systematic medical inspection can be justified as a State institution. But, Dr. Hogarth went on to say, medical inspection by itself is insufficient, medical treatment is the natural corollary. Experience, however, in the populous districts of England has shown that less than one-third of the defective children discovered by inspection are actually treated. Many of the children are not even presented for treatment, while many others are not efficiently treated, or, at all events, are not materially benefited.

The diseases which call for treatment are parasitic and contagious affections, defective vision, carious teeth, chronic diseases of the eye, ear, throat, and skin. The existing means for treatment are said to be wholly inadequate. There are family doctors, hospitals, and poor law dispensaries, none of which really fulfils the requirements. The family doctor does not exist in the home of the poor, and even a little higher in the social scale it is unreasonable to expect him to prescribe for children with defective vision or to cure such chronic complaints as discharging ears.

Again, hospitals are not suitable places for the treatment of such cases. That is not their *raison d'être*. The very weight of numbers is too great, the cases are too chronic, and the treatment too tedious for voluntary workers. Moreover, the central hospitals are quite inaccessible for the people living in outlying districts, and many of the patients must be kept waiting an inordinate length of time. Ignorance, apathy, and neglect of parents, inadequacy, and inaccessibility of existing institutions, real poverty of the people, the tedious nature of efficient treatment for chronic cases, and the general standing of the medical practitioner in poor districts are factors hindering treatment.

According to Dr. Hogarth the only practical remedy lies in the establishment of school clinics or centers for the medical treatment of school children under the guidance, direction, and control of the education authority. The school clinic should be modeled partly on the special clinics for the treatment of teeth at Strasburg, Bâle, Lucerne, and Zurich, and partly on the lines of the general polyclinics which have been established in Switzerland at Lucerne, La Chaux-de-Fonds, and Neuchatel. The proposed clinic should consist of a small building of five or six rooms, a large waiting hall and dispensary, consulting rooms for physician and for dentist, a dark room with special apparatus for examining eyes, throats, ears, etc., and a room for dental and other minor operations. A trained nurse should be in charge under the direction of the responsible medical officer of the education authority.

Such is a rough sketch of the proposed plan. The great obstacle to the consummation of this suggestion is the large primary cost, but it is argued that if it will have the effect of checking the degeneracy so evident in English manufacturing and other populous districts, the expenditure will be a matter of secondary consideration.

Color Photography in Medicine.

The applications of photography to practical medicine as well as for purposes of scientific record and research have become so manifold that it is not surprising that medical photographers have been quick to realize and take advantage of the possibilities afforded by the latest method of color photography. This, the Lumière process, differs from all its predecessors in that it requires no special apparatus whatever and involves only a single exposure, while the necessary manipulations are said

to be well within the technical powers of any but the merest tyro. Briefly stated, the method consists in using a plate which has between the glass and the silver film a layer composed of starch grains colored red, blue, and green. This layer is only one starch grain thick and the interstices between the grains are filled with an opaque material, so that all the light rays reaching the sensitive material must have passed through the colored grains. The plate is exposed with the glass side toward the lens so that the starch layer acts as a multiple ray filter, each grain allowing only the rays of its own color to act on the silver in the film. By appropriate manipulations during development a positive is secured, which by transmitted light shows an extremely realistic reproduction of the colors of the object photographed. The value of such a method for the purpose of recording the color as well as the form in photographs of pathological specimens, skin lesions, microscopic objects such as blood or bacterial preparations, and in medicolegal work is self evident and its practical applicability is attested by Benda (*Berliner klinische Wochenschrift*, December 2, 1907) who demonstrated a series of such pictures before a recent meeting of the Berlin Medical Society. The positives may be used in the projection apparatus for purposes of demonstration or instruction, but, of course, cannot be used for the production of colored prints. As yet these special plates are difficult to procure in this country, but they will probably soon be available in larger quantities, and though Benda is perhaps carried away by his enthusiasm when he says that before long every progressive physician will be making use of the method it will, no doubt, be found a very convenient addition to the means available for making records of medical observations of many kinds.

Is Ectopic Gestation Becoming More Frequent?

The *British Medical Journal* of December 7 comments on this question, basing its observations on a recent meeting of the Hamburg Obstetrical Society. In the discussion following the report of a case, one of the participants expressed his opinion that extrauterine pregnancy is more common now than formerly. Another speaker declared that the apparent increase in frequency is to be explained by our greater accuracy of diagnosis. These cases are no longer treated on the expectant plan, operation being avoided except in cases of rupture. He believed that the great extension of gonorrhea into the rural districts was a factor in the situation and also thought that trauma might be a cause of ectopic pregnancy. Our English contemporary believes that none of these arguments, pro or con, is free from objection. It declares that "Couvelaire's researches seem to show that inflammation is never the cause of the implantation of the ovum on the mucosa of the Fallopian tube. Clarence Webster attributes the implantation to the development of decidual tissue in the tubal mucosa—a change normal in the uterus but abnormal in the tube. This change, if it really occurs, may indicate an incipient degeneration of the stock amongst civilized women. As for trauma, a great deal more information about the clinical details of cases is needed before we can arrive at a satisfactory solution of the question."

The Ablation of the Tonsils.

Until the function of the tonsils has been definitely settled there are likely to be differences of opinion in regard to the treatment of the various pathological conditions to which they are subject. Some authorities regard them as the portals of entry of many different forms of infection; others look on them as valuable protective agencies, while still others consider them as not of very great importance in either direction. It seems not unlikely, however, that both of the first two of these views are correct, for it is perfectly conceivable that like most collections of lymphatic tissue the tonsils have a protective function, while at the same time if the toxic process becomes too severe they may be overwhelmed and themselves be converted into foci of infection. The question of whether or not the hypertrophied tonsils so frequently seen should be removed resolves itself largely into a consideration of their condition. If the hypertrophy is a simple one and the tonsillar tissue itself appears healthy the assumption is justified that the overproduction of lymphatic tissue has been a physiological process intended to compensate for increased functional demands, but if the hypertrophy gives rise to local disturbances or there is infection of the tissues themselves surgical treatment is indicated. Barth (*Deutsche medizinische Wochenschrift*, December 5, 1907) is convinced that it is only the diseased tonsil that affords a means of entry for systemic infections while a single hypertrophy does not necessarily demand treatment. He also points out that in removing the pharyngeal tonsil the submucosa should be left intact as, if the curetting is done too deeply and the entire mucous membrane is removed, the resulting cicatrization may lead to undesirable local conditions in the roof of the pharynx.

News of the Week.

International Tuberculosis Congress.—Active preparations for the International Congress on Tuberculosis to be held in Washington, next September, are under way in other countries. The National Committees for France, Germany, Sweden, Austria, Holland, Greece, Bulgaria, Cuba, Venezuela, Brazil, and Costa Rica have organized and have forwarded their membership lists to the Secretary-General.

United States Civil Service Commission Examinations.—An examination is announced for January 15, 1908, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of physician (male) in the Indian Service, at salaries ranging from $720 to $1,200 per annum. The age limit is twenty-five to fifty-five years on the date of examination. Applicants should apply to the United States Civil Service Commission, Washington, D. C., for application form 1312.

Street Railway Accidents.—The figures submitted to the Public Service Commission by the traction companies show that there was a considerable increase in the number of serious accidents during the last month. In September there were 216 of these, in October 171, and in November 243. Of the latter number 45 resulted fatally, making the total number of deaths for the three months 155, and the serious injuries 495.

Typhoid Fever in Porto Rico.—There is an epidemic of this disease in Caguas, a town with a population of about 6,000, situated eighteen miles southeast of San Juan. There are one hundred and twenty-five cases in the city proper and the outlying districts are also involved. The expenditure of $5,000 has been ordered for the erection of a temporary hospital.

Influenza at Cornell.—The epidemic of this disease in Ithaca has spread to the schools and over a

quarter of the four hundred students in the Ithaca High School were absent last week from this cause.

Yellow Fever in Cuba.—The Cuban Sanitary Department announces that the last case of yellow fever was discharged on December 16, and that there is on the island no case under observation or suspicion. The report of Dr. Carlos J. Finley, Chief of the Cuban National Department of Health, shows that since January 1, 1907, there have been seven cases of yellow fever in Havana city, of which only one case resulted fatally. During the same period there have been in the whole island outside of Havana 154 cases, of which fifty resulted fatally.

To Stop Vaccination in Illinois.—At a recent meeting of the Chicago Osteopathic Association resolutions were adopted declaring against compulsory vaccination. After saying that there is no law in the State compelling vaccination, the organization ordered that every possible means be directed against "the unlawful and unwarranted powers which these boards of health have arrogated to themselves." An appeal to the Legislature is advised.

Series of Dispensaries Established to Combat Tuberculosis.—The Chicago Tuberculosis Institute is inaugurating a series of dispensaries in connection with established hospitals and colleges, for the purpose of early diagnosis and home control of consumption, such control as will give the patient opportunity to recover and will safeguard the other members of the family and the fellow workers of the person sick. These meet the approval of the Chicago Health Department.

Unfed Berlin School Children.—In the first week of December, according to official statistics, from 245 out of the 285 primary schools of Berlin, no fewer than 11,947 children attended school, in most cases without breakfast, and in all cases without the prospect of obtaining a midday meal at home. Of those, 4,198 receive a simple daily meal from the fourteen canteens belonging to the Children's Canteen Society; the other 7,449 are totally unprovided for.

Coalition of Scientific Manufacturers.—The Bausch & Lomb Optical Company, the Bausch, Lomb & Saegmüller Company and the Carl Zeiss Optical Works have entered into a business combination. The Taylor Instrument Company of Rochester, has been enlarged in scope so that its products cover the entire field of meteorological and engineering apparatus.

Illinois Cigarette Law Inoperative.—The Supreme Court has declared the anti-cigarette law passed by the last Illinois Legislature unconstitutional on technical grounds. The law as passed contained provisions not enumerated in its title and did not prohibit the sale of cigarettes containing "pure tobacco."

Dr. Nicholas Senn Honored.—The Order of Merit of the Japanese Society of the Red Cross has been conferred on Dr. Nicholas Senn by the sanction of the Emperor of Japan. Dr. Senn has likewise been elected an honorary member of the Royal Medical Society of Budapest.

Dr. Felix D. Fontaine of Worcester, Mass., was the guest of honor at a banquet given on December 11 by his fellow physicians to celebrate the seventy-fifth anniversary of his birth and his fiftieth anniversary as a practising physician.

New Sigma Nu Alumni Association.—The fourth annual banquet of this organization was held at the Manhattan Hotel on December 14. The toastmaster was Dr. William J. Gies, and the introductory address was delivered by Dr. George B. Wallace. Dr. James Ewing spoke on the progress of pathology, Dr. Alexander Smith on specializing in medicine, Dr. William M. Polk on the physician as a humanitarian, Dr. Joseph D. Bryant on the physician's road to greatness, and Dr. Frank G. Meara on euthanasia.

East Side Physicians' Association.—At the regular meeting of this organization held on December 20, officers were elected as follows for the ensuing year: *President,* Dr. Henry Illoway; *Vice-Presidents,* Dr. Morris Cisin and Dr. George Dow Scott; *Secretary,* Dr. Sigmund Epstein; *Treasurer,* Dr. I. Seth Hirsch; *Trustees,* Dr. A. E. Isaacs, Dr. C. A. von Ramdohr, Dr. William S. Gottheil.

Norwalk (Conn.) Medical Society.—The election of officers for this society held at the annual meeting on December 12, resulted as follows: *President,* Dr. William J. Tracy; *Vice-President,* Dr. J. Milton Coburn; *Secretary* and *Treasurer,* Dr. H. C. Scherer.

Jackson County (Mo.) Medical Society.—At the annual meeting of this society held in Kansas City on December 10, officers were elected as follows: *President,* Dr. C. D. Hardin; *Vice-President,* Dr. F. E. Murphy; *Secretary,* Dr. E. L. Stewart; *Treasurer,* Dr. L. W. Luscher.

South Side Virginia Medical Association.—At the meeting of this organization, held in Emporia on December 10, the following officers were elected: *President,* Dr. L. Lofton of Emporia; *Vice-Presidents,* Dr. W. B. Barham of Newsom's, Dr. S. H. Mosley of Ebony, Dr. J. G. Renney of Petersburg, and Dr. C. W. Astrop of Surry; *Secretary,* Dr. E. F. Reese of Courtland; *Treasurer,* Dr. O. C. Wright of Jarratt.

Minnesota Valley Medical Association.—The twenty-eighth annual meeting of this association was held in Mankato on December 3, and the following officers were elected: *President,* Dr. F. A. Dodge of Le Sueur; *Vice-Presidents,* Dr. G. Luedke of Fairmont, and Dr. O. C. Strickler of New Ulm; *Secretary,* Dr. G. F. Merritt of St. Peter; *Treasurer,* Dr. A. G. Liedloff of Mankato.

Warren County (Miss.) Medical Society.—The following officers were elected at the meeting of this society, held in Vicksburg on December 13: *President,* Dr. G. F. Hicks; *Vice-President,* Dr. E. F. Crowther; *Secretary,* Dr. Sidney Johnson; *Treasurer,* Dr. Bonelli.

Bequest to St. Luke's Hospital.—The will of Miss Zela Gibbes of Newport and New York, who died in Newport last August, has been filed in the Probate Court. St. Luke's Hospital is the chief beneficiary, receiving $100,000 and the residuary estate.

Private Hospital.—The building formerly used as the Mt. Sinai Training School for Nurses at 149-151 E. 67th street, is to be converted into a private hospital in which physicians may retain the management of their patients.

Death of Lord Kelvin.—After an illness of several weeks Lord Kelvin (Sir William Thomson), one of England's foremost scientists, died on December 17. He was of Irish birth, being a native of Belfast, where he was born on June 26, 1824. While his researches in regard to theoretical subjects were of the greatest importance, he also was the inventor of many practical devices in the fields of telegraphy, electric power generation and transmission, navigation, etc. In 1867 he was knighted for his work in

connection with the first Atlantic cables and in 1892 he was raised to the peerage. He was president of the Royal Society and had held the same office in most of the other important scientific societies in the British Empire. He was a member of a majority of those of the entire world and received honors and decorations from nearly every Government on earth. His titles and honors and the letters that he was entitled to affix to his name take twelve lines of "Who's Who" for their recital. In 1904 he became chancellor of Glasgow University. He had made several visits to this country, the last one being in 1902. Lord Kelvin's body was interred in the nave of Westminster Abbey, near the monument of Sir Isaac Newton, on December 23.

The Late Dr. Charles H. Bailey.— At a special meeting of the visiting staff of the Mountainside Hospital, of Montclair, N. J., held December 19, 1907, the following resolution was adopted and ordered spread on the minutes:

The members of the visiting staff of the Mountainside Hospital have heard with genuine sorrow of the death of their friend and colleague, Dr. Charles H. Bailey.

Dr. Bailey was one of the original members of the staff and, until two years ago, when failing health compelled him to relinquish active practice, had been always zealous in his hospital work and faithful in performing the duties which devolved upon him. In the early years of the hospital his advice was particularly valuable when questions of enlarging the scope of the institution were discussed; and during all the time of his active connection with the staff he conscientiously did his work as attending surgeon and was always ready and willing to give to others the benefit of his counsel. His opinions on medical matters or on matters pertaining to the policy of the hospital were often sought and his clear, sound judgment made these opinions of great value. His colleagues on the staff feel that they have sustained a great loss, for Dr. Bailey was a good physician, a wise counsellor, and a firm and true friend. He was a man whom it was good to have known and his place will not easily be filled. To his sorrowing family the members of the visiting staff extend their deepest sympathy.

The secretary was directed to send a copy of this resolution to Dr. Bailey's family and to have it published in the Bloomfield *Citizen*, the Montclair *Times* the *Journal of the Medical Society of New Jersey*, and the MEDICAL RECORD. Henry B. Whitehorne, President; Richard P. Francis, Secretary.

Obituary Notes.— Dr. CHARLES H. BAILEY of Bloomfield, N. J., died on December 18 of apoplexy, at the age of sixty-three years. He was born in Catskill, N. Y., and at the age of eighteen enlisted in the 117th New York Volunteers, serving through the Civil War. He then studied medicine in the College of Physicians and Surgeons of this city, and on his graduation began practice in Bloomfield. When the Mountainside Hospital was organized twenty years ago Dr. Bailey was made a member of its staff and he retired only two years ago on account of ill health. He was for many years president of the hospital and at one time was president of the Board of Health.

Dr. NATHAN D. CALDWELL of Amsterdam, N. Y., died on December 20, at the age of fifty-one years. He was born in West Munroe, Oswego County, and was graduated from the Albany Medical College in the class of 1881. He was Health Officer of Amsterdam and of Hagaman and one of the staff of the Faxton Hospital of Utica.

Dr. FARQUHAR FERGUSON of this city died on December 14, in Atlantic City. Dr. Ferguson was born in Scotland in 1847 but came to this country early while a young man, and received his medical degree from the Long Island College Hospital in 1880. Failing health compelled him to give up active work about a year ago.

Dr. JOSEPH E. GARLAND of Gloucester, Mass., died on December 16, at the age of fifty-six years. He was born in Gloucester, his father, Dr. Joseph Garland, having been for more than fifty years Gloucester's leading physician. He was graduated from Phillip's Andover in 1868, and from Harvard in 1872. He then served as interne in the Massachusetts General Hospital and spent three years in postgraduate work abroad. Returning to this country in 1880 he began practice in Gloucester and had continued in active work until about two weeks before his death. He had held numerous public and professional positions.

Dr. OLE E. LINJER of Minneapolis, Minn., died suddenly on December 11, while making a professional visit. He was a graduate of the medical school of the University of Minnesota and had practised in Superior, Wis., and Starbuck, Minn., coming to Minneapolis about eight years ago. At the time of his death he was City Physician.

Dr. GEORGE J. HOLMES of New Britain, Conn., died on December 14 of pneumonia at the age of fifty-three years. He was born in Griswold and was graduated from the Albany Medical School in 1879. He immediately began practice in New Britain and of late years had made a specialty of diseases of the eye, ear, nose, and throat.

Dr. JOHN S. BARRETT, formerly of San Francisco, died on December 11 at Prescott, Ariz., at the age of thirty-seven years. He was born in Sacramento and was a graduate of St. Mary's College and Cooper Medical College.

Dr. CARLTON K. CHUBBUCK of Tecumseh, Neb., died on November 25 at the age of seventy years. He was born at Orwell, Pa., and was educated at the Orwell Seminary and Binghamton (N. Y.) Medical College. He practised for a time in New York State and later removed to Dickson, Ill. For over thirty-six years he had practised in Tecumseh.

Dr. MATTHEW W. BORLAND of Los Angeles died on November 20 of carcinoma. He was a native of Otsego County, N. Y., but spent much of his early life in Illinois. He served through the Civil War and at its close had attained the rank of captain. He then went to Chicago and was graduated from the College of Pharmacy, the Bennett College of Medicine, and Rush Medical College. He practised in that city until six years ago, when failing health compelled him to go to Los Angeles.

Dr. J. A. HUBBARD of Mason City, Ia., died on December 10, at the age of seventy-four years, after a long illness. Dr. Hubbard was a native of Burlington Flats, N. Y., and was graduated from Albany Medical College in 1858. Soon afterward he began practice in Dubuque, where he remained until a few years ago.

Dr. WILLIAM BAIRD of St. Johns, N. B., died at the age of ninety-four years on December 17. He was born in Kentville, N. S., and was graduated from the University of Edinburgh in 1837. The same year he began practice in St. John and continued in active work for seventy years. Last August on the seventieth anniversary of his graduation the University of Edinburgh conferred on him the honorary degree of LL.D. He had held many public positions, and in 1885 was president of the Canadian Medical Society.

Obituary.

HENRY PATTERSON LOOMIS, M.D.

NEW YORK.

Dr. Henry P. Loomis died on December 22 of pneumonia, after an illness of less than a week's duration. Dr. Loomis was the son of Dr. Alfred L. Loomis, well known for his work in diseases of the heart and lungs, and was born in this city April 20, 1859. He was graduated from Princeton University with the class of 1880, and three years later was graduated in medicine from the New York University Medical School. In 1887 he was appointed visiting physician to Bellevue Hospital, and for a number of years was Professor of Pathology in the University of New York. He was made visiting physician to the New York Hospital in 1896 and consulting pathologist to the New York Board of Health in 1897. Since 1898 he had been Professor of Therapeutics and Clinical Medicine in the Cornell Medical College. Dr. Loomis was a member of many medical and lay societies and clubs, and was an active and talented contributor to medical literature.

Correspondence.

PRACTITIONER AND CONSULTANT.

To the Editor of the Medical Record:

Sir:—Latterly it has seemed to me more evident than hitherto that a few words about the rôles of practitioner and consultant might serve a useful purpose. Whenever the consultant is called it is because: 1. The practitioner wishes his judgment in regard to the case, and rarely merely because in this way he believes the family will be better satisfied; and if disaster comes both they and he will feel relieved that another than the family physician has seen the patient. 2. The family have lost confidence somewhat, or they feel that two heads are better than one, or they consider it is a duty they owe the patient and themselves to have another opinion, and usually from an older and supposedly more experienced and wiser person. Now in how many instances are the presence and examination of the consultant really useful to the patient? Provided the consultant is all that he should be, his presence and conduct in the case should almost invariably be of real service. In the first place, if it be a difficult case, or even a simple one, his diagnosis corresponding as far as may be with that of the practitioner is a moral help and a decided one, because the loyal practitioner has but one desire, namely, the benefit to his patient, without regard to self. If there be a difference of opinion, it enables the practitioner to see and know the other side and to bear it in mind in the future conduct of the case. Does it mean, however, that the practitioner is wrong and the consultant right? By no means. At best, and in rough terms, it may be stated as about equally divided, as future events often prove. Of course, we are here presuming we have to do with a well-informed as well as upright practitioner. If, unfortunately, either of the parties be of a different order—well, in one word, God help the patient! But in a few more words, it is far better for a patient to have a good practitioner and a poor consultant than the reverse, because the sensible, honorable man, who is really doing the work and carrying the burden of the patient's illness, will call a halt when he finds the advice given is in any way pernicious.

Admitting what has been written as true, let it be understood of family and friends that they should not ask the consultant what he thinks, or what he advises, but they should address themselves to the practitioner and to the practitioner alone. He, the latter, should make his statement as agreed upon previously to the family and friends, and if there be any misstatement, wilfully or otherwise, then and there it can be corrected without prejudice to anyone concerned.

Further, let it be always insisted upon and understood by everyone present that an opinion, or judgment, of many cases, especially of acute disease, or whenever the condition of the patient is imminent, is subject to change, and that the sole right way of acting from day to day, or even from hour to hour, must finally and always remain in the hands of the practitioner.

It is clear, therefore, that in selecting their family physician people should be very careful in their own interest. The essentials of such a one are: Knowledge of his profession, devotion to his patient, horse-sense, and absolute rectitude of purpose. He should be confided in for small ailments; he should be as absolutely trusted when the sky, figuratively speaking, is dark and the outlook unpromising or dangerous. If they—the family—have mistaken their man originally they must be the sufferers; but better inform oneself first. "First, be sure you are right then," as David Crocket says, "go ahead"—and always trust the trusty one.

Beverley Robinson, M.D.

HIGH-FREQUENCY SPARKS IN THE TREATMENT OF CANCER.

To the Editor of the Medical Record:

Sir:—A few weeks ago the New York *Times* published a rather "yellow" cable dispatch announcing a new method of treating cancer introduced by Dr. de Keating Hart under the title of fulguration, and which consisted in the local application of high-frequency sparks. In your issue of December 21, 1907, Dr. Finley D. Cook alludes to this and gives the results of his own experience with it, calling it, however, "a new treatment."

The treatment is all right, but the claim for novelty is not. In a paper published eighteen months ago (*New York Medical Journal*, June 16, 1906) I wrote as follows: "Malignant or semimalignant lesions of the skin—epithelioma, lupus, lupus erythematosus, and sarcomata, when of small size and conveniently located, have been destroyed in very many instances by the caustic spark from a metallic electrode connected to one terminal of a coil transformer, the other terminal being grounded or connected to the person of the patient. This little operation is exceedingly painful for the moment, but as it lasts for but two or three seconds at the utmost it is usually borne without flinching. There are many reports in confirmation of this, chiefly from France, where it was first used. I know of no better means of aborting a commencing furuncle, as it does in a moment that which nature requires several days or a week to accomplish. In other words, the cocci are instantly destroyed, together with the follicular wall, and the leucocytes have simply a small inert necrotic plug to deal with, which they usually do with but little accompanying inflammatory action."

H. G. Piffard, M.D.

256 West Fifty-seventh Street, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL SOCIETY OF MEDICINE; OPENING DINNER, MEDICAL SECTION, EPILEPSY—GENERAL COUNCIL—ARMY MEDICAL MATTERS—HOSPITALS, ST. BARTHOLOMEW'S, ROYAL FREE, POPLAR FOR ACCIDENTS.

London, December 6 1907.

The inaugural dinner of the Royal Society of Medicine was held on Tuesday, and a very successful function it proved. We may now reckon the society is in full working order, for although meetings have been held, as I have reported to you, we could hardly regard the amalgamation as complete until the national institution of a dinner had put its seal on the combination.

Sir Wm. Church presided. Lord Methuen responded to the toast of the Imperial forces. Sir Clifford Allbutt proposed "Science, Art, and Literature," which was acknowledged by Sir Ray Lankester. Then came the toast of the evening, given by the chairman, who referred to early unsuccessful attempts to amalgamate the medical societies, and declared that the success of the present undertaking was guaranteed by the distinguished gathering present and that he was gratified to be able to testify to the willing sacrifices made by the federated bodies for the common good. Never had there been a time in which so wide a field had been occupied by medical men as the present. In every department science placed at their disposal new methods for the investigation and treatment of disease, and the ground to be covered in every branch was continually increasing. At present no man, whatever his intellectual gifts, could be fully acquainted with every branch; he must in his official studies take for granted the results of other workers. Hence specialism both in study and practice. To provide every facility for diffusing this increased knowledge and to enable the profession to keep in touch with what was going on around them, was perhaps at present the main object of the society, but he hoped the time would come when the Royal So-

ciety of Medicine, through the appointment of scientific committees formed of those most competent for the work, would be making additions to knowledge.

Turning to the practical work, the Medical Section has had a discussion on the Nature of Epilepsy, founded on a paper by Dr. Alfred Russell, who said the old notion that this and other convulsive attacks were due to a sudden failure of the cerebral circulation was worthy of reconsideration. That such failure could produce unconsciousness and convulsions had been proved by several investigators. A fainting fit offered both analogies and contrasts to an epileptic fit and intermediate cases might be difficult or impossible to diagnose. The cause of the cardiac inhibition must be sought in the vasomotor and cardiomotor instability, so marked in the disease. These were very sensitive in the child and might also explain the frequency of infantile convulsions. Considering cardiac inhibition as the precipitating factor of the fit, Dr. Russell submitted that it afforded a satisfactory explanation of the various phases of the fit and the recovery following the escape of the heart from inhibition. As to uremic convulsions, he adduced clinical and experimental evidence to show that the cerebral manifestations might be due to increased intracranial tension with resulting cerebral anemia. As to the difficulty of correlating this with Jacksonian epilepsy, he submitted that this cerebral anemia existed both in status epilepticus and in the epileptiform seizures of general paralysis.

Dr. D. Ferrier thought they ought to have some proof of a definite relation between cardiac disease and epilepsy before they agreed with Dr. Russell to transfer the origin of the disease from the brain to the heart. But there was no evidence of such relation. Epilepsy was not so much a matter of the circulation as of the nutrition of the nerve cells. He considered the condition of the circulation was secondary to the epileptic discharge from the cortical cells.

Dr. C. E. Beevor said by stimulating the thumb center a tonic localized contraction was produced, but a stronger current could bring on a fit affecting the whole body, and in such case there was no cardiac inhibition. In fits from cerebral tumors there might be no loss of consciousness; or such tumors might grow and cause fits just like epilepsy. These could not be ascribed to heart failure. In *petit mal* it seemed impossible for so limited an effect as unconsciousness without the patient falling down to be caused by heart failure. He believed the primary disease was in the cortex.

Dr. A. M. Gossage said if cardiac inhibition were the cause of the fits we ought to have more evidence of the occurrence of such inhibition.

Dr. J. Lindsay Steven of Glasgow was very doubtful whether sufficient weight had been placed on the factor of vasomotor anemia of the brain as a cause of cerebral disease and perhaps of epilepsy too. He drew attention to the relationship between Raynaud's disease and cerebral anemia.

Dr. Buzzard remarked that in the cases of brain disease associated with vasomotor spasms which had been brought forward the history showed absence of convulsions.

The General Medical Council has held its autumn session, which, as usual, is mostly occupied with penal business. Most of the time was accordingly devoted to a rather long list of inquiries into cases of alleged professional misconduct. The question of the medical degrees of the new University of Wales came up. There are to be no more minimal qualifications. A six-years' curriculum is required, three of which must be spent in the Welsh colleges. Candidates must also have a degree in arts or in science. So the youngest university is setting an excellent example.

The Army Council have decided to associate the Queen Alexandra Hospital with the Royal Army Medical College as an integral part of its medical school, so as to utilize the clinical material for furthering the education of officers of the Royal Army Medical College. They have further appointed medical and surgical consultants from the civil members of the profession, considering their experience in that field will conduce to the efficiency of the hospital as regards the investigation and treatment of diseases incidental to military life and that these appointments may foster greater interest in the Army Medical Service among civil members of the profession. The appointments made are: Consulting physicians, Drs. Mitchell Bruce, Kingston Fowler, and Prof. Osler. Consulting surgeons, Messrs. Barker, Bowlby, and Makins.

The Report of the Army Medical Department for 1906 —a heavy blue book issued last week—shows a distinct improvement in the health of the troops. Of those serving at home and in India there was a decrease of admissions to hospital of about 66 and 30 per cent. respectively, and that not due to the incidence of one disease but to improvement all round. One great cause is no doubt the increase of temperance, another improved sanitation. During the last sixteen years there has been a steady fall in the number of admissions from above 1,000 to less than 600 per 1,000 of strength. Comparing this with other armies, the French, German, and Austrian are all above 600, and the United States army figures appear above double that. The death-rate at home is 2.92, but abroad rises to 8.30, chiefly on account of acute tropical diseases. The loss from discharge as invalids is not increased by foreign service, probably because the men are carefully inspected before selection and many are sent home for change who are still able to continue in but who would be lost if they had not had the advantage of early change of climate.

The Director General of the Army Medical Department has continued to address assemblies of his professional brethren in various centers on his scheme for organizing the Medical Service of the Territorial Army. Last week he went to Cambridge and proposed to name the general hospital of that district after the university. There and elsewhere he has been received very heartily and his proposal to constitute the profession into a homogeneous corps seems generally approved.

The extension of St. Bartholomew's Hospital is being steadily carried out. A new out-patients' department is practically complete, and yesterday afternoon the foundation stone of the Pathological Block was laid by Lady Ludlow, who was accompanied by Lord Ludlow, President of the hospital. This building is to be in Portland stone and fireproof, about 90 feet fronting on the street and the height above ground 62 feet, with a basement of 10 feet. On the top floor is to be the P. M. room; on the third floor the pathological library; on the second accommodation for the junior demonstrator and the bacteriology and histology clerks; on the first, lecturers' laboratory and clinical and pathological research rooms; on the ground floor staff-rooms, and in the basement mortuary and mortuary chapel. The cost is estimated at £30,000, which it is hoped will be met by special donations. The stone contains an inscription stating when it was laid, etc., and mentioning the interesting fact that it is deposited on the site of the house of Dame Joanna Astley, Nurse of King Henry VI.

Princess Christian opened on Tuesday the extension to the Royal Free Hospital, of which she is President. This addition comprises two new operating theaters with the dependent rooms required for the work. They have been built and equipped on the most modern principles of construction and sanitation. The theaters are lighted by north windows and by electric lamps so arranged that the light can be concentrated on any part of the operating table. There are three galleries for the students. The cost, about £10,000, for a hospital with an annual expenditure of £16,000 and an income of only a third of that, seems disproportionate, and the committee may well feel anxious about the success of their appeal for the amount.

A remarkable contrast to the foregoing case to that of other hospitals is offered by the Poplar Hospital for Accidents, which held its fifty-second annual dinner on the previous evening, when the chairman was able to boast that the hospital "differed from others inasmuch as it did not indulge in any whining about money, for it has never been in debt and never will be." Think of it! A hospital fifty-two years old and never in debt! Can you match it on your side? On this, I believe, the record is unique. It is not said it will never be in want, but if subscriptions fail the work will be curtailed and wards closed. It may be hoped this will not be, for the work is most important and well done. The last year was very prosperous and £2,000 had been spent on the convalescent home. Donations at the dinner amounted to £1,600. I cannot tell you exactly how it is done, but next time one of my hospitals is getting up a "whine" I may, perhaps, propose that the secretary and auditor be sent to the East End to study the financial management of the Poplar Hospital.

OUR PARIS LETTER.

(From Our Special Correspondent.)

RADIOTHERAPY IN CANCER—ASPIRATION IN ACUTE PERITONITIS—CHOLELITHIASIS—OCCUPATIONAL ACCIDENTS.

PARIS, October 23, 1907.

THE twentieth French Congress of Surgery was opened in Paris on October 7 under the presidency of Professor Berger. The subject of the day, "The Influence of Röntgen Rays on Malignant Tumors," was discussed by Beclère, who, after having shown that it was possible to destroy a new growth by means of the rays without damage

to the surrounding tissues, considered the influence of the rays on the principal sites of malignant neoplasms. Certain distinctions, he said, were necessary in regard to growths of the skin. All epitheliomas not penetrating through the derma could be absolutely and completely cured by radiotherapy, and under these conditions this was the method of choice. When the epithelioma had pierced through the lower dermal layers, radiotherapy was often very successful, but the method sometimes resulted in undeniable failures which might even lead to the death of the patient. Radiotherapy was rarely successful in dealing with malignant growths of the mucous membrane, for on the one hand it was possible to reach only the regions in direct continuity with the skin, and on the other hand epitheliomas of the mucous membrane ordinarily developed very rapidly and were attended by early involvement of the lymphatics. Malignant growths of the breast could be more or less favorably influenced by the rays. When the neoplasm was limited to the mammary gland itself it might be caused to disappear without operation through the influence of the rays alone. After surgical intervention radiotherapy was very effective against cutaneous recurrences, but was powerless in the treatment of involvement of the deep lymphatics. Sarcomas were especially susceptible to the Röntgen rays, as was shown by their rapid regression and disappearance in spite of their subcutaneous position and sometimes even after only mild application of the rays. In leukemia radiotherapy was the treatment of choice; it had to be admitted, however, that although the therapeutic results obtained were often marvelous, they did not constitute a cure. Beclére then spoke of the dangers of radiotherapy. These were undeniable and nearly always resulted from excessive dosage, either that the seances were too long or too frequently repeated. He had never made any observation that led him to believe that the Röntgen rays properly applied were capable of hastening the progress of cancer or of contributing to its dissemination. In conclusion, radiotherapy should not be considered as a rival, but as an ally of surgery. A malignant growth should invariably be operated on and then radiotherapy could be resorted to for the purpose of preventing recurrences. In such cases the rays should be directed not only toward the operative field, but also over the region of the related lymph nodes.

At the close of this address, Pozzi summarized the respective indications of radiotherapy and fulguration, which, as is well known, consists in the use of sparks of high tension and high frequency. Fulguration gives results as brilliant as those of radiotherapy in cancroids, and in all malignant tumors sufficiently accessible it should be preferred. The two methods could also be associated. It had even been observed that the effect of the Röntgen rays was much increased if the tumor had first been subjected to fulguration according to the method of Keating-Hart. Imbert and Dupeyrac of Marseilles had treated 107 cases by radiotherapy and concluded that this method almost always cured cutaneous epitheliomas, greatly improved and often cured leukemias and sarcomas, sometimes caused improvement in recent recurrences of mammary carcinoma, but nearly always failed in other cases, particularly in epitheliomas of the mucous surfaces.

Villard of Lyons described a method of treatment of acute peritonitis by means of peritoneal aspiration. The treatment of this condition had as principal indication the evacuation as completely as possible of the fluid free in the peritoneal cavity. Villard considered that the peritoneal cavity could easily be brought to a state of dryness by aspiration. For this purpose he had designed a special aspirator consisting of a tube of which one end was covered with a cap pierced with holes and intended to prevent the intestinal loops from blocking the flow. With this aspirator introduced into the abdominal cavity through a small incision it was easy to remove completely all of the abdominal exudates. Wicks of gauze were then placed between the intestinal loops in order to encourage sacculation through the formation of adhesions. In five cases of general peritonitis originating in the appendix Villard had succeeded in saving the patients by this method.

Pauchet of Amiens reported sixteen gallstone operations. He considered that it was necessary to catheterize the biliary passages in all cases of simple cholecystectomy, since a stone might be present in the common duct. Furthermore, in draining this region it was necessary to pack the subhepatic space and keep the wound in the duct open in order to encourage the elimination of stones which might otherwise be retained. In very much weakened individuals he advised draining both the hepatic and the common ducts. The latter drain should be carried down to the duodenum so that it might be possible in case of vomiting to inject sugar water and bile.

Jeanbrau of Montpellier and Segond of Paris presented a communication on chronic surgical affections in their relation to industrial accidents. Jeanbrau had studied especially surgical tuberculosis in this connection. Traumatism might act in three different ways; sometimes it might reveal the existence of a tuberculosis previously unknown to the patient, as might happen in the case of strains, which sometimes were the effect and not the cause of a preexisting white swelling. Sometimes it aggravated the course of the disease by encouraging rapid suppuration; finally, it might create a spot of lessened resistance in a healthy region. As regarded the medicolegal bearing of such accidents Jeanbrau thought that the following conclusions might be drawn: Tuberculosis revealed by an accident entitled the patient only to temporary indemnity; tuberculosis that was aggravated entitled the patient to a reduced rate of indemnity, since the accident had only caused the condition to become worse; tuberculosis inoculated and localized in an apparently healthy individual demanded the payment of the full indemnity legally provided. Segond spoke more particularly on the association of cancer with the accidents of occupation. In most cases in which the complainants referred their tumors to a previous traumatism the growths were already present and their presence was simply revealed by the accident. In some instances the traumatism might hasten the growth of the cancer. It was therefore only fair to take this into consideration and give the accident medicolegal importance. An animated discussion followed and a resolution was adopted recommending that the law should be modified so as not to exclude *a priori* preexisting conditions and diseases from consideration in fixing the indemnity in accident cases. This would reduce the number of unjustified and trumped-up demands by enabling the exact amount of injury to be determined and the indemnity to be fixed accordingly.

(From Our Special Correspondent.

KOCH'S RETURN—COLOR PHOTOGRAPHY—ACCIDENT INSURANCE LEGISLATION—HEREDITARY SYPHILIS.

BERLIN, November 15, 1907.

ROBERT KOCH has returned from a scientific expedition that has kept him in tropical Africa for a year and a half. His work in large part consisted in formulating a system for combating sleeping sickness. The methods suggested, and especially the prophylactic measures, have already demonstrated their efficiency. The Government has conferred on Koch the highest title in its gift, that of Excellency. As in the case of his former expedition, the Berlin Medical Society will probably receive a report of his work and I shall be able to supply such details as are of interest.

That Lumière's method of color photography will be of service in medical work is evident from a paper by Benda and Biesalski read before the Medical Society on October 30, and illustrated with excellent photographs of this type. These showed stained preparations of the spirochetes of syphilis, of blood spreads stained in different ways, gunshot wounds, jaundice, brain specimens, leg ulcers, etc. The following presentation, which was by Buki and Ledermann, enabled one to compare the three-color process with the Lumière method, as the speakers showed photographs from Ledermann's Atlas of Skin Diseases, which is shortly to appear. The reproductions were exceedingly life-like and were in natural colors. They also had the advantage of being reproducible at will, which, of course, is as yet impossible with the Lumière plates.

As legislation concerning accident and health insurance is probably more radical in Germany than in any other country, a paper read by L. Hirsch before the Society of Social Medicine, Hygiene, and Medical Statistics will probably be found of interest. He discussed the drawbacks of accident insurance. It was only human that the patients should exaggerate their complaints in order to secure an increased amount of indemnity, but it was very reprehensible that the relatives of workmen dying entirely independently of any accident should attempt to obtain remuneration because of some insignificant accident suffered by the deceased at some previous time. There was no doubt that a suspicious attitude of the authorities in regard to such claims was entirely justified, but this very fact was a drawback of accident legislation, since it often reacted to the disadvantage of the insured. When the laws were drawn the earning capacity was made the criterion of the indemnity and the physician was expected to estimate to what extent the earning capacity was interfered with in any given case. This led to the establishing of stereotyped standards; for example, the earning capacity of the right hand was set at 50 per cent. and that of the right foot at

75 per cent. The earning power, however, depended very largely on the good-will of the patient, as appeared from observations made in the times before the accident insurance laws were enacted, which showed that many workmen were able to carry on their full quota of work in spite of severe injuries. It had been found that anyone who had once received assistance, even if he knew himself that he was entirely able to work, usually gave up every occupation if the indemnity amounted to 50 per cent. or over. Many injured workmen refused to submit to small operations of which the success was certain, for fear that their stipends might be reduced. The speaker made the following suggestions: Experts employed by the labor unions and therefore inclined to favor these in their testimony should not be called. Instead of taking the earning capacity as a basis, only the gravity of the injury should be considered. The unions should see that workmen under the age of thirty who were receiving assistance should be trained in some occupation, as it was an injustice to select a single cause of illness for indemnity, namely accidental injury, while persons suffering from chronic diseases were not given any assistance. The ideal would be to aid all really ill persons up to their death and also their widows and orphans. It was contrary to true humanity and the best interests of the State to encourage idleness among able-bodied workmen by giving them regular financial support.

In the Society for Venereal Prophylaxis Rosenthal discussed the hereditary transmission of syphilis. He advocated the erection of sanatoriums for syphilitics, just as they already exist for tuberculous patients. As it had been shown that in the year 1898, among 37,000 midwives, 157 became infected with syphilis in the course of their work, rigid supervision and treatment of these was necessary to prevent further transmission through them. It was advisable to establish a separate form of insurance for midwives. Nurses should also be carefully supervised, and giving children into the care of syphilitics should be guarded against. Homes should be founded in which children could be kept during their first three to five years. In one Berlin polyclinic, of all the children coming under observation 2.8 per cent. of those born in wedlock and 3.4 per cent. of those of illegitimate birth suffered from hereditary syphilis. Such homes could best be established in the country.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 12, 1907.

Cancer of the Male Urethra.—J. D. Barney reports two cases and refers to certain papers on this subject. The symptoms are practically those which might occur in any case of stricture or calculus and render diagnostic errors very easy to make, as also does the fact that the affection may occur in men who have never had any venereal history. The detailed history of the two cases is given. From the tissue removed it was possible to make a positive diagnosis of epithelioma in each instance.

Verrucae Plantares.—J. T. Bowen discusses this topic with reference to the occurrence of the affection in boys and young men and its pathology. With regard to the latter his views are those of Dubreuille, from whose recent paper on the subject he quotes at some length. Bowen has had 34 cases under close observation. Most of his patients have been schoolboys of the better class or college students. He could find no history of trauma in any of his cases. The question of contagion is uncertain. Most of the patients were accustomed to such exercises as tennis playing, etc., so an opportunity for irritation of the plantar surfaces was plainly offered. As to treatment, he found in a considerable proportion of the cases that a 10 per cent. solution of salicylic acid in collodion was efficient after some time in removing the lesions. It was painted on daily and the foot soaked on alternate days in hot water for twenty minutes. Pumice soap was then used to remove as much of the lesion as possible and the painting was then renewed. In cases rebellious to this plan he used chrysorobin in 10 per cent. strength added to the salicylated collodion. In other cases success was obtained by covering the lesions constantly with a 60 per cent. salicylated gutta percha plaster. Electrolysis and the strong caustics are very painful except under local anesthesia. The Paquelin cautery may be used under cocaine anesthesia, the round point being inserted in the center of the wart and swept around the whole periphery.

New York Medical Journal, December 14, 1907.

The Favorable Influence of Occupation in Certain Nervous Disorders.—C. E. Atwood declares that in the treatment of mental affections by occupation or diversion it becomes necessary, first, to study well the individual, considering in addition to his physical condition and form of disorder also his past life and natural characteristics, his age, muscle power, endurance, previous habit, etc. Second, to utilize manual labor partly for its fatiguing effects and its beneficial effects on metabolism; skilled labor to develop attention and limit the tendency to mind wandering and to restore confidence; music, art, and literature chiefly for the sake of altering the emotions and morbid trend of thought and providing safe fields for the imagination. Third, all occupations should be associated as much as possible with some pleasurable object and a temporary change of environment. Fourth, greater than slight mental and physical fatigue should be avoided. Fifth, variety is necessary, and simple forms of exercises may later be graded into those requiring some complex activity.

Results of the Work Accomplished by the Society of Sanitary and Moral Prophylaxis.—P. A. Morrow discusses the general lines of activity which have engaged the energies of this organization, declaring that its field of work is larger, more important, and more difficult than at first appeared. The value of this work is not to be measured by the mere diminution of the sum of venereal morbidity and mortality for the education of young men in matters of sexual hygiene and the inculcation in them of the principles of clean living tends to make of them not merely healthier men, but safer husbands, sounder fathers and better citizens. The general scope of the work is thus indicated: (1) The general dissemination of knowledge among the public respecting the extent of these diseases and their dangers to the individual and to society. (2) The education of the rising generation in a knowledge of the laws of life and sex, and the dangers which come from the unnatural or irregular exercise of the sex function. (3) General enlightenment of the public as to the communicative modes of these diseases, direct and indirect, and especially the terrible consequences to the innocent members of society from infections introduced into marriage. The author traces the growth of the work in other cities and finds that the propaganda of the parent society in New York is being well received. He maintains that it is eminently proper and fitting that women should interest themselves in this movement. It is largely a woman's question, for it is upon woman and the children who are a part of her being that the burden of suffering, disease, and death from this social scourge is chiefly laid.

A New Procedure and Instrument for the Artificial Ripening of Cataract.—J. H. Claiborne presents an illustration of the instrument he has devised and states that his new procedure is similar in many respects to one described in 1804 by Mooren, but radically differing from it in others. The new method is described in full and cannot be detailed here. Essentially it consists of two parts: (1) Iridectomy, coupled with simultaneous discission with a lance-shaped instrument based on the principle of an agricultural harrow, and (2) extraction at the propitious time. He thus sums up the advantages of the new method: (1) Greater ease in lacerating the capsule; (2) greater area of laceration; (3) the less likelihood of iritic complications and the less extensive if they do occur; (4) the presence of coloboma to forestall the occurrence of glaucoma or its relief in case it does occur; (5) the less likelihood of post-operative glaucoma; (6) simplification of the final extraction.

Journal of the American Medical Association, December 21, 1907.

Acute Rheumatic Fever.—S. Solis-Cohen recognizes acute rheumatism as an infectious disease, due probably to any one of a group of organisms, possibly cocci, allied to the organisms of scarlatina and erysipelas. He also admits a certain constitutional susceptibility or diathesis, intimately related to nervous function, and especially with the vasomotor apparatus and perhaps also with the tissues of the organs of circulation. He reviews the medicinal treatment, largely empirical, that has been found useful—the precordial blisters, the use of alkalies, which has a sort of clinico-pathological indication in the abnormally acid condition of the body fluids, the use of the tincture of the chloride of iron and the salicylates. The use of the latter, together with the alkalies, is not contraindicated, and he generally uses them in combination. Ferric medication can also be associated in the "mistura ferro-salicylata," introduced by him twenty-two years ago, the revised formula of which is given in a footnote. Special care should be given to the condition of the mouth, nose and

throat and avoidance of exposure to drafts for susceptible individuals. The resistance of the vasomotor system can be increased by such measures as massage, electric light baths and hydrotherapy. Regular and sufficient elimination is a necessary prophylactic measure and a regulated nutritious diet yielding a minimum of nitrogenous waste. The carbohydrates should be reduced and oils and fats substituted so far as possible. The diet, however, should be individualized to suit the case. The management of the attack is described in detail; the diet should be milk exclusively for at least two weeks and longer if necessary, the bowels should be kept open and the urine alkaline, but the most important measure is complete rest, and it depends on the case whether this be enforced for six weeks, which is Solis-Cohen's minimum, or whether it be continued to nine or ten weeks more. The great majority of subsequent chronic cardiac lesions are, he says, beyond question due to the neglect of the rest. Local treatment must be guided by the general condition and the patient's special needs; there are many applications and most of them are useful unless the patient has some idiosyncrasy. If the heart becomes involved during the attack the blisters and alkaline treatment can be kept up, but unless the articular symptoms are still severe, it is usually best to discontinue the salicylates. He speaks highly of the value of rectal, and, in severe cases, of intravenous injections of colloidal silver in cardiac complications, although he can not say they are always curative. Bromide of strontium or ammonium may be useful in quieting restlessness; a precordial ice coil or ice bag is useful. The two principal things he insists on in the treatment of acute rheumatism and its complications are individualization and rest, and the latter in all cases is the measure of supreme importance.

Treatment of Rheumatism.—N. S. Davis says that there is still clinical evidence that the alkaline treatment, though it can no longer be regarded as specific, has a beneficial action in preventing cardiac complications. The nearest to a specific in rheumatism are the salicylates, especially the salicylate of sodium, but the known physiological effects of these remedies, analgesic and antipyretic, etc., do not explain their beneficial therapeutic action in this disorder They are not equally effective in other arthritic affections, and in acute articular rheumatism they do not lessen the liability to cardiac complication, another fact that is not readily explainable. While the other salicylates having the same active principle, salicylic acid, are likewise effective, the salicylate of sodium is, in Davis' opinion, the most reliable, and he is also convinced that salicylate of sodium made from oil of wintergreen is best tolerated by the stomach. All the salicylates are most agreeably administered in capsules. Half a gram of the salicylate of sodium can be given in this way and two capsules will make an average dose. If thus given, care should be taken that water is also given in sufficient quantity to insure the prompt solution and dilution in the stomach. A charged solution of bicarbonate of sodium or effervescing sodium and potassium citrate may be drunk instead of water, thus combining the salicylate and alkaline treatments. Other drugs may be substituted for the salicylates in rheumatism, but they have their disadvantages. Antipyrin may be effective, but it increases the anemia and the convalescence is prolonged. Other coal-tar preparations are open to similar objections and, if given in sufficient doses, may be dangerous. Consequently, they are adapted for only very mild cases of short duration. In closing his article, Davis mentions the serum treatment of the disease, as proposed by Menzes and by Sherman, and says it is evidently still in a most elementary experimental stage and has not yet gained the confidence of bacteriologists generally.

The Tub-Bath Treatment of Cystitis.—The advantages of the continuous bath treatment of cystitis in women are pointed out by G. L. Hunner, who describes the method of its employment and reports cases in which it was employed. Its use seems to have been first suggested in the treatment of vesicovaginal fistula, for which it is especially adapted, rendering the patients more comfortable and less offensive to themselves and others, besides saving a great deal of labor and trouble in their care. Its advantages as an adjunct to the treatment of intractable cystitis, with or without accompanying fistula, are demonstrated in the case histories given. The tub used is of large size and the patient lies or sits on canvas strips stretched across the tub, which can be slacked or tightened as required for the sitting or recumbent positions. Light slats across the tub are covered by a blanket and mackintosh, and these in turn by a spread. This covering retains the heat, makes a "work table" for the patient, and presents a neat appearance. Arrangements are made by a siphon and tubing for continuous irrigation, if needed, and for a certain amount of water to be drawn off from time to time and replaced by warm water to keep up the temperature. Six cases are reported, illustrating the conditions for which this method is advisable. They are only a few of the worst out of many thus treated during the past seven years. Hunner mentions some things which experience has taught him to avoid: Curettage of an ulcer on the trigonum or near the ureteral orifice has in two cases been followed by ascending infection. The making of a vesicovaginal fistula causes trauma and swelling, and while he leaves gauze in the freshly made opening to prevent its immediate closure, he is careful to avoid pressure obstructing the ureteral orifice. The baneful influence of the retention catheter in causing pressure ulcers and infection can not, he declares, be too strongly emphasized, and when he has to use it he prefers a small smooth rubber catheter held in place by sutures or adhesive strips to the mushroom or bat-wing catheter. The tub-bath treatment can also be used in the male in cases of long-standing prostatic retention, in connection with irrigation through a suprapubic or perineal wound.

Will Radium Cure Cancer?—A. C. Haven reports a case of recurrent cancer of the scar tissue after hysterectomy treated with success by the introduction of a small tube of bromin of radium into the vagina where it was retained by a tampon and left over night, being removed in the morning. For the first six months of this treatment the results were discouraging; the disease progressed and extended, causing great pain, the inguinal glands enlarged, there was great weakness and mental depression and the disease culminated finally in a terrific hemorrhage. After this had been controlled and the bleeding granulating tissue curetted away, a change set in for the better, at first slow, but surely continuous, marked by less pain, less need of morphine, and fewer hemorrhages. The enlarged glands became smaller, weakness and depression disappeared, and healthy scar tissue replaced the cancerous granulations. At the end of six months no trace of the original disease remained, and the patient was to all appearance well. The vagina had contracted so that the little finger was introduced with difficulty. Later in the year a hard swelling appeared in the rectovaginal septum, which, when opened, discharged a grumous, sanguineous substance, analysis of which was negative. This recurred several times the next year, but finally completely healed. Now, two years and a half after the hysterectomy, the patient is apparently strong and well. Haven thinks that there can be no possible doubt as to the nature of the growth; it was pronounced cancer by competent pathologists. He thinks that the method of using the radium and the persistence in the treatment under discouraging conditions very probably had their influence in bringing about the apparent favorable result, and that failure in other cases may have been due to discarding the remedy too early.

The Lancet, December 7, 1907.

Carcinoma of the Ovary in a Child of Seven Years.—The patient of E. W. Parry began to complain in December, 1906, of abdominal pain. In February of the current year abdominal enlargement was first noticed and there was distinct emaciation. Examination showed the abdominal cavity filled with a round, hard mass, with an irregular surface, rising to just below the ribs. Some six weeks later an exploratory laparotomy was performed. Some clear fluid escaped from the cavity and the tumor was found to be of right pelvic origin. There were extensive old and recent adhesions of the tumor to the great omentum. These were partly separated and partly ligatured off and divided until the tumor could be delivered out of the abdomen. The right Fallopian tube was ligatured off separately and divided. The peritoneum of the pedicle was then divided circularly and ligatured by two unlocked ligatures of silk, the tumor cut away, and an additional ligature put round the whole stump. The abdominal wall was closed in one layer. Recovery was prompt and uneventful. The child appeared perfectly well for awhile, but four months later she was again seen and was obviously wasting, while the abdomen showed signs of recurrence with free fluid in the cavity. Examination of the tumor had shown it to be of a carcinomatous nature.

Treatment of Neuralgia by Injection of Osmic Acid into the Gasserian Ganglion.—The histories of two

cases are given by G. A. Wright, his patients being a man of 58 and a woman of 55. The first patient was placed under chloroform and an incision was made from above the zygoma downwards and curving forward along the lower border of the jaw. The zygoma was resected and turned down and the coronoid process was divided and turned up. The inferior dental and lingual nerves were found and traced up to the foramen. By means of a curved dental syringe a few drops of 2 per cent. osmic acid solution were injected into the ganglion through the foramen. The nerves were then torn away and the wound was closed. Very little shock followed the operation in spite of the feeble condition of the patient and he was up and walking about in the grounds of the hospital on the fourth day. Some discharge of saliva from the wound caused inconvenience for a time, but practically there was no other trouble. Some six months later he had had some attacks of severe pain in the first division of the nerve, but the second and third portions had given no trouble. The second patient underwent practically the same procedure and at last reports was doing well. Both patients had had various operations done before the acid injections. The author does not claim for the latter permanent success in the relief of the pain, but it is an operation causing so much less strain upon an exhausted patient than does the removal of the ganglion that the author thinks it worth a further trial. The effects of injection of osmic acid in producing degeneration of tissue are very well marked and, if the ganglion can be destroyed by the means described relief may be obtained at considerably less risk than is incurred in the operation for its removal.

A Plea for Uniformity of Conditions in Vaccination.—A. H. Gerrard complains that the lymph used for vaccination is under no official control or supervision except in case of public vaccination. The private practitioner may obtain his vaccine from wherever he likes, he may carry out the procedure in whatever way he may wish, and he may scarify in as many or as few places as his convictions or his patients dictate. He may also, if he cares to, return the slightest reaction as successful vaccination. He is under no supervision whatever. In such an important matter as vaccination, where the benefit to the patient is not immediately apparent, it is very serious if the operation is carried out by any means not ideal from a surgical point of view. All these objections could be met, he claims, by having vaccination completely under State control. He believes that the cases handled by the public vaccinators are better protected against variola than are those of the average private physician. Comparison of official and non-official lymph with regard to bacterial content were much in favor of the former, as shown by tabulated results. It must be remembered that the author is speaking of conditions in England. In the United States the lymph manufactured by the civic authorities can be purchased by local physicians even for private patients if the latter are too poor to pay, and the charge has been made so low that it can almost be disregarded.

The Treatment of Dysentery.—F. M. Sandwith considers this question under the headings of "bacillary" dysentery and "amebic dysentery." In the former type the bowel should be cleaned out with castor oil or magnesia. Rest in bed should follow, with warm clothing, perhaps a hot-water bottle, and certainly a pad of cotton wool on the abdomen surrounded by a flannel bandage. Physiological rest for the intestines, so far as possible, must be obtained by stopping all solid food and giving only small quantities of liquid every two or three hours. When the tongue is fairly clean boiled or sterilized milk, pure or diluted with rice water, or peptonized, is the best food. The daily examination of stools, as in enteric fever, will tell you whether we are giving too much milk or whether it is necessary to peptonize it. When the tongue is thickly coated or the patient loathes milk, we may have to give chicken broth, albumin water, whey or rice water for a day or two. Alcohol will not help the dysentery and is bad for the liver, so should be withheld unless the heart requires it; brandy in such circumstances is the best stimulant. All food should be given tepid, neither hot nor cold, and even then a small judicious meal may cause immediate peristalsis and an action of the bowels. We must treat dysentery just as carefully as we would enteric fever if we wish to cure the patient. The author has hearty commendation for the serum treatment. In the amebic variety of the disease the same general régimen is followed as above outlined. We may give bismuth by the mouth, with tannigen or some astringent added. Many still rely on ipecac in combination with opium. Calomel is not indicated. Sulphate of magnesia may be given alone or combined with sulphate of soda. Rectal irrigations are of great value and should be begun early. Quinine may be used, 1-500 or 1-1000. Silver nitrate, 1-1000, or copper sulphate in the same strength.

British Medical Journal, December 7, 1907.

Some Cases of Unexplained Fever in Infants and Children.—H. Ashby says it is generally admitted that the common cause of fever is the presence in the blood of toxins due to bacterial action, the toxins leading in some way to increased tissue change, but it can hardly be admitted that the action of bacteria is the sole and only cause of fever. There must be a reflex or vasomotor variety, in which the toxins play no part, to account for the rise of temperature following hysteria, excitement, catheterization, etc. The author believes that many of the "unexplained" cases are in reality due to gastrointestinal infection, though there is no vomiting and no diarrhea. Moreover, examination of the stools does not lead to the isolation of any definite infecting organism. Pyelitis is another cause and the pyemia may not occur till after the subsidence of the acute symptoms. In the urine of such cases the colon bacillus is largely in evidence. In many of these cases the infant has been taking for long periods sterile foods, and these may have acted in some way as a predisposing cause. Alteration in the diet, giving whey and fresh milk, with orange juice and citrate of potassium, quickly brings about an improvement. From the fact that nearly all the sufferers are girls, it looks very much as if the urethra was the port of entry of the colon bacillus into the urinary tract. The early stadia of pneumonic cerebrospinal meningitis, influenza, subacute disseminated tuberculosis must all be borne in mind. In older children some of the feverish states with which we have to do are plainly due to gastric insufficiency. Again, in the absence of actual disease, but after excitement, tiring muscular exertion, overwork of brain, the temperature will go up. In many of these cases a stay in the country is the best medicine.

The Urinary Mucous Tract as the Route of Invasions by Pathogenic Organisms.—C. J. Bond refers to a class of cases which clinically reproduce the features usually associated with pyelitis, in which there is on superficial observation a curious absence of any apparent cause for the illness. The majority occur in women and the condition is especially apt to arise during the pregnant state. It is probably true that in most of these cases the infection travels upward through the urinary mucous tract to the renal pelvis. In a general way infective processes originating in the excretory ducts of organs or glands or in mucous canals probably depend on these canals as the route of invasion, while infective processes originating in the parenchyma or cortical portions of the same organs or glands depend on the blood stream for the entrance of pathogenic organisms. This view is also in harmony with the observed phenomena of toxic processes. Cytotoxins circulating in the blood exert their cytolytic action primarily and chiefly on the epithelial cells of the cortex of an organ—the tubules in the case of the kidney, the secretory epithelium in the case of the liver—while the epithelium of the excretory duets at first escapes injury, thus showing that the resisting power of the latter is at least as great as, and probably greater than, that of the secretory epithelium. Whereas, in all the cases we have been considering of pyelitis, cholangitis, etc., due to mucous invasion, this duct epithelium has been the first to suffer. The author therefore insists on the importance of impressing patients with the necessity of safeguarding the orifices of these canals opening on the surface of the body. Frequent bathing, rigid cleanliness, and personal hygiene will do much if regularly practised among hospital patients, indeed, among all classes of patients, to prevent infection of these canals.

Tincture of Iodine in Puerperal Fever.—Aldo Mergari reports his method of using iodine as an intrauterine injection in cases of puerperal fever. It has had favorable results even in severe cases. He disinfects the vagina, in case it is necessary lightly curettes the endometrium, and by using a Doleris sound injects into the uterus from 150 to 100 grams of a mixture of equal parts of tincture of iodine and warm water. It is necessary to make sure of a return flow. After some minutes, or on the slightest pain, the fluid is allowed to flow out, and the cavity is washed out with boiled water to remove the excess of iodine. No tampons are used. The author has obtained a cure in seven cases of puerperal fever with very rapid results from the injections. The good results are ascribed to the large amount of iodine used and the nascent state of the iodine.—*La Riforma Medica*

Book Reviews.

THE MEDICAL RECORD VISITING LIST, or Physicians' Diary for 1908. New Revised Edition. New York: William Wood and Company.

THIS popular visiting list is on the same plan as heretofore. There are about thirty pages of miscellaneous information, and then follow the usual pages devoted to the visiting list, consultations, engagements, addresses, cash accounts, etc. The printing and general get up of the book are all that can be desired, and physicians who have used this list in the past are sure to want the edition for 1908.

THE PHYSICIAN'S VISITING LIST (Lindsay and Blakiston's) for 1908. Fifty-seventh year of its publication. Philadelphia: P. Blakiston's Son and Co.

THIS well-known visiting list contains the usual blank leaves for visiting list, addresses, engagements, cash account, records of births and deaths, etc.; there are also notes on incompatibility, poisoning, metric weights and measures, dose table, etc. The paper has a good writing surface, the pages are well ruled, and the book is of handy size.

DIE VERWUNDUNGEN DURCH DIE MODERNEN KRIEGSFEUERWAFFEN, IHRE PROGNOSE UND THERAPIE IM FELDE. Von Stabsarzt Dr. GRAF und Dr. HILDEBRANDT. II. Band. Spezieller Teil. Berlin: Verlag von August Hirschwald, 1907.

WAR is a curious procedure. We devise weapons to kill or maim each other in a conflict which cannot be settled by more peaceable means, and then with equal zeal study the methods by which the unfortunate ones who may have come into intimate contact with such projectiles may be restored to duty. The task of the military surgeon has been made difficult by the fact that the modern weapon is more apt to kill with its projectiles than to maim. Thus bullet wounds of the head, for example, were less often serious in the old days, because the bullet, having less force, would glance off when it struck the hard substance of the skull and produce merely a wound of the soft parts. The projectile from the modern high-powered rifle usually penetrates the skull and enters the brain. The authors of the book here noted take up in detail the effects of the modern arms of warfare on different parts of the body, basing their work mostly on the surgical reports of the recent wars. The uncertainty which attended in former years the infliction of a wound by a bullet has now been largely overcome by a more universal employment of the *x*-rays, and the "probing" for bullets, formerly so largely necessary, has now, thanks to this aid, been superseded to a great extent by more direct operative procedures. Graf and Hildebrandt's book is well written and the contents classified in a most satisfactory manner, so that it may be made to serve as an excellent work of reference.

THE DEVELOPMENT OF THE HUMAN BODY. A Manual of Human Embryology. By J. PLAYFAIR MCMURRICH, A.M., Ph.D.; Professor of Anatomy in the University of Toronto; Formerly Professor of Anatomy in the University of Michigan. Third Edition, Revised and Enlarged. With 277 Illustrations. Philadelphia: P. Blakiston's Son & Company, 1907.

THE value of Professor McMurrich's book both for teaching purposes and as a work of reference has come to be widely recognized and is attested by the large number of medical schools that recommend it as a text-book for their students. In its present edition it has been somewhat enlarged and the necessary changes to bring it fully down to date have been made, so that it represents a most satisfactory treatise on this highly important subject, perhaps the best available for English and American readers.

THE TECHNIQUE OF MODERN OPERATIONS FOR HERNIA. By ALEXANDER HUGH FERGUSON, M.B., M.D., C.M., F.T.M.S.; Professor of Clinical Surgery, Medical Department of the University of Illinois, etc. Illustrated by Drawings from the Author's Collection. Chicago: Cleveland Press, 1907.

THIS book is intended by the author to present only the purely surgical phase of the subject of hernia and is largely dominated by the results gained from many years of personal experience. The work is well written and suitably illustrated by numerous large plates, which demonstrate very clearly in almost every instance the various anatomical and surgical features. The book is divided into two parts, in the first of which the author describes the general technique, the wound, the operative complications and discusses the results of the various methods of treatment. In the second portion the detailed operative procedures for the different anatomical forms of hernia are discussed in a very satisfactory and complete manner.

In classifying herniæ Ferguson believes that the abdominal varieties may be arranged most suitably with reference to their topography and accordingly divides them into anterior, posterior, superior, inferior, lateral, and internal. Being anatomical, this method seems logical enough, but we doubt whether it will displace that so long in vogue which is based on the etiology and the form of the lesion. Although less logical it is sanctioned by custom, which is usually a difficult thing to overthrow. The operation known by the author's name is minutely described and it is claimed that among 2,500 cases operated upon by this method by the author and others no instance of a return of the trouble has been noted. The operation is essentially anatomical, the internal oblique muscle and its tendon being sutured to the inner aspect of Poupart's ligament, as low down as possible, after ablating the sac and strengthening the internal ring with a few stitches above the cord. The cord is not diverted from its original bed, for this step is considered empirical and endangers the testicle. Almost all the other operations for the relief of hernia are also described, so that the book constitutes a valuable monograph on the surgery of this condition. It may, moreover, be called a "personal book," although this in no way detracts from its interest and value.

ALTE UND NEUE GYNÄKOLOGIE. Herrn Geheimrat Prof. Dr. Franz Ritter von Winckel zur Feier seines 70 Geburtsfestes überreicht von den Aerzten der Kgl. Gynekologischen Universitäts-Poliklinik im Reisingerianum zu München. Mit 30 Abbildungen im Text und 5 Tafeln. Herausgegeben unter Mitwirkung von Dr. E. AULHORN, Dr. R. BENNDORF, Dr. H. ELTZE, Dr. M. KACHEL, Dr. TH. PETRI, Prof. Dr. SAKURI und Dr. A. STOECKER, von Prof. Dr. GUSTAV KLEIN, Vorstand der Kgl. Gynäkologischen Universitäts-Poliklinik, München: J. F. Lehmann's Verlag, 1907.

THE first part of this entertaining work comprises three historically interesting papers by Klein and Stoecker, one of which is devoted to a description of the early pictorial representations of the female genitals from the ninth century to the time of Vesalius, another to an early Spanish treatise on pregnancy, and the third to an account of the works and labors of some of the famous obstetricians of the sixteenth and seventeenth centuries. The illustrations reproduced from these sources show how well cultivated the powers of observations of these early investigators were and if we omit the grotesque features from their pictures we cannot but admire the accuracy with which they depicted anatomical facts. The second part of the book is occupied with a number of scientific papers. Aulhorn presents the results of blood examinations in a large series of gynecological conditions and also describes a case of malignant chorioepithelioma. Benndorf as the result of extended observations finds that silk-worm gut may be safely used for uniting the fascia in laparotomies. Eltze finds that the employment of hot air in gynecology is more apt to be followed by an improvement in the subjective than the objective symptoms. Petri discusses the permanent effects of the various suspensory operations of the uterus and advocates early operation, but thinks that the prophylactic measures are the most important. In a comparative study of the length of labor in European and Japanese women, Sakurai states that for various, mainly physical, reasons the length of the second stage is diminished by one-third to one-half in the latter race. A number of other papers are presented, all of which make up an interesting and valuable souvenir of the natal day of one of the nestors of the profession in Germany.

MERCK'S 1907 INDEX (Third Edition). An Encyclopedia for the Chemist, Pharmacist, and Physician, Stating the Names and Synonyms; Source or Origin; Chemical Nature and Formulas; Physical Form, Appearance, and Properties; Melting and Boiling Points; Solubilities, Specific Gravities, and Methods of Testing; Physiological Effects; Therapeutic Uses; Modes of Administration and Application; Ordinary and Maximum Doses; Incompatibles; Antidotes; Special Cautions; Hints on Keeping and Handling, etc., of the Chemicals and Drugs Used in Chemistry, Medicine, and the Arts. New York: Merck & Co., 1907.

THIS is a very useful work for the physician who may desire to inform himself regarding the origin or composition, therapeutic uses, and doses of drugs. The information which it gives is indicated in the subtitle of the book, and it gives it concisely in a few lines. It is not confined to a description of the drugs manufactured by the house of Merck, but includes all—crude drugs, alkaloids, synthetics, and organic extracts which are used in medicine.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

212th Regular Meeting, Held December 6, 1907.

THE PRESIDENT, DR. ROBERT ABBE, IN THE CHAIR.

A Case of Tumor of the Pituitary Body with Symptoms of Acromegaly.—Dr. ABBE showed a woman, forty-two years old, who for the past two years had suffered from facial tic on the left side of the face. The tic was of a grave form and involved all three branches of the facial nerve. Three years ago the patient had lost the sight of the left eye. There was a striking enlargement of the lower half of the face and lips, and tenderness of the scalp. There was also a gross enlargement of the hands, both in breadth and thickness. The patient stated that she formerly wore a six and a half glove and her size now was seven and a quarter. She also exhibited photographs showing a distinct change in the expression of her face during the past two years. The feet were not enlarged. The patient complained greatly of excessive perspiration. Dr. Abbe said the patient had been sent to him on account of her facial tic, but he had thus far refused to operate on account of the symptoms which indicated a tumor of the pituitary body. The patient had also been seen by Dr. M. Allen Starr and Dr. Pearce Bailey, and she had received some pituitary and thyroid extract. A good Roentgen ray picture showed a loss of the bone outline of the site of the pituitary body—definitely showing a pituitary tumor.

Dr. ANDREW J. MCCOSH said that during the past summer, while in Vienna, he saw a case where von Eiselsberg had removed a pituitary tumor about the size of a walnut, and at the end of six months the patient was in excellent condition. The operation was followed by a slow but steady improvement in the patient's sight and general symptoms, and the case looked exceedingly promising. Access to the tumor was gained through the temporo-frontal region, making a very large flap. Dr. McCosh said that Horsley had operated on thirteen cases for removal of the pituitary body; of these, a few had died and a certain number had completely recovered.

Dr. CHARLES L. DANA said that in the case shown by Dr. Abbe it was difficult to explain the total loss of vision on one side without any effect on the limitation of the field of vision on the opposite side. The symptoms might perhaps suggest something else than an ordinary symmetrical pituitary tumor.

Some Unclassified Dangers of Anesthesia.—By Dr. JOSEPH D. BRYANT. (See page 1053.)

Dr. MCCOSH said that in consideration of the fact that the class of men who administered the anesthesia in our hospitals were rather inexperienced in that special branch of surgery, it was wonderful that more accidents did not occur in consequence. While it would be a distinct advance to have a paid hospital anesthetist, the expense of such an innovation would be so great that it was practically out of the question at present. The speaker said he did not think the new methods of giving anesthesia with gas and ether, and the new apparatus that was employed, had produced any reduction in the death rate over the older methods with the Allis cone, etc.

Dr. L. BOLTON BANGS said that even among those men who claimed to be specialists in the administration of anesthesia the work seemed to be more or less temperamental. Some men seemed to be able to restrict themselves to the giving of the anesthetic and paid no attention to the operator; others, owing either to their temperament or to the confidence they possessed in their method of administering the anesthetic, paid more attention to the operator than they did to their own work. The speaker called attention to the fact that there was a great difference in the amount of ether used by different anesthetists; this factor was important in view of the secondary effects of the ether on the kidneys.

Dr. V. P. GIBNEY said he did not think the old-time charge that the anesthetist paid more attention to the operation than he did to the anesthetic could be brought against the modern skilled anesthetist. The question arose, what constituted a skilled anesthetist? Was it the fact that he had invented some new form of apparatus for the purpose of giving anesthesia? That was the impression that seemed to prevail. Another question that arose was, who was responsible in the operating room, the operator or the anesthetist? The public were being taught to believe that if the patient died from the effects of an anesthetic that was administered by a paid anesthetist, the latter was responsible for the fatal outcome, but some surgeons still clung to the old idea that they were responsible for the patient's welfare; others were willing to ship the responsibility to the anesthetist. Dr. Gibney said that while a salaried anesthetist in all the hospitals would be a welcome addition to the staff, that was probably impracticable on account of the expense. In a small institution like the Hospital for the Ruptured and Crippled they had a visiting physician whose title was "Anesthetist and Instructor in Anesthesia," whose duty it was to instruct the junior physicians in the proper method of giving anesthetics.

The President, Dr. ABBE, said that in considering this question from the standpoint of the greatest good to the greatest number he had always held the view that by instructing the entire hospital staff as to the proper method of giving anesthetics they were conferring a greater benefit upon the community than by allowing all of the work to be done by a single expert anesthetist. These hospital internes, after their term expired, scattered far and wide, and it was important that they should receive proper instruction in this branch of surgery. He also held that the senior operator should not only have an eye on the operation, but also on the patient and the anesthetist. Unless he was cognizant of all that was going on, it might seriously interfere with his work. He did not approve of the method adopted at one of our large hospitals of having a screen placed between the operator and the anesthetist, for the reason that it hid the patient's face from the former. Dr. Abbe said his favorite method of administering anesthesia was to start with nitrous oxide gas and then give the least possible amount of ether by the drop method or the open cone method. In that way the least amount of anesthesia necessary could be maintained without cyanosis. He emphasized the fact that the responsibility of the entire operation, including the anesthesia, should belong to the operator, and personally he always regarded the anesthesia as part of his general work and took a delightful sense of responsibility in it.

Dr. JAMES said the remoter dangers of ether anesthesia, such as an ether pneumonia or nephritis, were often far more important than the immediate ones.

Dr. JOHN WINTERS BRANNAN said that some years ago, after the occurrence of one or two deaths under anesthesia, this general subject came up for discussion in connection with Bellevue and the allied hospitals, and as a result two anesthetists were appointed for Bellevue and one for each of the smaller hospitals. Those at Bellevue still held their position, but in the smaller hospitals the experiment was not a success and the men were allowed to go. It was the intention to have these anesthetists train the house staff in the proper methods of giving anesthesia, and give their personal services in important operations. In connection with each operation, a printed blank had to be filled out, giving the amount of the anesthetic used, the duration of the anesthesia, the condition of the patient's heart, lungs, and kid-

neys, and whether or not the attending surgeons or the assistant surgeon operated or was present. The rule was that either the attending or the assistant attending surgeon should be present at operations where a general anesthetic was necessary.

Dr. GIBNEY agreed with Dr. Brannan that either the attending or the assistant surgeon should be present at all serious operations.

Dr. MCCOSH said there was no such rule at the Presbyterian Hospital, but there was an understanding to the effect that at any major operation or anything approaching it either the surgeon or assistant should be present.

Dr. ABBE said that at St. Luke's Hospital that rule existed and was invariably carried out.

Dr. BRYANT, in closing, said that two of the chief factors that had induced him to present this paper were, first, that in his opinion too much attention was being given to the apparatus or paraphernalia connected with the giving of anesthetics, and second, not sufficient attention to the possible ill-effects of the anesthetic. The old-fashioned cone method of giving ether was very satisfactory, provided the man who administered had a proper knowledge of the method. It would be unwise, the speaker thought, to place this work entirely into the hands of experts, for by depriving the young men in our hospitals of a proper knowledge of the subject we would not be conferring the greatest good upon the greatest number. This instruction should be given by a properly qualified person, and should embrace not only the various methods of giving anesthetics, but also the physiological effects of the drugs that were used to produce anesthesia. In that connection the speaker called attention to an article by Dr. Horatio C. Wood, Jr., on the comparative danger of scopolamine-morphine anesthesia, which was published in *American Medicine* in December, 1906. In this article the author made the statement that the mortality by this method of anesthesia reached the astounding figure of one death in 221 anesthesias, and added that "it must be either a very bold or a very ignorant surgeon who will persist in its use." Of the older methods of anesthesia, Julliard collected 161 deaths in 524,507 cases of chloroform anesthesia, a rate of one in 3,258; from ether there were 21 deaths in 314,738, a rate of one in 14,987. According to Ormsby, chloroform gave 53 deaths in 152,260 administrations, a rate of one in 2,873; ether, four in 92,815 administrations, a rate of one in 23,204. The statistics collected by Gurlt in Germany from 1891 to 1897 gave a death rate from chloroform of one in 2,039 and from ether one in 5,000. The statistics from St. Bartholomew's Hospital from 1875 to 1890 were as follows: Chloroform, 13 deaths in 19,526 administrations, a rate of one in 1,502; ether, three in 8,491, a rate of one in 2,830; "gas and ether," one in 12,941, a rate of one in 12,941; ethyl chloride, one in 13,000 cases. Expert anesthetists, Dr. Bryant said, were not disposed to use morphine or other such remedies excepting for some specific purpose.

A Family Type of Combined Sclerosis Associated with Grave Anemia.—Dr. CHARLES L. DANA said he had recently had under his care a patient in whom it might be said that pernicious anemia and combined sclerosis was a family disease. The patient was an unmarried woman, fifty-eight years old, coming from old New England and Pennsylvania stock. She had lived a temperate and fairly healthy life, though subject rather easily to diarrheas, and having at times what Dr. Delafield terms "morning diarrhea." Very early in life she had a severe attack of dysentery, but had had no subsequent attack until eight years ago. She had other attacks seven, six, five, and four years ago, but none since. Besides the dysentery, within the past eight years she had had a distinct tendency to mild attacks of enterocolitis, and two years ago she was treated for a long time for this trouble, during which period she passed a great deal of undigested food and gas in her stools. Her physician detected an ulcer in the sigmoid flexure. She recovered from this, however, and had been fairly well for nearly a year. Within the past six months she had noticed a peculiar numbness of the feet, with weakness and unsteadiness in walking, and a similar condition in the hands. When Dr. Dana first saw her she had a decided pallor, with an almost yellowish tinge to the skin. She was rather thin, but not much more so than her ordinary habit. Subjectively, she felt fairly well, excepting for the weakness and uncomfortable numbness of the extremities. She had an ataxic gait, and the Brauch-Romberg symptom. There was also some ataxia of the hands, so that she could not sew or do fine work with them, but she was able to write and dress herself. There was some general weakness of the extremities, but no distinct paralysis. The knee jerks were present, but there was no ankle clonus and no Babinski. While she complained much of the paresthesia, she had no actual cutaneous anesthesia. Examination of the patient's blood showed 3,200,000 red cells, 8,800 white cells, and 66 per cent. of hemoglobin. She had a curious and persistent inflammatory condition of the gums, which kept her mouth rather sore. Cultures made of this region by Dr. F. M. Huntoon showed the ordinary microorganisms of the mouth, excepting that there were certain spirilla. An examination of the stools made by Dr. Christian A. Herter showed indications of excessive putrefaction, with an abundance of the *Bacillus aërogenes capsulatus*. There was an excess of hydrobilirubin and skatol, with absence of indol. A second examination of the blood, made three weeks later, showed a further decrease of the red cells to 2,780,000, with a similar condition of corpuscles, excepting that there were no megaloblasts. The hemaglobin was reduced to 58 per cent.

In this case, Dr. Dana said, the patient presented a very clear-cut type of grave anemia, with combined sclerosis. As to the family history, the patient stated that her mother had also suffered from "morning diarrhea," and had a tendency to weakness of the bowels. Her father died of apoplexy. One brother died at the age of fifty-two from a trouble similar to her own, namely, he had a great deal of diarrhea followed by sensory disturbances, anemia, and weakness of the extremities. One sister died in the same way, and one maternal grandmother had a similar trouble. The disease, apparently, ran through three generations. In the second generation it produced only a moderate disturbance. In the third generation, out of four children, three had been affected. The case might be classed as a family form of pernicious anemia, or a family form of combined sclerosis, or, more properly, it was a family form of enteric weakness which secondarily led first to an anemia and then to a spinal cord disorder. There were some authorities, however, who still asserted that the enteric trouble was not a primary one, but was secondary.

Painful Cyst of Testicle.—Dr. L. BOLTON BANGS reported this case and showed the specimen. The patient from whom it was obtained was a man of fifty-seven who complained of pain in the testis. Upon examination Dr. Bangs found a large varicocele and in addition a small tumor at the upper aspect of the testis, and to this the patient attributed all his pain. Upon operation it proved to be a small, elastic, translucent tumor springing from the tunica albuginea. He regarded it as an unusually situated spermatocele. The interesting features of the case were the unusual location of the tumor and the pain it had caused the patient.

Tea and Coffee.—Americans are drinking less tea and more coffee. The importations of coffee in 1896, less the quantity exported, aggregate 804,692,275 pounds, as compared with 843,625,918 pounds in 1906. There were 10,270,376 pounds less of tea imported in 1906 than in 1896.—

Books Received.

The Medical Record *is prepared to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Temperance in England.—According to recent statistics, since 1900 the consumption of beer per head in England has fallen from 32.29 gallons, the highest point reached in the history of the trade, to 27.81 gallons, or 14 per cent. This still leaves a consumption of rather less than four pints a day for the adult male population. During the same period the consumption of spirits declined from 1.18 gallons per head to .91, which is 23 per cent.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending December 20, 1907:

INDEX.

A

Abbe, Robert, the specific action of radium as a unique force in therapeutics, 589; test of the string-cutting method for impermeable esophageal strictures, 890.

Abdomen, subcutaneous injuries to the, 440.

Abdominal incisions, curvilinear, 329; operations, care of the patient during serious, 156; supports, restoration of tissue tonus in the, 416.

Abortion, a campaign against criminal, 67; criminal, 457.

Abortionist, long sentence for a, 990.

Abrahams, R., diagnosis of renal calculus, 193.

Abrams, Albert, the heart reflex and the mechanism of angina pectoris, 969.

Abscess, perianal and perirectal, 841.

Absinthe not to be forbidden, 24.

Academy of Medicine, anniversary meeting of the, 948.

Acetonuria, 817.

Achilles reflex and alcoholic heart failure, 112.

Acid intoxication theory, 111.

Acidification of the viscera as a symptom of death, 206.

Acne and eczema, treatment of, 407; the internal treatment of, 22.

Acromegaly and the sexual function in women, 366.

Actinomycosis, human, 532.

Addison's disease in a negress, 324; in children, 323; the nature of, 188.

Adenoids, methods for the removal of, 537; in infancy, 827; secondary hemorrhage after the removal of, 782; symposium on, 707; the indications for and method of removal of, 707; the removal of, 789.

Adhesions, prevention of peritoneal, 530.

Adler, Lewis H., impaction of feces, 392.

Age, advanced, as a contraindication to operation, 642.

Agglutination reaction, a simple method of performing the, 113.

Air, contamination of the, in Greater New York, 836; subcutaneous injections of, for relieving pain, 955.

Aix-les-Bains, some notes on, 291.

Albee, Fred H., skiagraphy in orthopedic surgery, 1063.

Albuminuria, the genesis of, 999.

Albumosuria, myelopathic, 579.

Alcohol and marksmanship, 1031; and prescriptions, 272; and the infant, 366; exposition in Munich, 863; pathological changes produced by, 829; problem, relation of the doctor to the, 835; the use of by medical men, 190.

Alcoholism, apomorphine in acute, 144.

Alden, Cynthia W., eye boring of sightless children, 445.

Alfonso, an operation on King, 487.

Algonquin, for a hospital at, 487.

Allen, Dell B., cancer of the head of the pancreas, 938.

Alternating currents of low frequency in the treatment of muscular atony, 604.

Alvarenga prize, the, 697.

Amboceptors, concerning the specific action of, 400.

Ambulance system, for a central, 1032.

American Electrotherapeutic Association, 526.

American Hospital Association, 525.

American Journal of Neurology, 990.

American Journal of Orthopedic Surgery, 907.

American Medical Association, conference of the committee on medical legislation of the, 1030.

American Medical Editors' Association, 151.

American Physiotherapeutic Association, 738.

American Public Health Association, 272.

American Roentgen Ray Society, 526.

American Society of Sanitary and Moral Prophylaxis, 572.

Amputation at the ankle joint, a method of, 364.

Amsterdam, letters from, 489, 574.

Anal dilatation, gradual, by a new method, 685; fissure, 567.

Anemia, chronic splenic, 1,001; experimental, 277; early pernicious, 29; the diagnosis of, 363; symposium on, 79; the treatment of, 364, 826; two cases of pernicious, 784.

Anesthesia, an improved inhaler for, 531; apparatus for, with nitrous oxide and oxygen, 458; local *vs.* general in rectal surgery, 788; rectal, 529; relative value of inhalation and injection methods of, 328; technique of spinal, 737; anesthetizing, 459; the thymus and death in the course of, 691; unclassified dangers in, 1053, 1080.

Aneurysm, blood pressure determinations in, 1039; of the aorta, diagnosis of, 334; of the aorta, paraplegia caused by an, 59, 81; of the dorsalis pedis artery, 156; of the popliteal artery, extirpation of, 578; of the subclavian artery, 997.

Angina pectoris and anginoid conditions, 736; and the heart reflex, 969; treatment of with the arc light, 702.

Angioma, the treatment of racemose arterial, 484.

Angioneurotic edema, 323; a fatal case of, 744.

Animal psychology, a laboratory of, 610.

Anorectal malformations, 1038.

Anthrax, 356; bacillus on horse hair, 319; in Orange County, 319.

Antitoxin, free distribution of, 191; treatment of diphtheria, the bearing of anaphylaxis on, 269.

Antivivisection play, a, 738.

Anuria, fatal, following urethral examination, 785.

Aphthous fever, 1067.

Apomorphine in acute alcoholism, 144, 445; the hypnotic action of, 489; the therapeutic value of, 511.

Apophysitis in growing children, 947.

Appendical stump, the disposition of the, 788.

Appendicectomy, the incision and treatment of the stump in, 563.

Appendices epiploicæ, 570.

Appendicitis, acute, 482; and the oxyuris, 829, 1067; another theory of, 402; caused by a clove, 448; diagnostic sign in, 66; primary typhlitis without, 66, 152, 321; streptococcemia accompanying, 732; the causation of, 777.
Appendix, actinomycosis of the, 578; calculi in the, 448; discharge of the, through the rectum, 157; operation, the W. Gill Wylie, 648; removing the, in gynecological operations, 325; typhoid perforation of the, 57.
Archives of Pediatrics, 192.
Army Medical Bill in Congress, 1068.
Army, medical education in the, 324.
Arterial degeneration, experimental, 983; degeneration, spontaneous in rabbits, 617; tension, a case of high, 792; tension, manifestations of 334.
Arteriosclerosis, abdominal, 73; and otic sclerosis, 786; primary of the pulmonary artery, 366; pulsating points in the diagnosis of, 279; the treatment of, 1041.
Arthritis deformans, pyroligneous acid in, 413; rheumatoid, 287; treatment of rheumatoid, 660.
Asphyxia neonatorum, 868.
Asthma and pulmonary edema, 871; the use of morphine in, 157.
Atmosphere, the influence of the weather, refuse heaps, etc., on the bacterial content of urban, 21.
Atwood, Charles E., the longevity of idiots, 352.
Aural suppuration, operation in chronic, 198.
Autointoxication, intestinal, in infants, 871.
Automobile accidents, 325, 404, 687.
Automobiles for Viennese physicians, 907.
Bacteria, the *de novo* origin of, 986.

B

Bailey, the late Dr. Charles H., 1072.
Baker, A. H., the prevention of venereal disease, 16.
Ballenger, Edgar, the diagnosis of kidney diseases with special reference to the significance of slight albuminuria, 901.
Banti's disease, a case of, cured by operation, 278.
Bardes, Albert, tuberculosis of the middle ear, 313.
Barker, M. R., what is the function of the gall-bladder? And why the folds of Heister in the cystic duct? 555.
Barlow, W. Jarvis, report on 200 charity patients of pulmonary tuberculosis under sanatorium treatment at Los Angeles from 1903-1907, 303.
Barnes Medical College of St. Louis, 360.
Barton, Joshua L., contradictory advice to consumptives, 825.
Bassler, Anthony, gastric exfoliation as a feature in the production of acute gastric ulcer, 899.
Bead test, the, for the digestive functions, 673.
Beard, John, on the asymmetry of the cycle of life, being "the end of the thread," 633.
Beer, Edwin, a note on the sensibility of the human visceral peritoneum, 565.
Bell, Robert, the local treatment of cancer, 306.
Bellevue Hospital decision, 106; patients to pay, 235.
Benzidin test, the, 778
Beriberi, 525; and rice, 11
Berkeley, W. N., formalin in typhoid fever, 613.
Berlin, letters from, 275, 446, 699, 1036, 1075.
Berry, T. D., an account of the destruction of mosquitos in the "original infected district" in the New Orleans epidemic of 1905, 421.
Bettmann, Henry W., the evolution of gastroenterology, 169.
Bier's hyperemia in acute articular rheumatism, 569; in gynecology and obstetrics, 365; in otology, 366; treatment, 323.
Bile, removal of, for examination, 1034.
Bilharzia disease in Cyprus, 587.
Biliary and pancreatic ducts, landmarks in the, 297.
Birth certificates, payment for, 443; failure to register not an offense, 863; rate, low French, 948; reporting of in Illinois, 320.
Bishop, Louis F., a useful manometric table, 992; heart disease and blood pressure, 63.
Bissell, Joseph B., syphilitic tumors of the breast, 14; the incision and treatment of the stump in appendicectomy, 563.
Bladder case, an unusual, 22; chronic perforating ulcer of the, 17; neuroses of the, 789; operations for stone in the, 1; ruptured with recovery, 870.
Blake, Joseph A., the surgical aspects of malignant endocarditis, 943.
Blastomycosis of the skin, 583; systemic, 577.
Blind children, eye boring of, 445; new school for the, 1031.
Block, Siegfried, mental defectives, an attempt to treat some cases with medicine, 728.
Blood, clinical methods for determining the alkalinity of the, 276; direct transfusion of, 37, 669; hemorrhages and coagulation diseases of the, 279; injections, in bone affections, 240; in the feces, a modification of the Boas test for, 203; methods of staining, 277; test, a new, 201, 242; the benzidin test for, 861; the guaiac test for, 871.
Blood pressure and heart disease, 63; and pain, 785; as a guide in hemoptysis, 288; estimations in diagnosis, 1048; in children, 922; in diabetes, 72; in fevers, 781; studies in typhoid fever, 407.
Bobbin, a soluble, for intestinal anastomosis, 363.
Bodily posture and cardiac signs, 364.
Bolus, in gastrointestinal disorders, 1040.
Book Notices:
Alcohol, the sanction for its use, by J. Starke, 746.
Alimentation, the physiology of, by Martin H. Fischer, 1042.
Amnésie au point de vue semeiologique, by G. Dromard and J. Levassort, 662.
Anatomical terminology, by Lewellys F. Barker, 114.
Anatomy, human, by George Piersol and collaborators, 872.
Anatomy, manual of, by A. M. Buchanan, 367.
Anatomy, Morris's human, by Henry Morris and J. P. McMurrich, 787.
Animals, experiments on, by Stephen Paget, 533.
Auscultation and percussion, by Samuel Gee, 114.
Bacterial infections, the common, of the digestive tract and the intoxications arising from them, by C. A. Herter, 367.
Baederbuch, das Deutsche, 610.
Blood serum therapy, notes on, by Walter Jowett, 289.
Brain, the abdominal and pelvic, by Byron Robinson, 662.
Catholic Churchmen in science, by James J. Walsh, 75.
Cerveau et la moelle épinière, by C. Debierre, 280.
Chemical pathology, by H. Gideon Wells, 916.
Chemistry, a text-book of elementary analytical, qualitative and volumetric, by John H. Long, 75.
Chemistry and toxicology, essentials of, by R. A. Witthaus and R. J. E. Scott, 243.
Chemistry, manual of clinical, by A. E. Austin, 764.
Chemistry of commerce, the, by Robert K. Duncan, 916.
Chemistry, practical physiological, by Philip B. Hawk, 787.
Chest, surgical diseases of the, by Carl Beck, 1,000.
Children, a manual of treatment of the diseases of, by W. F. Radue, 746.
Children, atlas and epitome of diseases of, by R. Hecker and J. Trumpp, edited by Isaac A. Abt, 830.
Clinical diagnosis, a manual of, by Chas. E. Simon, 1042.
Colon, treatment chirurgical du cancer du, by Joseph Okinczyc, 662.
Cornea, ulceration of the, by Angus MacNab, 533.
Déchloruration, la cure de, by Fernand Widal and Adolphe Javal, 580.
Dementia præcox, Psychologie der, by C. G. Jung, 580.
Dentistry, atlas and text-book of, by Gustav Breiswerk, edited by Geo. W. Warren, 450.
Dermatology, the principles and practice of, by William Allen Pusey, 704.
Development of the human body, by J. Playfair McMurrich, 1079.
Diagnosis, a dictionary of medical, by Henry L. McKisack, 872.
Diagnosis, practical, by Hobart Amory Hare, 1042.
Dictionary, American pocket medical, by W. A. Newman Dorland, 450.
Dining and its amenities, by A Lover of Good Cheer, 114.
Directory, American Medical, 619.
Disease, the treatment of, by Reynold W. Wilcox, 109.
Drink problem, the, in its medico-sociological aspects, by T. N. Kelynack and collaborators, 243.
Ear, nose, and throat, manual of diseases of the, by John J. Kyle, 830.
Electricity, the medical and surgical uses of, by A. D. Rockwell, 916.
Embryology, a text-book of, by John C. Heisler, 411.
Epilepsy, by William A. Turner, 243.
Eye, a manual of the diagnosis and treatment of the, by Edward Jackson, 367.
Eye, manual of diseases of the, for students and general practitioners, by Charles H. May, 787.
Eye, the muscles of the, by Lucien Howe, 114.
Fermentation, on, by A. E. Taylor, 662.
Food and dietetics, practical observations upon the chemistry of, by J. B. S. King, 787.
Foods and their adulteration, by Harvey W. Wiley, 957.
Fractures and dislocations, a practical treatise on, by Lewis A. Stimson, 830.
Genito-urinary organs, surgery of the, by J. W. S. Gouley, 76.
Green's encyclopedia of medicine and surgery, 158.

Gynäkologie, alte und neue, by Gustav Klein and collaborators, 1079.
Gynécologie pratique, manuel de, by J. Barozzi, 76.
Gynecology, practical, by E. E. Montgomery, 158.
Harvey lectures, the, by various authors, 200.
Heart and blood pressure, by Louis F. Bishop, 1042.
Hernia, modern operations for, by Alexander H. Ferguson, 1079.
Hip disease, rational and effective treatment of, by P. Bruce Bennie, 9 and Alex B. Bennie, 916.
Histology, the essentials of, by E. A. Schäfer, 243.
Hygiene, a manual of personal, edited by Walter L. Pyle, 619.
Hygiene of nerves and mind in health and disease, by August Forel, trans. by Herbert A. Aikins, 411.
Hygiène, traité de, by Brouardel, Mosny, and collaborators, 31.
Hygromedry, by Henry E. Wetherill, 31.
Igienista, manuale pratico dell', by C. Tonzig and G. Q. Ruata, 704.
Immune sera, by Chas. F. Bolduan, 1000.
Infancy and childhood, diseases of, by Louis Fischer, 787.
Infections, hints on the management of the commoner, by R. W. Marsden, 450.
Infectious and parasitic diseases, introduction to, by Millard Langfeld, 327.
Injured, the immediate care of the, by Albert S. Morrow, 114.
Internal secretions and the principles of medicine, by Chas. E. DeM. Sajous, 1,000.
International clinics, edited by A. O. J. Keely, 158.
International clinics, edited by W. T. Longhope, 746.
Intestines and peritoneum, diseases of the, by Hermann Nothnagel; edited by H. D. Rolleston and Alfred Stengel, 957.
Johns Hopkins Hospital reports, studies on hypertrophy and cancer of the prostate, 31.
Kitty Dickson, Belle of the South Anna, by C. A. Bryce, 619.
Klinik für psychische und nervöse Krankheiten, by Robert Sommer and collaborators, 533.
Kranksinnigen in Deutschland, Verpflegung der, by Konrad alt, 495.
Kriminalisten, Einführung in die gerichtliche Medizin für, by Hugo Marx, 957.
Lateral curvature of the spine and round shoulders, by Robert W. Lovett, 872.
Life, the efficient, by Luther H. Gulick, 327.
Lungs, diseases of the, by Robert H. Babcock, 280.
Mal de Pott, traitement du, by F. Colot, 158.
Maladies tropicales, prophylaxie des, by R. Wurtz, 158.
Massage, lessons on, by Margaret D. Palmer, 450.
Materia medica and therapeutics, a practitioner's handbook of, by T. S. Blair, 280.
Materia medica, applied, by J. H. Schroeder, 199.
Materia medica for nurses, a textbook of, by George P. Paul, 411.
Materia medica, therapeutics, pharmacology, and pharmacognosy, by William Schleif, 662.
Medical jurisprudence, forensic medicine, and toxicology, by R. A. Witthaus, Tracy C. Becker, and collaborators, 75.
Medicine, a system of, edited by Thomas Clifford Allbutt and Humphrey Davy Rolleston, 495, 957.
Medicine, a treatise on the principles and practice of, by Arthur R. Edwards, 533.
Médecine et thérapeutique, nouveau traité de, by P. Brouardel and A. Gilbert, with collaborators, Vol. XLII., 31.
Medicine, makers of modern, by James J. Walsh, 280.
Medicine, modern, edited by William Osler and Thomas McCrae, 200, 746.
Merck's 1907 index, 1079.
Metabolism and practical medicine, by Carl von Noorden and collaborators, edited by I. Walker Hall, Vol. I., Vol. II., 830.
Miracle worker, the, by Gerald Maxwell, 580.
Nervous diseases, diagnosis of organic, by Christian A. Herter and L. Pierce Clarke, 450.
Nervous diseases, organic and functional, by M. Allen Starr, 327.
Nervous system, the integrative action of the, by C. S. Sherrington, 580.
Neurasthenia, clinical lectures on, by Thomas D. Savill, 243.
Nose, polypus of the, by E. S. Yonge, 243.
Nose, throat, and ear, a manual of diseases of the, by E. B. Gleason, 450.
Nugæ medicinæ, by John Godfrey, 450.
Nursling, the, by Pierre Budin, trans. by William Maloney, 411.
Nutrition, elements of the science of, by Graham Lusk, 411.
Obstetrics, by J. Whitridge Williams, 1042.
Obstetrics, a manual of, by A. F. A. King, 31.
Opuscula selecta neerlandicorum de arte medica, 280.
Paraffine in surgery, by William H. Luckett and Frank I. Horn, 199.
Pathologie interne, précis de, by Balthazard Cestan, H. Claude, Macaigne, Nicolas, and Verger, 580.
Pediatrics, by Thomas M. Rotch, 76.
Pharmacology and some allied sciences, a text-book of, by Torald Sollmann, 200.
Pharmacopœia and the National Formulary, Physician's manual of the, by C. S. N. Hallberg and J. H. Salisbury, 367.
Pharmacopœia, the extra, by W. H. Martindale and W. W. Westcott, 76.
Photographic exposure record and diary, Wellcome's, 280.
Physical chemistry in the service of medicine, by W. Pauli, translated by M. H. Fischer, 158.
Physical diagnosis, by Howard S. Anders, 704.
Physiology, a text-book of, for medical students and physicians, by William H. Howell, 916.
Physiology, element of human, by Ernest H. Starling, 619.
Physiology, the essentials of chemical, by W. D. Halliburton, 450.
Plague, studies in the bacteriology and etiology of oriental, by E. Klein, 114.
Pleurésie, étude experimentale de la, by P. Cartier, 662.
Post-operative treatment, by Nathan C. Morse, 872.
Practical medicine series, Vol. I. General medicine, edited by Frank Billings and J. H. Salisbury; Vol. II., general surgery, edited by John B. Murphy; Vol. III., the eye, ear, nose, and throat, edited by C. A. Wood, A. Andrews, and G. P. Head, 704; materia medica and therapeutics, preventive medicine, climatology, forensic medicine, edited by G. F. Butler and collaborators, 158.
Progressive medicine, edited by Hobart Amory Hare and H. R. M. Landis, 75, 495, 1042.

Electrolysis and the nervous system, 529.
Ely, Leonard W., the treatment of joint tuberculosis in children, 941.
Embolus, an operation for, 617.
Emphysema, the surgical treatment of, 609
Empyema, the aspiration treatment of, 838, 839.
Endocarditis, bacteria in relation to malignant, 958, 1059; malignant in children, 958; six cases of malignant, 925, 958; the surgical aspects of malignant, 943, 958; ulcerative, 120.
Endometritis, treatment of chronic, 703.
Enema, a simple nutrient, 606; poisoning after oil, 915.
Enteritis, prophylaxis of infantile, 242.
Enteroptosis surgically considered, 639.
Enuresis, etiology and treatment of, 691; in children, 157.
Epilepsy, symposium on, 923; the nose in relation to, 848; with general tuberculosis and syphilis, 1015.
Epithelial proliferation, experimental, 783, 1040.
Epithelioma, multiple benign, 543.
Ergot, the indications for aside from its obstetrical uses, 851.
Erysipelas, 783; pathology and treatment of, 37; the treatment of, 155, 482.
Erythema circinatum bullosum, 582.
Erythromelalgia, a case of, 827.
Esophageal strictures, test of the string-cutting method for, 890, 917.
Esophagus, spasm of the, 499.
Eugenics, the new science, 651.
Euglobulin, the excretion of, 22.
Explorer, medical, the, 524.
Exudation diathesis of Czerny, 418.
Eye, a new schematic, 236; the relations of, to the nose, 258; examinations, in the children of Memphis, 276.
Eyesight of poor city children, 579.

F

Facial nerve, the origin of, 955.
Fat assimilation, abnormal and intestinal diseases, 277; incapacity in infants, 1003.
Fecal bacteria, 364; toxemia, 354.
Feces, impaction of, 392.
Fecundity in the aged, 614.
Fee, a large, 654; medical, in France, 488, 610; medical, in Germany, 404.
Feeding, natural and artificial in infancy, 521.
Feet, a lever for the correction of deformed, 250.
Femur, separation of the acetabular epiphysis of the, 155.
Fenugreek, cultivation of, 403.
Ferris, Albert W., the manifestations of paranoia, 263.
Fever, early reaction in eruptive, 326; heat formation in, 73; of New England, the three long-continued, 447; relapsing, 946; slow, 240; the effect of, upon the resistance of the organism to infection, 439; the origin of, 915.

Fibroma molluscum and pendent tumor of the breast, 567.
Finger prints in banking, 486.
Finley, Dr., honored, 821.
First aid chests in factories, 403; instruction for railroad employees, 236.
Fisk, Eugene L., the therapeutic value of apomorphine hydrochloridum, 511.
Fitch, William E., correction of faulty fashions in dress an important factor in the treatment of diseases of women, 644.
Flat foot, 913; and bone tuberculosis, 989; plaster casts for the treatment of, 703.
Flatulence and its treatment, 437.
Fletcherism, 995.
Flies as carriers of infection, 277, 611.
Flint, Carleton P., the operative treatment of fractures involving the elbow joint, 465.
Florence Nightingale honored, 948.
Florida, climate, the effect of, 288.
Food, a method of estimating percentage of proteids, fats, and carbohydrates in, 202; prepared and predigested, 77; preservatives and coloring matters, 106; the question of pure in Great Britain, 608.
Foot, causes and characteristics of the weak, 337; radiograph of a mummified, 817; relation of the height of the arch to the functions of the, 608.
Football casualties, 907; in England, 987.
Foreign bodies, removal of from the hand or foot, 828.
Formaldehyde disinfection, 946.
Fountains, private cups at public, 443.
Fourth of July celebration, deaths caused by the, 67; the, in Chicago, 106.
Fractures, the open treatment of, 790.

Hemoptysis treated with ice bags, 112.
Hemorrhage, calcium chloride in, 198.
Hemorrhoids, a new operation for, 330.
Hernia, a simple operation for, 956; diagnosis between chronic and recent, 742; high frequency currents in the treatment of, 921; intraparietal, 784; paraffin injection treatment of, 37; the most frequent in childhood, 197; the saccular theory of, 330, 956; treatment of inguinal in children, 790.
Hinsdale, Guy, Hot Springs, Virginia, 1066.
Hirschsprung's disease, the pathogenesis of, 579.
Homeopathic graduates, admission of, 696.
Honors for American medical men, 486.
Hospital appointments, duplication of, 735; conference, 780; progress, some phases of, 682; the relation of the, to medical education, 323.
Hospitals, bequests to, 696, 770, 908, 990; two new city, 697.
Hot Springs, Virginia, 1066.
Housing question, general aspects of the, 456.
Humerus, fracture of the, 840.
Hunter, an appreciation of, 19.
Hussakof, Louis, on recent investigations of the action of radium on plants and animals, 89.
Hutchinson's teeth, 625.
Hydroa puerorum, 584.
Hydrocele, a fifteen pint, 241.
Hydrochloric acid, diminution of the gastric in cancer of organs other than the stomach, 407; the origin and destination of, 875.
Hydronephrosis, infected with anomalous ureter, 785; intermittent treated by operation, 156.
Hydrophobia and its prevention, 239; in Chicago, 66.
Hygiene and heredity of disease, 28.
Hyoscine anesthesia, 826.
Hyperacidity and gastric ulcer, lack of gastric mucus in its relation to, 876.
Hyperostosis of the superior maxilla, 241.
Hypodermic medication, 413.
Hypopharyngoscopy, a note on, 408.

Hypophysis, removal of a tumor of the through the nose, 148.
Hysterectomy, abdominal, 332; and appendicectomy in a patient of 74, 1040.
Hysteria and neurasthenia, 121.
Hysterical patients, responsibility of, 326.

I

Ice bag, a new abdominal, 84.
Idaho State Medical Society, 697.
Idea, back to an old, 667, 910.
Ileum, congenital occlusion of the, 870.
Illinois State institutions, expense of, 571; medical law, to amend, 1030.
Imbecility, and dementia precox, the differential diagnosis of, 458; the medicolegal aspect of, 458.
Immigration law, the new, 23; the effect of, on social ethics, 750.
Indiana University School of Medicine, 487.
Indicanuria, the source of, 190.
Indigestion, treatment of chronic, 447.
Indigocarmine in the diagnosis of the kidney function, 401.
Inebriate, what can the family doctor do for the, 744.
Infant mortality in the summer months in Yonkers, 832.
Infantile atrophy, the cause of, 154; paralysis, treatment of, 317.
Infectious diseases, clinical observations in the, 161; control of minor, 748; the prodromal period of acute, 408.
Inflammation, recent ideas on local, 447.
Influenza, gastrointestinal disturbances in, 71.
Infusions, the possible dangers of saline, 650.
Insane, judicial disposal of the, 575; responsibility of the, 869.
Insanity, alcoholic, 869; alcoholic delusional, 938; care of convalescents from, 359; in Great Britain, 486; the relationship of trauma to, 813.
International Association of Stomatology, 611.
International Association of Urology 779.

Stokes-Adams disease, the, 829.

Stomach, a method of testing the motility of the, 278; diagnosis and treatment of neuroses of the, 71; diagnosis of cancer of the, 995; disturbances of the, caused by hernia, 201; eight cases of perforated ulcer of the, 930, 961; erosions of the, 73; gastric exfoliation in the production of ulcer of the, 899; gastric juice in the fasting, 494; modern methods in the treatment of diseases of the, 876; surgical treatment of ulcer of the, 105, 838, 846, 876; the effect of metals on the, 449; the use of the Roentgen rays in diagnosing diseases of the, 271; treatment of disorders of the, 149; ulcer of the, 203; ulcer of the, the treatment of perforated, 915.

Stow, Bond, paraplegia caused by an aneurysm of the arch of the aorta, 59.

Street car accidents, 571, 907, 1070.

Street cleaning commissioner, a new, 67.

Streptococcus and pneumococcus infections, the serum treatment of, 366.

Stump, William, treatment of malaria in the vicinity of New York City, 103.

Sturgis, F. R., the business of medicine, 612.

Suicides among German children, 191; of animals, 273.

Sulphur dioxide as a cause of respiratory disease, 239; in the urine of sulphur miners, 579.

Suppuration, abortive treatment of, 567.

Surgeon-general of the army, report of the, 607.

Surgery, observations on four decades of American, 117.

Surgical suggestions, 201, 420, 627, 884, 963.

Sutures and ligatures, their material and use, 245.

Sweating, hysterical, 493.

Swimmers, the cause of sudden death in, 906.

Switzerland, loss of life in, 907.

Sydenham Society, the, 745.

Syncytium, 248, 578.

Synthesis, in the production of remedial agents, 678.

Syphilis and massage, 601, 624; as a cause of stomach disease, 148; cerebrospinal lymphocytosis in hereditary, 1041; congenital of the small intestine, 409; diagnosis of hereditary, 279; experimental in rabbits, 325; heredity and, 742; instructions to those having, 395; intravenous treatment of, 860; latent hereditary, 417; mercurial injections in, 239; mercury in the treatment of, 323; ocular, 448; of the long bones, radiographic findings in, 624, 962; quarternary or attenuated hereditary, 623; reinfection with, 138; serum diagnosis of, 492, 995; some plain truths about, 213, 248; sulphur waters in the treatment of, 95; symposium on, 166; the clinical value of serum diagnosis in, 402; the present status of our knowledge of the parasitology of, 623; the prophylaxis of, 904; the treatment of, 625; the treatment of with suppositories of mercury, 871; things not generally known about, 1037.

Syracuse University College of Medicine, 487.

Syringomyelia, radiotherapeutics in, 251.

T

Tabes dorsalis and cardiovascular disease, 1041; motor paralysis as an early sign of, 855; the early recognition of, 355.

Tachycardia and bradycardia, epileptoid attacks in, 365; paroxysmal, 291.

Tait, Lawson, and his work, 910.

Talbot, George H., the identity of visual and color sensations, 1023.

Talmey, B. S., cryptorchism complicating imbecility, 814.

Taylor, Robert W., syphilis and massage, 600.

Tea as a beverage, 146.

Telephony, a discovery of hygienic value in, 906.

Temperance Federation, the scientific, 71; movement, the, in Germany, 908.

Temperature, unexplained high in a child, 417.

Temporal bone, surgical relations of the, 1038.

Testicle, cyst of the, 1081; tuberculosis of the, 777.

Tetanus and antitetanic treatment, 165; the treatment of by magnesium sulphate, 277; toxin, and the nervous system, 850.

Texas Medical Board, 320.

Therapeutic hints, 124; measures, the estimation of, 413.

Thompson, John M., prostatic concretions with special reference to etiology and treatment, 223.

Thoracic disease, abdominal symptoms of, 111; operations and the pneumatic cabinet, 157.

Thorax, infections within the, 1037.

Thrombosis, prevention of post-operative, 233.

Thrush, H. Clayton, appendicitis due to the presence of *Oxyuris vermicularis*, 1067.

Thumb, a new method of reducing dislocations of the, 924.

Thymus gland, the, 588.

Thyroid gland, the action of iodine and phosphorus on the, 778; implantation in a child, 1002; tumor, apparent death during the removal of a, 438.

Tibia, treatment of pseudoarthrosis of the, 494.

Ticks, loss due to cattle, 822.

Tongue, epithelioma of the, 539.

Tonsils, ablation of the, 1070.

Tonsillar ring, systemic infection through the, 500.

Tonsillotomy, hemorrhage following, 912.
Tooth development, nutrition a factor in, 428.
Torticollis, the treatment of, in the Boston Children's Hospital, 406.
Toxemia, fecal, 354.
Tracheal injections in the treatment of chronic diseases of the lungs, 522.
Trachoma, a causative agent in, 660; etiology of, 23, 310.
Transudates and exudates, the cystoscopic examination of, 998; the differentiation of, 915.
Trauma, the relationship of, to insanity, 813.
Trendelenburg posture, paralysis following the, 753.
Trichinosis, the eye symptoms of sporadic, 179.
Trigger finger, 36, 616.
Trinity Hospital, closing of, 360.
Triplets, a case of, 362.
Tri-State Medical Association, 949.
Tri-State Medical Society of Illinois, Iowa, and Missouri, 572.
Trolley hospital, a, 442.
Tropical climate, research work on the effects of on the white race, 347; diseases, prophylaxis of, 742; skin diseases and the navy, 621; ulcers of the Philippines, 622.
Trypanosomiasis at Mauritius, 702.
Tubercle bacilli, intracellular occurrence of in sputum, 829.
Tuberculins, and sera, 934; experiences with, 371; inoculation with in adults, 745; reaction in ophthalmology, the, 784; reaction, Pirquet's, 661; reaction, the diagnostic value of local, 568; suppositories, 493; the diagnostic utility of, 358; treatment in the tuberculosis of children, 818.
Tuberculosis, a diagnostic aid in, 947; a new diagnosis of, 920; acute, following intubation, 1008; among factory employees, 375; among school children, 408; and abortion, 653; and schools, 375; and weather, 992; animal therapy in, 1038; artificial pneumothorax in pulmonary, 860; auscultation in pulmonary, 110; bacteriological examination of the feces as a means of diagnosis in, 372; classes, the organization of, 447; Commission, report of the British, 905; cutaneous in the City of Mexico, 541; diagnosis and home treatment of pulmonary, 98; diagnosis of lingual, 325; diet in, 695, 826; diet in pulmonary, 119; early diagnosis of pulmonary, 976; environment and personal hygiene as causes of, 1056; hemoptysis due to, 577; high altitudes in, 749; in infancy, 786; in London, 223; in the war department, 191; infection in, 652; International Congress on, 778; Kuhn's lung-suction mask for the treatment of pulmonary, 757, 793; medication in, 370; mixed infections in pulmonary, 370; of children, the opsonic index in, 159; of the kidney, 664; of the nasal sinuses, 451; of the nose and larynx, the treatment of, 493; of the testicle in children, 325; patients, contradictory advice to, 735; patients, supervision of, 197; phagocytosis in sputum as a measure of resistance in, 372; primary of the tonsils and other organs, 61; problem, a, 778; report of the Royal Commission on, 737; sanatoria, 999; sanatoria in Germany, 107; serum, Marmorek's, 493; 16 years' experience with tuberculin in the treatment of pulmonary, 383; surgical and the opsonic index, 112; symposium on, 119, 289; tent for outdoor life, 399; the administration of proteids in, 474; the campaign against in the United States, 32; the class method of treating in the homes of the poor, 372; the effect of high and low altitudes in, 289; the operative treatment of, 862; the ophthalmo-reaction for, 1029; the relation of polymastia to, 701; the relationship between avian and human, 998; the treatment of, 413; the treatment of, by means of emulsion bacilli, 433; the treatment of joint in children, 941; the treatment of surgical by hyperemia, 253; treatment of with Marmorek's serum, 829; the varieties of, 371; tuberculotherapy in, 868; 200 charity cases of pulmonary under treatment at Los Angeles, 303; ventilation in, 996.
Tuberculous adenitis, medical treatment of, 326; cattle on Randall's Island, 697; pus, a rapid test for, 989.
Tuckerman, J. E., apomorphine in acute alcoholism, 445.
Tugboat whistles, 191.
Tulane, a new building for, 487.
Tumors, histogenesis of, 110; inflammatory abdominal, 1001; retroperitoneal, 786; the treatment of inoperable, 821.
Turbinate, non-operative treatment of the middle, 29.
Typhlitis, primary, 693; primary, without, perityphilitis, 274.
Typhoid bacilli carriers, 745; treatment of, 829; in institutions, 441.
Typhoid bacilli in lice, 661.
Typhoid fever, a new diagnostic sign in, 569; and water supplies, 748; and wine, 786; at Gouverneur Hospital, 486; at Jamestown, 190, 403; at the Trenton State Hospital, 486; at Tuskegee, 151; blood cultures in, 692; cold tea in, 514; contagion in the spread of, 827; formalin in, 613; hemiplegia as a complication of, 240; in Chicago, 403; in infancy, 670; in intercurrent surgical and renal cases, 427; in New Jersey State Hospital, 151; in Pittsburg, 68; infection, *Bacillus coli* as a cause of, 1001; in Trenton, 1032; iodine in, 241, 324; isolation in, 616; relapses in, 112; serum treatment of, 658; suppurative mammitis after, 279; surgical complications of, involving the liver and gall-bladder, 700; surgical treatment of perforations in, 668; the bacterial diagnosis of, 271; the ocular diagnosis of, 745, 1028; the period of infection in, 737; the serum treatment of, 945; the transmission of, 833.

U

Ulcers, skin flaps in the treatment of, 703.
Uncinariasis in Florida, 749.
Underfeeding and its associated ills, 954.
Ureter, a suppurating supernumerary, 576.
Ureteral and renal diagnosis and surgical treatment, 245; calculi, the expulsion of, 73; urethra, growths of the, 877; radical cure of stricture of the, 30; treatment of stricture of the, 782.
Uric acid and diet, 567; elimination, 491; symptoms and their relief by colchicum and the salicylates, 549; the treatment of, 691.
Urinary acidity, a study of, 203; infection in children, 836, 1038.
Urine and bile, the morphology of, 785; formation, 407; sago bodies in massage, 954; separation of the, of the two kidneys, 174.
Urticaria chronica, the thyroid as a factor in, 583.
Uterine adnexa, conservative surgery on the, 918.
Uterovesical fistula, 1044.
Uterus, abdominal extirpation in cancer of the, 113; end results in operations for prolapse of the, 665; fibroid tumors of the, 332, 790, 1020; fibromyoma of the, with salpingitis, 918; incarceration of the retrodisplaced, 658; menorrhagia in arteriosclerosis of the, 84; operations for retrodisplacement of the, 790; sarcoma of the, 248; suppurating fibroids of the, 734; symposium on the treatment of fibroids of the, 709; treatment of chronic inversion of the, 504; vaginal implantation of adenocarcinoma of the, 61.

V

Vaccina, generalized, 409.
Vaccination in Pennsylvania, 235; of soldiers, 636; to stop in Illinois, 1071; wholesale in Porto Rico, 486.
Vaccine therapy, 742; virus, bacilli resembling those of tetanus in, 602.
Vagina, formation of an artificial by intestinal transplantation, 666; primary epithelioma of, 660; treatment of post-operative inversion of the, 504.
Valvular disease, the prevention of, 365.
Van Baggen, N. J. Poock, the misuse of the voice and its cure, 390, 857.
Varicocele as a symptom of malignant kidney tumors, 401.
